physician. A biopsy was then performed by his attending physician at home and the tissue was submitted to Dr. Ewing for examination. He gave the following report: "The tissue from the femur which you sent me shows a process which it is difficult to interpret, but which I think we must regard as a malignant tumor. There is hardly enough tissue to decide between some form of myeloma and endothelioma, but it is certainly one or the other. In young children I have repeatedly seen cases which proved to be endothelioma, but which were accompanied by much osteomyelitis, and I think this is one of those. Yet, I am not entirely certain that it is not myeloma, complicating chronic osteomyelitis.

"In any case, it is a malignant tumor, and should be treated as such, with fair doses of x-ray of moderate degree, about 300 R, frequently repeated over wide portals and over a long period. In any case I fear the outlook is unfavorable, but not hopeless. I would be interested to know the outcome of the case."

The patient received, elsewhere, four courses of irradiation treatment during October and December, 1934, and February, 1935, and appeared to improve until about two and a half months prior to his second visit to the clinic.

The boy again registered at the clinic in July, 1935. The history revealed that he had been well until about ten weeks previously. However, at that time, pain had recurred in the thigh and was accompanied by a temperature ranging from 100 to 102° F. (37.8 to 38.9° C.), a loss of weight and malaise. Recent roentgenograms of the body has been reported as normal, but there had been an increase in the number of leukocytes to 14,000 per cubic millimeter. Examination revealed marked improvement in the condition of the right femur from the roentgenologic standpoint. The periosteal changes in the bone had disappeared and there was a sclerotic appearance of the upper portion. The child had fallen from a wagon and there appeared to be a fracture through the trochanteric region of the femur. The temperature was 100° F. (37.8° C.) at this time. The roentgenograms of the thorax did not show evidence of metastasis.

Death occurred as a result of multiple metastatic lesions on December 3, 1935, sixteen months from the time of admission at the clinic and twenty-six months following the onset of symptoms.

Case 5.—A student, aged twenty-three years, registered at the clinic on November 1, 1920, because of pain and swelling in the right shoulder. He gave a history of injury to the shoulder while playing football two years prior to registration; a year later, he had noticed pain and stiffness on exercise and eight months prior to admission he fell on the shoulder while playing basketball. Following the latter injury his shoulder was very painful, sore and stiff and the roentgenograms revealed evidence of a fracture and tumor, possibly sarcoma, at the site of fracture. Operation had been considered, even forequarter amputation, by the physicians consulted. Dull pain continued in the upper portion of the arm with extension of the pain

to the hand and there was an associated stiffness and weakness.

The patient was 5 feet, 7 inches (167.5 cm.) in height and weighed 173 pounds (78.6 kg.) which was about his normal weight. The blood pressure was 140

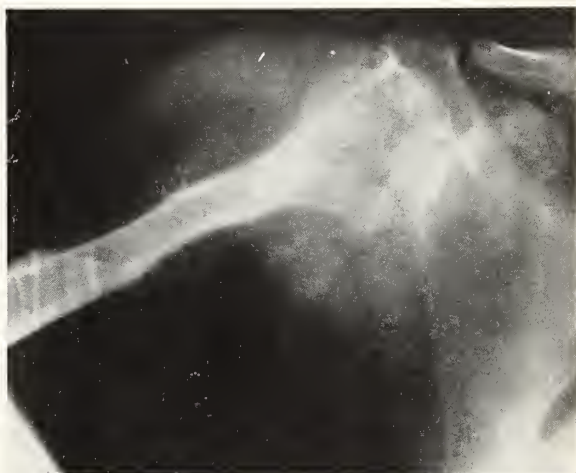

Fig. 5. Anteroposterior view taken with the arm externally rotated, showing absorption of the upper portion of the humerus resulting from Ewing's tumor. The tumor eventually invaded the soft tissue.

mm. of mercury, systolic, and 72, diastolic. The pulse rate was 76 per minute and the temperature 99° F. (37.2° C.). The right shoulder was slightly larger than the left and slightly tender. The arm could be abducted 95 degrees and other motions were good. A pilonidal cyst was present; the region was tender, hot and there was an opening through which pus was discharging. Roentgenologic examination revealed evidence of a tumor of the upper third of the right humerus with involvement of the soft tissue and a diagnosis of sarcoma was made (Fig. 5). Roentgenologic examination of the thorax gave negative results.

Various methods of treatment were discussed and on December 3, 1920, an excision of the tumor was done, and the wound was packed to control hemorrhage; the patient was advised at this time that ultimately amputation might be necessary. The pathologist made a diagnosis of medium round-cell sarcoma. The patient coöperated well and reported at regular intervals for observation. He gained weight rapidly. Dermatitis developed around the wound, the result of the irritating discharge and irradiation; this, however, was not serious.

Following exploratory operation for the tumor of the upper third of the right humerus December 3, 1920, radium was applied four times into the wound at different levels from December 9 to 21; a 50 mg. tube was used for fourteen hours at each application. This was followed by checkerboarding the entire right arm and upper part of the thorax into twelve areas. At a distance of 2.5 cm. from the skin, 50 mg. of radium was applied for fourteen hours over each area from December 24 to 29. The same principle of external treatment was applied February 5 to 11, 1921, using seventeen areas; a 50 mg. tube was applied for twenty

hours to each area. In April, 1921, a similar series of treatments was carried out over eighteen areas around the upper portion of the right arm and shoulder; 50 mg. of radium was applied for twenty hours to each area. Also, a similar series was carried out in July, 1921, and in September, 1921. Each of these series aggregated a total of slightly more than 10,000 milligram hours. In February, 1922, a 50 mg. tube of radium was inserted into a sinus in the right arm for a dosage of 400 milligram hours and on March 28, 1922, a 50 mg. tube was inserted into the sinus for a dosage of 700 milligram hours. On May 11, 1922, a 50 mg. tube of radium was inserted into the sinus in the right arm for a total of 800 milligram hours.

On February 7, 1921, roentgen rays were directed toward the right supraclavicular and infraclavicular regions through three anterior fields, one above the right clavicle and one below that clavicle and additional treatment was given through one posterior field in the scapular region. Each of these fields was exposed to roentgen rays generated at 135 kv., filtered through 4 mm. of aluminum, and was given at 6 milliamperes for eight minutes, at a focal-skin distance of 12 inches (30 cm.). On April 4, 5, and 7, 1921, a second course of treatment was given through two supraclavicular fields, one on each side, and through five anterior thoracic fields, three extending transversely from the right shoulder to the left shoulder and two perimedial fields below this down to the level of the ensiform cartilage. Additional treatment was given through four posterior fields, two on each side of the spine extending from the upper border of the scapulas down to the level of the eleventh thoracic vertebra. Each of these fields was exposed to roentgen rays generated at 135 kv., filtered through 6 mm. of aluminum, at a focal-skin distance of 12 inches (30 cm.), and each received at 6 milliamperes for eleven minutes. On April 28 and 29, 1921, a third course of treatment was given through two supraclavicular fields, one on each side of the median line, two upper thoracic fields, one on each side the midsternal line, two to the lateral aspect of the right arm extending from the point of the shoulder downward, and two posterior fields, one through each scapular region. Each of these fields was exposed to roentgen rays generated at 135 kv., filtered through 6 mm. of aluminum at a focal-skin distance of 12 inches (30 cm.) and received at 6 milliamperes for twelve minutes. On May 25, 1921, a fourth course of treatment was given through three fields, one right supraclavicular, one right infraclaviculo-axillary and one posterior scapular field. Each field was again exposed to roentgen rays generated at 135 kv., filtered through 6 mm. of aluminum, at a focal-skin distance of 12 inches (30 cm.) and received at 6 milliamperes for twelve minutes. On July 6, a fifth course of treatment was given through three fields similar to those used for treatment on May 25. The technical factors of treatment were precisely the same. A sixth course of treatment, similar to the last two, was given on September 7, 1921. On December 6, 7 and 8, a seventh course of treatment was given through two supraclavicular fields, one on each side of the median

line, and two anterior thoracic fields extending from the clavicle to the ensiform cartilage, and from the median line laterally to include the anterior aspect of the axilla on each side. Besides this, each axilla received separate treatment. Each of these fields was exposed to rays generated at 90 kv., filtered through 0.5 mm. copper plus 1 mm. of aluminum, at a focal-skin distance of 12 inches (30 cm.), and received at 5 milliamperes for thirty minutes. On September 13, 14, and 15, 1923, another course of roentgen therapy was given through one large right anterior thoracic field, extending from the upper border of the clavicle to the inferior border of the fifth rib in the mid-clavicular line and laterally from the midsternal line to include the anterior aspect of the axilla. A second lateral field was directed through the upper part of the right arm and a third large posterior field extended from the left midclavicular line to include the mediastinum, the region of the scapula and the posterior aspect of the right axilla. The anterior and posterior fields measured 20 by 20 cm., and the lateral field through the right arm measured 10 by 10 cm. Each of these fields was exposed to roentgen rays generated at 180 kv., filtered through 0.75 mm. of copper plus 2 mm. of aluminum, at a focal-skin distance of 50 cm. (20 inches), and received at 4 milliamperes for seventy-five minutes. On November 28 and 30 and on December 1 and 3, 1923, another course of roentgen therapy was given through two large anterior thoracic fields and two corresponding posterior thoracic fields. These extended from the upper border of the clavicle to the ensiform cartilage and from the midsternal to the midspinal line, to and including the anterior and posterior aspects of the axilla. Each of these four fields was exposed to roentgen rays generated at 200 kv., filtered through 0.75 mm. of copper and 2 mm. of aluminum, at a focal-skin distance of 50 cm. (20 inches), and received at 5 milliamperes for eighty minutes.

The patient was examined at the clinic on August 2, 1922, when a sequestrum was removed from the right humerus. He returned on May 15, 1923, or two and a half years following the original operation. The sinus had increased in size and there was a pathologic fracture of the right humerus; a section of the deltoid muscle and bone was removed; the latter apparently was necrotic. The pathologic examination revealed a mixed-cell sarcoma.

On August 20, 1923, the patient was again seen and an ununited pathologic fracture and ulceration were found. The tumor had invaded the muscle. This region was removed and the patient requested that disarticulation of the arm be performed, although he did not wish to have a forequarter amputation. Disarticulation of the arm with complete removal of the deltoid muscle was performed on August 22, 1923.

The patient again reported in November, 1923, when he had gained in weight, looked well and there was no evidence of metastasis. He was seen in September, 1924; the wounds had remained healed, there was no evidence of metastasis and he had gained further weight. In February, 1925, he reported for observation and had

gained yet more weight, the wounds had remained healed and there was no evidence of metastasis. He was last seen in 1933, when he weighed 212 pounds, looked healthy and was working. He reported at intervals from then on and was last heard from in November, 1939, when he stated that he was in the best of health, that the shoulder had given him no trouble, that he had gained more weight and that he was carrying on his usual occupation.

Summary

In reviewing the features common to Ewing's tumor and osteomyelitis we wish to indicate the necessity for careful study of the clinical, roentgenologic and microscopic findings in order that an accurate diagnosis may be reached without loss of time.

Ewing's tumor may simulate a minor affection

so closely that even those skilled in diagnosis may be deceived. On occasions, it would appear that one condition had become engrafted on the other; yet, even when this occurs, we feel that a careful investigation will reveal almost invariably the more serious nature of the disease process.

With earlier recognition and comprehensive treatment by means of surgery, irradiation and Coley's toxins, the mortality rate in cases of Ewing's tumor has been greatly reduced and we are now able to give a more favorable prognosis.²

RAT MITE DERMATITIS IN MINNESOTA

WILLIAM A. RILEY

University of Minnesota

Minneapolis, Minnesota

THE fact that the so-called Tropical Rat Mite, *Liponyssus bacoti*, will readily attack man and that it is often the cause of an irritating dermatitis has long been known. Cases have been reported particularly for Egypt, Abyssinia, Australia and Argentina.

In 1923, Bishopp reported that it had recently attracted attention in Texas, and, in one instance, in Mississippi, as an annoyance of man. Since then, there have been a number of records of the mite occurring in various parts of the South. McIntosh reports it as attacking employees in stock yards in the St. Louis area.* It has also been taken in New York City and Boston. These last records from seaport towns might readily be explained on the basis of accidental importation, and have not served to alter the general opinion that the mite is, as its common name implies, a tropical or subtropical species.

Over a decade ago there was brought to the attention of the writer, a case in which the offices of a Minneapolis company were invaded by hordes of small red mites shortly following fumiga-

tion to kill rats and mice in the building. The mites were determined as *Liponyssus bacoti* but the fact that the presence of mammalian red blood corpuscles in them was readily demonstrated, did not serve to shake the belief of the exterminator that they came from the samples of wheat in the laboratories.

A second case was that of a Saint Paul apartment house where the tenants complained bitterly about the attacks of the mites. The house was rat infested and was near a dump which harbored many rats.

In late January of the present year a physician from Pipestone, Minnesota, submitted to the State Department of Health specimens of the same species which were annoying employees of a local department store and causing "peculiar itching macular skin eruptions." Very shortly thereafter a similar complaint accompanied by specimens, came from Blue Earth, Minnesota, and there have been several other instances in which it seemed highly probable that mites of this species were causing trouble, although specimens were not found. It is evident that this troublesome parasite is not limited to the South or to tropical countries and physicians anywhere

*While this article was in the hands of the printer, Dr. L. F. Weber reported (*Jour. A.M.A.*, April 13, 1940, p. 1442) five cases of rat mite dermatitis among employees of a Chicago department store.

in this country may encounter puzzling cases of dermatitis due to its attacks.

In general, the severe cases are more likely to be those of children, although they are by no means limited to such. Dr. B. Shelmire of Dallas, Texas, was the first American worker to publish careful studies of the clinical aspects. His attention was attracted to the problem in 1928, when three members of a Dallas, Texas, family consulted him regarding a skin eruption diagnosed by a local physician as scabies. In their report, in 1931, Shelmire and Dove state that since these first cases, as many as 200 additional ones had been brought to their attention. In the case of adults they found the eruption to consist of small urticarial wheals and papules varying in size from that of a pinhead to that of a split pea. On young children they were in the form of papules, urticarial welts and, often, frank vesicles which were not confined to the hands and feet but diffusely distributed. In some instances the eruption simulated chicken pox.

On epidemiological grounds, followed by laboratory experiments, these workers concluded that *Liponyssus bacoti* was a carrier of endemic typhus from rat to rat and to man (Dove and Shelmire, 1931, 1932). Although this work is often overlooked, because of the present-day emphasis on the rôle of rat fleas, it was so carefully carried out that there can be no doubt that the mite is a potential vector.

In superficial appearance, *Liponyssus bacoti* resembles the common red mite of poultry. The failure to find the mites when they are present is not surprising, in view of the fact that the fully fed female does not exceed a twenty-fifth of an inch in length and the male is little more than half that size. The newly hatched young are much smaller. In all stages they attack man or their rodent hosts and after a brief period of feeding they drop off and hide in cracks and crevices where they molt and are again ready for a meal.

The presence of this mite in Minnesota is another of the many reasons for more active efforts to exterminate its vicious rodent host. Only through reduction of the rat and mouse populations can the mite be eliminated. Under some conditions fumigation with hydrocyanic acid gas will prove effective in eliminating both rodents and their parasites from buildings, but the hazards of such treatments are too great to justify its use by inexperienced persons.

KNOWLEDGE OF DISEASE

Knowledge of disease has now advanced so far that it is very often desirable to treat the patient before he knows that he is sick. People stricken with acute disease hasten to their doctor for aid. Those suffering from a chronic disease of insidious onset tend to put off their visit to a doctor and to seek relief by self treatment. Yet we know that, in many diseases, the best hope for cure depends on early treatment; treatment even before the symptoms appear. This is not only true of tuberculosis but of several other diseases including the two at the top of the list of causes of death: cancer and heart disease. It is true of diabetes, of many cases of syphilis, and of certain kidney diseases which though so slight as to be overlooked may cause high blood pressure later on. An attempt has been made by the American Medical Association to adjust the private practice of medicine to this situation but periodic medical examinations have not been widely accepted.—J. ROSSLYN EARP, M.D., *Health News*, May, 1940.

HISTORY OF MEDICINE IN WINONA COUNTY

(Continued from May issue)

Biographies

It has proved impossible to work the lives of all the Winona physicians, between 1850 and 1900, into the text of this essay. A biographical dictionary seemed to be a solution.

All available material concerning Winona physicians up to 1885 has been used and for those who practiced after 1885 brief sketches only have been given. Those about whom very little is known have been listed in order to give an idea of the approximate number of men who practiced in the county. In many cases, men referred to as "doctor," or even listed as physicians in the directories, were dentists, druggists, veterinaries, or quacks. No biographies of physicians now living in Winona County are given.

Rudolph Alberti came to Winona City in 1871. He was popular among the Germans there, and had quite an extensive practice. The reason for his departure in 1874 is unknown. The *Chicago Times* referred to Dr. R. Alberti as being involved in a questionable case in Davenport, Iowa, in 1869. He practiced in Saint Paul at some time previous to his stay in Winona (See Ramsey County).

Dr. Allen came to Winona as a practicing physician in the fall of 1853. According to Dr. D. B. Pritchard, Allen was the first man to practice medicine in Winona County. Little is known of him. He remained until the spring of 1854, and then moved to Chatfield.

E. H. Allen lived in Winona about 1880, and was gone by March, 1882. Apparently he graduated from the Medical Department of the University of Pennsylvania. He may have moved to Freeport, Illinois.

J. R. Andrews came from New York City and died in Winona City in June, 1870, at the age of fifty-two. He came in hope of improving his health, but lived only a few weeks after his arrival. He was president of the New York Medical College for Women at the time of his death.

Isaac Watwood made use of magnetic cures. In 1875-1878 he had a Turkish bath establishment. He contemplated opening a Turkish bath institute at Rochester in March, 1877. In August, 1878, he was still a resident of Winona City, and at that time he agreed to occupy a building and install Turkish baths at Arcadia for two years.

Henry N. Avery, A.M., M.D., came to Winona City in July, 1873, from New York, with the intention of locating there permanently. He was the son of Professor Charles Avery of Hamilton College, New York. Dr. Avery had been professor of physiology and clinical lecturer in diseases of the

throat and lungs in the Homeopathic Medical College of New York. He was, at the time of his arrival, a member of the State Board of Medical Censors of the State of New York. He brought with him to Winona recommendations from the Hon. Hiram Barney, a former collector of the port of New York, Professor Theodore W. Dwight of Columbia College, Hon. Roscoe Conkling, and others. His card published in August, 1873, read:

HENRY N. AVERY, M.D.

Homeopathic Physician and Surgeon

Special attention given to Diseases of the Throat
and Lungs, also to Chronic Diseases of all forms.
Office—4th street between Washington and Johnson.
Hours—8 to 10 A. M.—2 to 3 P. M.
6 to 8 P. M.

When in May, 1877, he moved to Galesville, the Winona paper said, "The people of Galesville will find in him a public spirited and cultivated member of the profession." In the spring of 1882, he moved with his family from Galesville to Minneapolis.

L. A. Babcock opened an office and started practice in Winona about 1859 and remained until about 1862.

John L. Balcombe came to Winona early in 1852 on an exploring trip. He returned the next year, built a farm house on a claim and lived there until his death, September 24, 1856. He did not make a business of medicine. Dr. Balcombe was a highly respected and influential citizen.

J. W. (or J. G.) Baldwin practiced in Lewiston from about 1873 until 1890 or later.

Dr. Baldwin testified in a court case at Utica in January, 1882. He may have practiced there. Probably he was from Plainview, Wabasha County.

G. W. Barck, physician and surgeon, opened an office and started practice in 1860. He was gone in 1866.

O. F. Bardwell lived in Winona in 1866. He moved to Wisconsin, then returned again to Winona in March, 1883, with his family. He was listed in that year as a pile specialist.

S. R. Beckwith practiced at Winona in 1865.

Charles Benson, M.D., physician and surgeon, came to Winona in 1857. He had a drug store for a time and in 1861 had a book store. Drs. Benson and Bunson appear to be confused in several reports.

J. W. Bentley lived at Minnesota City during the winter of 1852-1853. Then he made his permanent residence at the town of Utica, where he became postmaster and justice of the peace. In the years 1859 and 1862 he was listed as a clerk in Utica township.

D. W. Bingham was listed as a Winona physician in 1865 (possibly meant to be Dr. R. H. Bingham).

R. H. Bingham was referred to in September, 1856, as a candidate for county treasurer. He served three years during the Civil War as surgeon of

the 9th Minnesota Regiment, and returned to Winona in 1865. Dr. Bingham moved from Winona to Chicago. When he returned on a visit in 1879, he was referred to as "an old time resident but for many years past of Chicago."

E. C. Blodget was listed among Winona physicians in 1864.

A. W. Blunt, M.D., homeopathic physician and surgeon, was a resident of Winona in 1866. He left and again returned to Winona in 1879, intending to make it his permanent home. Dr. Blunt was son of the chief engineer of the Winona and Saint Peter Railroad. He was a graduate of the Chicago Homeopathic College and for some time previous to 1879 had been in charge of the Central Homeopathic Dispensary and Hospital. He came with fine recommendations and associated himself with Dr. T. A. Pierce. At this time his card appeared in the *Winona Republican*. He moved to Saint Charles in March, 1880, and in May of the following year was called to Clinton, Iowa, to take the place of a former classmate who had been killed in a railroad accident. Dr. Blunt was well liked in Winona.

A. C. Boyd came from Mazeppa and took up his residence at Lewiston in August, 1881. Dr. Boyd graduated from Rush Medical College in 1881. In 1885 he became a member of the Winona County Medical Society. In March of that year, he is recorded as engaged in the drug business.

Sheldon Brooks was born in Redfield, Oswego County, New York, on May 20, 1811. He lived there until his health compelled him to come to Minnesota, and he located at Beaver in 1856. He at once took an active interest in the development of the territory. He served as one of the county commissioners under the territorial organization, and after the state was admitted became a member of the legislature (1860-1861). In 1862 he built a grain warehouse at Minneiska and moved there, engaging in the grain business until May, 1874, when he retired and moved to Winona. He was a man of integrity; was very successful in business and was held in high esteem by all who knew him. Dr. Brooks died in Winona of progressive paralysis on May 19, 1883.

Bradley Bunnell located at Homer in the early 1850's and died there on June 9, 1857, aged seventy-five years. By his kindness and skill as a practitioner, he gained many friends in the community. Dr. Bunnell probably came to Winona County from Buffalo, New York.

Lafayette Houghton Bunnell arrived at the present site of Winona in 1844. However, he did not take up his residence in Winona County until some years later. No definite report of his residence in the county is found until 1871, when he was a settler of Homer. He was the son of Dr. B. Bunnell. During the interval between 1844 and his settling at Homer, he was probably living at La Crosse. Dr. Bunnell was the author of the "Discovery of the Yosemite," and of a series of historical sketches of Winona. He had much to do with the first Winona County history, published in 1883. He also wrote a record of his life among the Indians since 1844. Dr. Bunnell was born in Rochester, New York, in 1824, and died in Winona in July, 1903. He is recorded as having served in the Mexican War. There is no indication of his having practiced his profession while in Winona County.

Charles Bunson's card, which appeared in the Winona paper in August, 1876, read as follows:

DR. BUNSON

Physician, Surgeon and Accoucheur

Consultations in German, French and English.

Office—Second Street over Hollingworth's store.

Residence—Center Street

Dr. Bunson remained in Winona until April, 1882, when he moved to Galesville, Wisconsin.

H. V. Burnett was recorded as a physician of Winona County in 1865.

J. W. Burns settled in Utica with his family in January, 1878. Dr. Burns was considered to be a skillful physician and surgeon. He came to Winona County from Wisconsin.

John A. Burt, a homeopathic physician, graduated from the Hahnemann College, Chicago, in 1867. In 1885 he was practicing in Saint Charles.

E. V. Casteneg was listed as a physician of Winona County in 1865.

William A. Chamberlain graduated from Rush Medical College in 1882. He located at Saint Charles, Winona County, in February of that same year. In January, 1883, he purchased a stock of drugs. Then ten months later, he came to Winona to engage in the drug business. He continued his store in Saint Charles under a manager and introduced Dr. Knapp of Maine as a successor to his practice there. Early in the year 1883 Dr. Chamberlain was elected a member of the Winona County Medical Society.

Arthur Chambers came to Winona City in 1855. He advertised wholesale and retail drugs soon after his arrival. On December 18, 1855, his physician's card appeared in the Winona paper reading thus:

DR. A. CHAMBERS

Operative Surgeon

Office at his residence, corner Third and LaFayette streets, Winona, M. T.

Dr. Chambers' ample opportunity and experience as a Surgeon for several years in the East is a sufficient guarantee of his ability and success.

Operations and advice to the poor, FREE OF CHARGE, every Saturday, at his office.

In November, 1860, the following notice appeared:

A. CHAMBERS

Attorney and Counselor at Law

and

Dealer in Real Estate

George F. Childs was a member of the pioneer squad of the Western Farm and Village Association. He came to the present site of Winona from New York in May, 1852, and took a claim, upon which he lived for several years. He was a botanic physician but never practiced his profession in this vicinity, or did so only to a very limited extent. He engaged in mercantile business for a year or two after he sold his land. In the fall of 1855 he was elected a trustee of the First Baptist Church in Winona. In 1857 he moved up-river to Minneiska, Wabasha County. There he remained for some time, but later returned east. In 1883 he is recorded to have been in charge of a benevolent institution, a home for aged people, in Maryland.

Coleman N. Clark graduated from the University of Buffalo in 1865. The next year he came to Winona County and located at Saratoga. Dr. Clark was a charter member of the Winona County Medical Society organized in 1869. In 1881 he served a year as president of the society. At that time he lived in Saint Charles, having moved there about 1878. He became a member of the Minnesota State Medical Society in 1882. He was health officer of Saint Charles in 1885-1886.

Elisha Fessenden Clark was born in Conway, Massachusetts, in 1804. He had his academic and medical education at Deerfield, Massachusetts. He first practiced his profession in the lake regions of central and southern New York. In 1834 he went to Mississippi, where he had an extensive practice, but the malarious climate seriously impaired his health and he moved to Iowa in 1849. He came to Winona in 1856, and resided in the city until his death in February, 1879.

James B. Cole, son of Dr. J. M. Cole, graduated from the University of Michigan in 1882. He took up practice in Minneiska soon after receiving his degree. In 1883, he became a member of the Winona County Medical Society, and during the same year he was elected to membership in the State Medical Society.

James M. Cole came to Winona in June, 1854. He was the first practicing physician in Winona and remained more than four decades, up to the time of his death. Dr. Cole was born at Fayetteville, New York, February 4, 1824. He read medicine with Dr. Horace Seamon of Millport, New York, attended lectures in the Geneva Medical College and finished his medical education in 1846. Later, he practiced under the exemption law.

Upon his arrival from New York State in 1854, the following card appeared in the Winona paper:

DR. J. M. COLE
Physician and Surgeon
Office—Corner Third and Johnson Street
Winona, M.T.

In May, 1856, Dr. Cole and Dr. S. B. Sheardown became office partners, an arrangement which was discontinued in June of the following year. It was at that time that many physicians were forced by the depression to engage in other pursuits for a living. An urgent request to "pay up accounts" to Cole and Sheardown was entered in the paper, and immediately thereafter Dr. Cole opened a livery stable. In 1861, he again took up the practice of his profession. The following notice and card appeared at that time:

The attention of persons in need of medical attendance is directed to the card of Dr. J. M. Cole elsewhere. He is a pioneer of this place, and in an extended practice and strict attention to his profession has been enabled to learn the peculiarities of this climate and the wants of the invalids. Volunteers' families will find his name recorded among physicians who offer gratuitous service.

J. M. COLE
Physician and Surgeon
Office—at resident near Huff's Hotel
Will promptly attend to calls either day or night.

Dr. Cole served in many municipal offices. He served on the local Board of Health in 1866. In 1869, he was appointed to furnish medical attendance to the poor at the county poor farm. In 1873, he was elected city physician, being the first to hold this office. He continued to serve in that capacity in 1874, 1875 and 1876. During the years 1874 and 1875, he was county physician. It is of interest to notice that the office then paid \$600 a year. Dr. Cole was one of the organizers of the Winona Preparatory Medical School and was an instructor there. He served as school director or as a member of the school board in Winona continuously from 1875 until 1883. In 1883 he was president of the school board. Dr. Cole was a charter member of the Winona County Medical Society. In 1871 and again in 1882 he was president of that organization. He became a member of the Minnesota State Medical Society in 1870. In 1882, he attended the meeting of the American Medical Association in Saint Paul as a representative of the Winona County Medical Society.

Dr. Cole was an active Mason and Odd Fellow. He took an active part in the Democratic county conventions, and in 1877 he became a member of the State Legislature. He was chairman of the Board of Directors for the North-Western Fair held in August, 1876.

When the "Winona County History" was compiled in 1883, Dr. Cole gave assistance and supervision.

J. R. Cone arrived in Winona City in May, 1856. His card appeared in the *Winona Republican* on the 20th and read as follows:

J. R. CONE

Physician and Surgeon

Office—on 2nd street, over R. D. Cone's store.

Would respectfully offer his services to the citizens of Winona and vicinity in the above capacity. A share of public patronage is solicited.

In October, 1859, when he was running for county treasurer, the newspaper defended him against slanderous reports circulated by the Democrats. Dr. Cone died in Winona in April, 1863, of pulmonary consumption. He was forty years of age at the time of his death.

C. H. Connelly may have practiced in Winona County in 1858 (see Goodhue County).

D. M. Cool may have practiced in Winona County in 1865.

Dr. Corkins was in Winona City in 1875 and may have practiced there.

J. C. Crandall practiced medicine at Witoka in 1880. He was a homeopathic physician and not having graduated from a medical school, he practiced under the exemption law.

E. N. Cushing was listed as a practicing physician in Winona County in 1865.

C. B. Dayton, M.D., physician and surgeon, put his card before the public of Winona City in June, 1857. In 1859 he became the partner of Dr. D. C. Patterson. Dayton left Winona about 1861.

Dr. Dixon of Saratoga, Winona County, received the appointment of surgeon to the Fifth Minnesota Regiment in July, 1863, and started for

Vicksburg immediately. Prior to that date, he probably practiced in Saratoga.

H. W. Driver was listed as a physician in Winona County in 1865.

M. N. Dyer was listed as a physician in Winona County in 1864.

W. C. Edmund was mentioned as a physician in Winona in 1859.

William I. English was born in Wisconsin in 1864 and was educated at the University of that state. He graduated from the College of Physicians and Surgeons of Chicago in 1886. He practiced medicine at Arcadia, Wisconsin, for four years and in 1891 came to Winona, where he was associated with Dr. Stewart. He died in Winona in February, 1899, after a short illness, from pneumonia.

D. C. Estes was mentioned as a Winona physician in 1859, and again in 1866.

W. M. Evans was born, raised, and studied medicine in Winona. He practiced in Granite Falls in 1881.

O. M. Farrington came to Winona in 1855. His card, published in October, read:

DR. O. M. FARRINGTON

Physician and Surgeon

Office—corner of Main and Third Sts., Winona,
Minnesota

Dr. Farrington is prepared to attend to all calls within the village or country, and hopes by strict attention to the duties of his profession, to merit and receive a share of patronage.

N. B. Particular attention paid to diseases of the Eye.

In the spring of 1857, when few of the medical fraternity could make both ends meet, Dr. Farrington started a hardware establishment. In 1867 and 1868 he served on the Board of Education. He continued in the hardware business until 1876, at which time he and W. S. Farrington opened a drug store. He sold out his drug business in February, 1879, and went to New York, where he studied in a hospital for a time. In May, 1880, he took up his profession in Huron, Dakota Territory, and he died there in September, 1881.

A. S. Ferris, M.D., came to Winona City in May, 1856, and opened a store at the corner of Center and Levee Streets with a large assortment of drugs, paints, and oils. In September of that year, he published the following card:

A. S. FERRIS, M.D.

Office

Corner of Center and Front Sts., Winona, M.T.
will attend to all calls as Physician, Surgeon, and
Accoucheur, in town or country, either day or
night.

In April, 1862, Drs. Ferris and Hebard associated themselves in the practice of medicine and surgery. Dr. Ferris became county coroner in 1863. He was a school district trustee in 1858.

(To be continued in the July issue.)

President's Letter

DO the physicians of Minnesota want Government control of medical practice? Do we want regimentation such as exists in Germany and Austria, or the cheap makeshift Panel System used in England? Do we want sickness insurance controlled by Government bureaus and enforced by local politicians? Do we want increased taxation to pay us reduced incomes? If so, do nothing and they will come.

Because the Wagner Bill of last year has not been passed is no evidence that the danger of Government control of medical practice is over. The desire to control our profession is just as strong as ever, but a general election has crowded it temporarily into the background. The European war may be another factor.

The latest news is to the effect that socialized medicine is a political issue in California. This brings the threat to our very door. To offset cut-rate clinics and this danger of socialized medicine (state control of medical practice), the five thousand physicians in California are placing their hopes in the California Medical Service plan. For Government control of medical practice has been the death-knell to freedom for the physician in every country in which it has been introduced.

What effective measures can be used against this danger? There are several.

First of all in importance is the physician himself. Every doctor has patients and friends who trust him. Every physician owes it to himself to become thoroughly informed on these matters and to pass this knowledge on to every individual within his range of contact; church organizations, service clubs, fraternal societies, and social contacts of all kinds should be used in a thorough educational program.

The State Committee on Interprofessional Relations plans on holding four large district meetings this year. The members of the other professions must realize that if our profession is regimented, their turn will come next; already the lawyers are hearing rumblings.

But the only organization of national scope in this country to carry on this work is the "National Physicians Committee for the Extension of Medical Service." This is an organization of physicians formed for just what its name indicates—the extension of medical service, and to fight the threatened imposition of socialized medicine. This Committee is made up of physicians of national reputation and each member is of the highest standing. It includes a recent past-president and several trustees of the American Medical Association; all are leaders in organized medicine. Annual financial contributions to this Committee will enable it to carry out carefully prepared plans to educate the public to increased appreciation of what the American medical profession has accomplished, what it is doing, as well as to offset and effectively oppose all efforts to force socialized medicine through legislative bodies. Already about 8 per cent of the physicians of the country have subscribed to this important work and in Minnesota about 8.5 per cent. The average contribution has been ten dollars. What the Committee needs is an annual contribution from every physician in the country.

If you would do your part in the preservation of the American standards of medicine, send your check to Dr. N. S. Davis, III, Treasurer, National Physicians' Committee for the Extension of Medical Service, Pittsfield Building, Chicago, Illinois.

B. S. ADAMS, President
Minnesota State Medical Association.

APROPOS OF "THE MAGIC BULLET"

WE owe much, in our time, to the movies. They are as widely distributed and available as gasoline. With gasoline we drive to other cities and states; we see their attractions and improve our understanding. Via the movies our eyes encompass the creations of other minds; we view on the screen the world of yesterday, today and tomorrow. We travel for many obvious reasons other than amusement and yet those vending travel inducements (the New York Fair) have found the public curiously repelled and balky where low forms of clap trap burlesque is soft pedaled. It seems that movie theatres suffer similarly.

*A Warner Brother's film starring Edward G. Robinson in the title rôle as Ehrlich.

Recently one of our larger motion picture theaters showed the "The Magic Bullet," a portrayal of the life of Ehrlich and some of the great scientists of his time, to a disappointingly small audience. The time originally allotted had to be shortened because of the lack of interest on the part of the theater-goers. The part of Ehrlich was very capably played by Edward Robinson. The entire cast was correspondingly well suited. In the first place, the film was badly named. The idea that Ehrlich's discoveries dealt chiefly with 606 (a cure for syphilis) may have been publicized only sufficiently to cultivate a distaste among some sensitive people. This title, therefore, concealed much that was beautifully and astoundingly portrayed with a simplicity and fidelity to historical facts and settings previously missed for the most part in the distortions offered under the guise of the drama of scientific discovery. The contacts of Ehrlich with Koch and VonBehring, the allusions to the Frenchman, Roux, the type of German hospital ward, nurses and dispensaries reproduced—all were very true to form—indeed a masterpiece of technical reconstruction. For example, it is shown that when Robert Koch discovered the bacillus that carries his name, its easy identification through staining was suggested and worked out by Ehrlich. His intensive studies in immunity led him to attempt the first chemotherapy with selective dye-stuff. We should not need to be reminded that the recent achievements following Domagk (now so very fruitful and promising) represent the return to Ehrlich's early work and to his courageous outlook.

In passing, this may be a good time for us to pay homage to these German scientists, despite all the present-day Nazi outrages. Just as Lincoln's name belongs to the world because of his imperishable words and deeds in terms of eliminating slavery, so men like Ehrlich and VonBehring and the others, regardless of national origin, belong to the world for freeing mankind from shackles of disease. Those living today find it hard to appreciate the horrible menace of diphtheria that obtained at the beginning of this century. It is not generally known that syphilis

—here in Minnesota—is rapidly becoming a vanishing disease. Our profession is attempting various ways and means of giving to the public correct appraisal of the part we have played and propose to perform in keeping people alive and making living worth while. Let us not neglect a vehicle such as this outstanding Hollywood product. Let those who have seen this movie pass the word on to their friends; let those who have not seen it seek the first opportunity they have to do so.

E. L. TUOHY, M.D.

THE CASE FOR PRIVATE MEDICINE

AFTER the appearance of the articles in the March numbers of *Fortune*, *Liberty* and the *American Magazine* so derogatory to medical practice and the profession in our country, the admirable article entitled "The Case for Private Medicine," which appeared in *Nation's Business* for May, was a surprise and cause of considerable satisfaction.

If anyone believes that the profession has been manifesting evidence of psychopathic delusions of persecution, he should read this article which gives in detail the steps that have been taken in an attempt to fully socialize medical practice in the United States.

"The Case for Private Medicine" is the fifth of a series of articles advocating private initiative in contradistinction to regimentation, the previous articles having dealt with insurance, investment banking, power and light and distribution.

We believe in the great power of public opinion. Although frequently the majority shows stupidity in its choice of leaders or public measures, this is generally due to lack of information. In the long run, the opinion of the majority seems to muddle through and is safer to rely upon than the leadership of one individual or a small group. It is, therefore, satisfying to find this article giving in detail "The Case for Private Practice" in the organ of the National Chamber of Commerce, which has a circulation of 350,000.

Our system of medical practice is only one of a great number of activities that have been attacked by a group in government circles with the obvious aim of doing away with private enterprise.

While there has been a distinct trend in public thinking in favor of more government control of business activity in order to eliminate certain

bad practices and to alleviate misfortune, such as that due to non-employment and old age, the pendulum has swung so hard that government has come not only to control, but has interfered with business, and in any number of fields has entered into competition. In no sphere has government competition been more in evidence than in medical practice.*

Certainly the majority of American citizens do not favor a socialistic form of government. Calling attention to the trend in that direction should be sufficient to halt government control to the point of obstruction and competition with private enterprise.

DOCTORS HAMILTON AND WRIGHT

AT times we become rudely awakened to the fact that time is "swift a flying." The recent loss through death of two former members of the Editing and Publishing Committee of MINNESOTA MEDICINE, Dr. Charles B. Wright and Dr. Arthur S. Hamilton, has been a double blow.

Dr. Hamilton became a member of the committee in 1929 and gave the Committee the benefit of his mature judgment until illness incapacitated him in January 1935. Loved and respected by all who knew him, he was a valuable addition to any committee meeting. His long years of illness although relieved by a period of remarkable improvement was a source of sadness to all. His passing on June 2, must have been a welcome relief. Our next issue will contain a detailed sketch of his life.

In 1935 Dr. Hamilton was succeeded on the Committee by Dr. C. B. Wright. Intensely interested in all affairs of medical organization his years of experience in county, state and national medical affairs made his opinion on matters of policy of special value. His passing on May 31 came as a shock to many who did not know of his recent illness. A sketch of his unusually active medical career appears elsewhere in this issue.

MINNESOTA MEDICINE owes much to these two men and takes this occasion to express its appreciation of their gratuitous but none the less valuable services. The individual members of the Committee who met and came to know both Dr. Hamilton and Dr. Wright feel a very personal loss.

*In this connection it may be noted the intention of the Veterans Bureau to add 700 beds to the Fort Snelling Veteran's Hospital. Also that admissions to Veteran's Hospitals in 1939 totaled 165,576 (an increase of 8 per cent over the previous year), 92 per cent of which were for disabilities not connected with war service.

A VERY IMPORTANT COMMUNICATION WHICH EVERY PHYSICIAN SHOULD READ

Supreme Court of Minnesota Rules Injured Workman May Select Own Physician under Workmen's Compensation Act

In an opinion written by the Hon. Clifford L. Hilton, Associate Justice, the Supreme Court of Minnesota on May 3, 1940, unanimously held that under the Minnesota Workmen's Compensation Act an employee who insists upon treatment of his compensable injury by a physician of his own choice, can obtain from his employer, or the employer's insurance carrier, the reasonable value of the services rendered by such physician, notwithstanding the fact that the employer is ready and willing to furnish and pay for medical treatment by a physician designated by the employer. Written notice of this decision of the Supreme Court has previously been sent to every member of the Minnesota State Medical Association, and the Supreme Court's opinion is published in full below.

The decision of the Supreme Court was rendered in the case of Carmody v. City of Saint Paul, and arose from the attempt by certain Municipal officials to compel City employees, who were injured in line of duty, to be treated by one of five Saint Paul physicians who were designated, and who served at the pleasure of the Corporation Counsel. Mr. Carmody, a fireman, was injured in line of duty and insisted upon being treated by his family physician. Notwithstanding the fact that the City of Saint Paul paid the hospital bill and Mr. Carmody's wages, it refused to pay for medical care in the sum of \$110.00 which had been stipulated as a reasonable amount for the services rendered. The case was heard before the Industrial Commission and a decision was rendered in favor of the City of

Saint Paul. Mr. Carmody after conferring with the Central Council of Public Service Employees of the City of Saint Paul appealed to the Supreme Court of Minnesota. At the September 1939 meeting of the Council of the Minnesota State Medical Association it was unanimously voted to request permission of the Supreme Court of Minnesota to file a brief amicus curiae (as friend of the Court) in the case, particularly in favor of a medical allowance to Mr. Carmody, and for reversal of the order of the Industrial Commission. Such a brief was prepared and filed by legal counsel for the Minnesota State Medical Association. A similar brief was also filed by legal counsel for the Minnesota State Federation of Labor. A brief in support of the position taken by the City of Saint Paul was filed by legal counsel for the Minnesota Employers Association.

The Council of the Minnesota State Medical Association is very much gratified by the results achieved in this case, and especially by the clear cut opinion written by Justice Hilton. The question involved in this case has been recurring in one form or another during the past eleven years, notwithstanding the fact that the Supreme Court of Minnesota in 1922, in the case of Lading v. The City of Duluth, held that an injured workman had the right to be attended by a physician of his own choice. The law has now been definitely established; therefore the Council of the Minnesota State Medical Association wishes to point out and to emphasize to each member of the medical profession, his direct responsibility:

1. To render proper medical care to the injured employee;
2. To make a reasonable charge for the services rendered.

It goes without saying that, in the past, an extremely small number of physicians have taken

Industrial Commission

Hilton, J.; Gallagher, C. J.; Stone, J.
concur specially.

John J. Carmody,

Relator

-vs-

City of Saint Paul,

Respondent.

Endorsed:

Filed May 3, 1940

Grace Kaercher Davis, Clerk
Minn. Supreme Court.

SYLLABUS

Certiorari to the industrial commission.

Held, that under the workmen's compensation act, an employee who insists upon treatment of his compensable injury by a physician of his own choice can obtain the reasonable value of the services rendered by such physician although the employer is willing and ready to the knowledge of the employee to furnish and pay for proper medical treatment by a physician of the employer's choice but not otherwise.

Order reversed and cause remanded with directions.

OPINION

HILTON, Justice.

Certiorari to the industrial commission.

Relator was employed by the city of Saint Paul as a fireman. On December 29, 1938, he suffered an injury during the course of his employment. Upon entering the hospital, relator requested and obtained his family physician, Dr. H. A. Molander, to render the necessary medical attention. Relator refused treatment by doctors designated by the city to minister to employees injured in the line of duty. Compensation during the period of disability and hospital expenses have been paid by the city. It refuses to pay the \$110.00 incurred for medical treatment on the ground that relator refused its proffered assistance by one of its designated physicians. There is no question that the city was ready, able and willing to give proper medical treatment through one of its specified physicians and would have done so but for relator's refusal.

Previous to the time of the injury, the city council determined that in some instances, which it thought occurred too frequently, injured city employees were being given improper treatment and the city was being overcharged by doctors. Proposing to remedy the situation, a resolution was passed providing for the designation of five doctors to treat employees. Notices were posted in fire barns giving the names of the physicians and directing that "any employee * * * injured in the line of duty, shall report to any of the following doctors for treatment. The City of Saint Paul will not be responsible for medical bills incurred elsewhere." By the resolution, it was provided that if the injured employee had a family physician the city "shall pay the reasonable cost of consultation by said physician when such consultation is requested of the City by the employee or any member of his or her family." Relator was fully acquainted with the contents of the cards that were posted.

Presented then is the question whether an employee, who insists upon treatment of his compensable injury by a physician of his own choice, can obtain under the workmen's compensation act the reasonable value of the services rendered when the employer is willing and ready to the knowledge of the employee to furnish and pay for proper medical treatment by a physician of the employer's choice but not otherwise.

The referee and the industrial commission both took the view that the relator's claim should not be allowed.

Decision requires that the provisions of the compensation act as amended from time to time be con-

advantage of the employer, or his insurance company. In fact such a situation resulted in the suspension of a member of the Ramsey County Medical Society for fourteen months. It is, however, unnecessary to admonish the great majority of the medical profession to do good work and charge a reasonable amount for their services. On the other hand, it should be distinctly understood that any abuses in the future that are of a deliberate or wilful nature, will be severely dealt with, not only with respect to membership in the Minnesota State Medical Association, but also, I am confident, insofar as state licensure is concerned; moreover other penalties are available under the laws of this state. The Minnesota State Medical Association cannot, and does not intend, to sit idly by and have the rights and privileges of the majority of the ethical practitioners endangered by a few physicians who seem to have little regard for their public obligations.

The Council requests that every member acquaint himself with this decision of the Supreme Court. Justice Hilton's opinion clearly sets forth the construction that is given to this section of the Workmen's Compensation Law, and the law is now definitely settled that an injured employee, who is entitled to benefits under the Workmen's Compensation Act, may be treated by his family physician or a physician of his own choice.

The Council of the Minnesota State Medical Association is working on a plan whereby certain difficulties that may arise in the future, not only with reference to the type of medical care being rendered, but also as to the fee charged by the physician, may be referred to a committee of physicians for such recommendation as may be proper under the circumstances. A similar plan has been employed successfully throughout the State of Minnesota in relief cases. It is the duty of the medical profession to be fair to the injured employee, to the employer, to the insurance carrier, and to the medical profession as a whole. The Council therefore earnestly requests the highest type of coöperation from all the members in this matter.

Most respectfully,

Minnesota State Medical Association,
By H. Z. GIFFIN,

Chairman of the Council.

sidered for here is the source of much of the disagreement.

The original compensation act adopted in 1913, L. 1913, c. 467, Sec. 18, provided:

"Such medical and surgical treatment * * * as may be reasonably required at the time of injury and thereafter during the disability, but not exceeding ninety (90) days, to cure and relieve from the effects of the injury, the same to be provided by the employer and in case of his inability or refusal seasonably to do so, the employer to be liable for the reasonable expense incurred by or on behalf of the employee in providing the same; provided, however, that the total liability * * * shall not exceed the sum of one hundred dollars * * *."

In 1921, after study by an interim committee, amendments were made to the 1913 law. By L. 1921, c. 82, Sec. 19, it was enacted that such medical and surgical treatment "as may reasonably be required at the time of the injury, and during the disability for not exceeding ninety (90) days and not exceeding one hundred (\$100.00) dollars in value, to cure and relieve from the effects of the injury, shall be provided by the employer and in case of his inability or refusal seasonably to do so, the employer shall be liable for the reasonable expense incurred by or on behalf of the employee in providing the same * * *."

Added to the compensation act in 1921 was the following:

"The Commission may upon the petition of an **employee** and a proper showing of cause therefor order a change of physicians and designate a physician suggested by the injured employee or by the commission itself in such case the expense thereof shall be borne by the employer * * *" on the same terms as provided in the section previously quoted. (Bold supplied.)

The report of the interim committee of the house of representatives to the 1921 legislature stated with reference to the provision permitting the commission to order a change of physicians on the petition of the employee as follows:

"(11) Provision authorizing the Industrial Commission to order a change of physicians on the application of the injured person to some physician named by the injured employee or the Commission itself. This provision is intended to overcome the objection to permitting the employer to select any physician and require the employee to accept him."

At this point the case of Lading v. City of Duluth, 153 Minn. 464, 190 N. W. 981, decided December 1, 1922, must be inserted into the picture. Lading, an employee of the city of Duluth, suffered compensable injuries. The city had in its employment a physician who would have treated plaintiff had he consented. Instead, plaintiff called one of his own choice. He then sought to obtain the reasonable value of the physician's services. The city resisted the claim on the ground that since there was a regular city physician who would have rendered medical treatment, the employee was not entitled to be reimbursed. Section 19, of the 1921 compensation law, was the statute which we had to consider. We held that Lading could not recover the reasonable value of the rendered services since "To justify a recovery of the reasonable value of the services of a physician called by the employee, it must appear either that the employer was unable to furnish one or that he refused to do so. Upon this the statute leaves no doubt but the requirements thereof were not met by the plaintiff." Under the statute of 1921, one of these alternatives had to be established before the reasonable value could be recovered. However, it was also held that the employer was liable to reimburse Lading to the extent of \$100.00, the statutory limit at this time. We there said, p. 467,

"But we are of the opinion that the statute should not be construed to impose upon the employee the unqualified obligation to accept the physician selected by the employer, or forfeit the right to reimbursement

there given. It often happens, a situation perhaps more or less general, that the employee has a family physician to whom he prefers to turn in case of injury or sickness, rather than accept the services of another with whom he has no acquaintance or in whom perchance he has no confidence. In that situation, he should have the option or unquestioned right to choose his medical attendant, or accept the one tendered him by the employer but within the limits of liability on the part of the employer imposed by statute. The statute contains no language unconditionally requiring the latter to accept the physician tendered him or relinquish the right of reimbursement altogether, and we construe it to give him that option * * *."

If the report of the interim committee exemplifies the intention of the legislature in amending the provision with respect to medical treatment, there is little room for doubt that the construction adopted by this court diametrically opposed the purpose of the law makers. But before we can consider impeaching the Lading decision, attention to legislation after that case was determined must be given. In this, perhaps, will be found convincing reasons why we should not alter that decision.

In 1923, the legislature convened and amended section 19 which had been the subject of construction in the Lading case. As amended it read, L. 1923, c. 300, Sec. 6,

"The employer shall furnish such medical * * * treatment * * * as may reasonably be required at the time of the injury, and during the disability for not exceeding ninety days to cure and relieve from the effects of the injury, provided that in case of his inability or refusal seasonably to do so, the employer shall be liable for the reasonable expense incurred by or on behalf of the employee in providing the same; * * *"

"The Commission may at any time upon the request of an **employee** or **employer** order a change of physicians and designate a physician by the injured employee or by the Commission itself and in such case the expense thereof shall be borne by the employer * * *." (Bold supplied.)

As we understand the statutes, despite the fact that in the 1921 enactment the words "shall be provided by the employer" were used while in the 1923 statute it reads, "the employer shall furnish * * *," the fundamental rights and duties of the employer and employee are substantially the same under both statutes except that the financial limit on the employer's liability is removed by the 1923 law and the employer is given the right to apply for a change of physicians. Manifestly the 1923 legislature could have specifically provided that the employer could designate a physician which the employee must accept or forfeit any claim against the employer for physician's services. But it did not. Instead it enacted a statute which was, so far as substance is concerned, the same as the 1921 statute except for the two mentioned changes. It must be remembered that the Lading decision was decided under the 1921 enactment. As additional evidence that the 1923 legislature accepted the holding of the Lading case is the fact that in 1923 the employer was given the right to apply for a change of physicians. By removing the \$100.00 limitation found in the 1921 statute, the substantive obligation of the employer as determined in the Lading case was not destroyed.

In 1929, the legislature convened and adopted amendments to the compensation law. L. 1929, c. 248 (1 Mason Minn. St. 1927, Sec. 4279) amended the medical provisions of the 1923 act. The provisions of the 1923 law were for all practical purposes re-enacted except that the 90 day limit was dropped. Consequently, despite more than ample opportunity to alter the rule of the Lading case, the legislature has not done so. With this background, we do not think it is fitting that we should now re-examine the Lading decision to determine its soundness or unsoundness as an original proposition. Since the legislature has, in effect, adopted that holding and it has become a part of the compensation law, it

is more proper that if any change is to be made at this late stage the legislature should do it.

We think that the employe should have been awarded the mount claimed which the parties have stipulated is reasonable. Under the statute, if the city is of the opinion that improper care is being given an employe, it can apply for a change of physicians. If the occasion again arises where the city officials think excessive charges are being made, application can be made to the commission for a determination. These safeguards have been adopted by the legislature to prevent abuses which might arise.

So that there may be no doubt in the future, it is proper to discuss some of our decisions which counsel have cited.

In *Bookman v. Lyle Culvert & Road Equipment Company*, 153 Minn. 479, 190 N. W. 984, the decision of the Lading case was applied in a situation where the employer denied liability for the injury. Nothing in the opinion is in conflict with the Lading case.

Zobitz v. Oliver Mining Company, 167 Minn. 424, 209 N. W. 313, involved a case where the employe had his injury treated by the physician designated by the employer. The treatment continued for more than 90 days, the statutory limit at that time. Nearly a year after the injury, the employe went to a doctor he selected. Since the employe never obtained an extension of the period of treatment, the employer was not liable for the additional treatment. Consequently, it was immaterial to the decision to say anything about the failure of the employe to apply for a change of physicians. The question presented here was never actually reached in the *Zobitz* case.

Lund v. Biesanz Stone Company, 183 Minn. 247, 236 N. W. 215, is relied upon by respondent. There is nothing to show that the employe involved there ever objected to treatment by a physician designated by his employer nor did the parties question the power of the commission to order submission to treatment by a physician selected by the employer. We do not think the issue here raised was there involved.

In *Clausen v. Minneapolis Street Ry. Co.* 186 Minn. 80, 242 N. W. 397, the employer denied liability for the injury and the employer's selected physician told the employe to return to the doctor he first consulted. On these facts, it was held that the commission was fully justified in requiring the employer to pay the expenses of the employe in obtaining the treatment. Obviously the case never decided the question here.

Fitzgibbons v. Clarke, 205 Minn. 235, 285 N. W. 528, did not involve anything touching upon the present case.

Relator will be allowed \$100.00 attorney's fees in this court.

Since it has been stipulated that the amount of the claim is reasonable, the order is reversed and the cause is remanded with directions to award relator the \$110.00 spent in employing his own physician.

Order reversed and cause remanded with directions.

GALLAGHER, Chief Justice, concurring specially:

It seems to me that the court misconstrued the provisions of L. 1921, c. 82, Sec. 19, in *Lading v. City of Duluth*, 153 Minn. 464, 190 N. W. 981, when it held Sec. 19 thereof to vest in an injured employe the right to select a physician of his own choice. That section required an employer to furnish such medical, hospital and other expenses specified as might reasonably be required, within limits as to time and amount provided in the act, to cure and relieve an injured employe from the effects of an injury. Then followed the provision which gave to the employe the right to petition the industrial commission for a change of physicians clearly indicating a legislative intent to give to the employer the original right of selection. It reads:

"The Commission may upon the petition of an employe and a proper showing of cause therefor order a change of physicians and designate a physician suggested by the injured employe or by the Commission itself and in such case the expense thereof shall be borne by the employer upon the same terms and conditions as hereinbefore provided in this section for medical and surgical treatment and attendance."

While the exact question presented in the *Lading v. City of Duluth* case, supra, does not appear to have been before the Court since that case was decided in 1922, the principle involved has been referred to in a number of subsequent decisions. *Zobitz v. Oliver Iron Mining Co.* 167 Minn. 424, 209 N. W. 313; *Lund v. Biesanz Stone Co.* 183 Minn. 247, 236 N. W. 215; *Clausen v. Minnesota Steel Co.* 186 Minn. 80, 242 N. W. 397. These references have all indicated a view out of harmony with that expressed in the *Lading* case. The courts of other states having compensation acts similar to ours have almost universally followed the opposite rule. *Johnson v. Roberts*, 212 Ala. 535, 103 So. 563; *Cella v. Industrial Accident Commission*, et al. 38 Cal. App. 760, 177 P. 490; *Olstead v. Lamphier*, 93 Conn. 20, 104 A. 488; *Johnston v. A. C. White Lumber Co.* 37 Ida. 617, 217 P. 979; *Swift & Co. v. Industrial Commission*, 288 Ill. 132, 123 N. E. 267; *Indiana Liberty Mut. Ins. Co. v. Strate*, 83 Ind. App. 493, 148 N. E. 425; *Almquist v. Shenandoah Nurseries*, 218 Ia. 724, 254 N. W. 35; *Coleman v. Butler*, 166 La. 138, 116 So. 828; *Gardner v. Michigan Sugar Co.* 231 Mich. 331, 204 N. W. 100; *Schutz v. Great American Ins. Co.* 231 Mo. App. 640, 103 S. W. (2) 904; *Radil v. Morris & Co.* 103 Neb. 84, 170 N. W. 363; *Grogan v. Granger*, 16 N. J. Miscellaneous 533, 2 A. (2) 884; *Johnson v. Armstrong*, 41 N. Mex. 206, 66 P. (2) 992; *Szold v. Outlet Embroidery Supply Co.*, 159 Miscellaneous N. Y. 911, 289 N. Y. Supp. 411; *Skelly Oil Co. v. Barker*, 132 Okla. 279, 270 P. 566; *Smith v. State Industrial Accident Commission*, 104 Ore. 640, 208 P. 746; *Security Union Ins. Co. v. McClurkin*, (Tex. Civ. App.), 35 S. W. (2) 240; *City of Milwaukee v. Miller*, 154 Wis. 652, 144 N. W. 188.

However, the legislature has seen fit to permit the compensation act to stand substantially as it was when the *Lading* case was decided, altering its effect, in so far as the right to select a physician is concerned, only to the extent of permitting the employer, as well as the employe, to petition the industrial commission for a change of physicians. (L. 1923, c. 300 Sec. 6.) Because of the failure of the legislature to amend the statute so as to negate the *Lading* case, I feel compelled to join the other members of the court in accepting the rule there enunciated as the law.

There is much to be said in favor of permitting an employe who is injured to select his family physician or some other physician of his choice. There is also much to be said in favor of giving to the employer, who is required to pay the bills, a voice in the selection of the physician. This is a matter of policy, however, for determination by the legislature and is not a question which concerns the court.

STONE, Justice.

I concur in the opinion of Mr. Chief Justice Gallagher.

MINNESOTA'S RELIEF PLAN

The close working agreement recently cemented between the medical profession of Minnesota and the Division of Social Welfare occupied the center of the stage at the Rochester meeting.

It was praised as a practical strategic measure and as a symbol of democracy at work.

It was generally accepted as an instrument by which most of the vexing problems of medical care for Minnesota's needy may be satisfactorily solved.

In outline, the plan is as follows: A State Medical Advisory Committee of which Dr. A. W. Adson of Rochester is chairman, has been appointed by Walter Finke, director of the Division, from a panel of names drawn up by the Council. The committee has a quasi-official status and it meets regularly once a month. It came into being at the request of Mr. Finke and has the assurance of this enterprising lawyer-executive that no medical policies will be issued by his Division without its approval.

Committees Revived

The first joint act of the Division and the Committee was to proclaim the need for similar medical advisory committees to act with the local welfare boards in each county. With the approval of the Council the old County Contact committees, lately inactive in many quarters, were resurrected to assist the welfare boards in each county until new personnel could be appointed by the county medical societies involved—provided the societies wished to make such changes. The name "County Contact Committees" was retained temporarily but was to give way to the name "County Medical Advisory Committees" as soon as the House of Delegates could take official action at the annual meeting.

The committees thus established are to be active, essential parts of the relief and welfare machinery in every county. They will determine medical needs, settle medical differences, aid in solution of the problem of medical emergencies, help county boards to hospitalize clients economically, and efficiently and prevent, if possible, large expenditures for hospitalization plus transportation and other living expenses at the University hospitals for cases which can be cared for at home.

This is the plan. It will work if the county boards utilize the committees to the full as they have already been urged to do by the state administration—and if the doctors who comprise the committees serve faithfully, impartially and with intimate understanding of the problems of the board as well as of physicians and patients.

Discipline Included

It will work if the doctors are, furthermore, determined to discipline the occasional practitioner from their own membership who overcharges or who attempts to take advantage of the program to recoup private losses.

Questions which cannot be settled by local adjustment may be referred to the state medical advisory committee and settled in consultation with the Division of Social Welfare.

The entire plan was described by Governor Harold E. Stassen in his banquet address Tuesday, April 23, as a pattern for the proper approach to the sphere of coöperation between a profession and the government in meeting social problems.

Profession Praised

"If and when we are content to let government solve these problems, we are submitting to totalitarianism and dictatorship," Governor Stassen said.

"The medical profession has not adopted this attitude of 'let the government do it.' Instead it has proceeded on the fundamental tenet that if a problem can be solved by private initiative, then that is the manner in which it must be solved. And it is in this manner that we must solve our problems in America if we would save our democracy."

On the same day Mr. John Pratt, executive secretary of the National Committee of Physicians for Extension of Medical Services, declared that the Minnesota system of Advisory Committees to consult with County Welfare Boards commends itself to national attention.

"Problems Would Be Settled"

"If the physicians and welfare officials in every county in the United States would work together as you plan to do here in Minnesota," he said, "the problem of medical care for the indigent would be settled in six months."

As a result of the collaboration of the state committee and Mr. Finke's Division three new sets of regulations have been issued, by the Division, to date, to County Welfare Boards. They concern, first, the establishment of the Medical Advisory Committees; second, the new arrangements for medical care of recipients of Old Age Assistance; and third, new arrangements for medical care of the recipients of Aid to Dependent Children.

Study Announced

A thorough-going study of the entire problem of medical care to relief clients is now under way under auspices of Mr. Finke's department. This study will go into every phase of previous experience under the State Relief Administration and into experience of physicians as well.

Out of the findings, it is hoped that a sounder estimate of the relative place of medical costs in the relief appropriation may be arrived at and also a better and more uniform standard for payment of physicians' fees.

In the meantime, the threat of a return from the free-choice-of-physician basis to a county physician basis has threatened in several quarters where County Welfare Boards have been charged or fancied they have been charged an exorbitant amount for medical services.

All physicians everywhere are urged to cooperate closely with their local boards to keep their charges within limits mutually determined in their own counties by physicians and officials. In many localities the fees may be totally inadequate but every effort should be made to keep the principle of free choice in the plan of caring for the needy, pending adjustments that will undoubtedly follow upon the studies of costs made by the Division of Social Welfare.

NATIONAL COMMITTEE HEAD SPEAKS

Praise for starting the ball rolling which later became the National Committee of Physicians for Extension of Medical Service was extended to Minnesota physicians by Mr. Pratt in an address before the Minnesota branch at a luncheon meeting arranged at Rochester, April 23, by Chairman F. J. Savage.

The first organization meeting of the Committee was held in Minnesota, Mr. Pratt reported, and that first Minnesota meeting preceded the National organization meeting in Chicago by several days.

This new movement among physicians is the first of its kind in the history of medicine, Mr. Pratt declared in Rochester, and its objectives are: first, to inform the public about the accomplishments of medicine during the past 150 years; second, to convince the people that they have a vested interest in medicine which nothing must be allowed to imperil and third, to extend

medical service, wherever extension seems to be needed.

"We must get to the American people the story of what medicine has accomplished," Mr. Pratt said. "It is a story that has no equal in the history of the world.

"We must also convince the people of their own interest in medical service so that they will act to protect that interest and we must work to extend the service, step by step, so that no one in America will ever be forced to go without needed care."

The first essential to a proper handling of the economic problems associated with medical service is to establish the dividing line between the medically indigent and those who can and should pay for their own service, Mr. Pratt pointed out.

"The theory that every man, woman and child is entitled as of right and without charge to the ultimate in medical service is essentially false," he said. "I know of no way to cope with the medical aspects of our social and economic problems except to build block by block as the need arises and as you propose to do with the aid of your Division of Social Welfare in Minnesota."

A remarkable extension of interest in the new organization in all parts of the United States was reported by Mr. Pratt. Membership has grown amazingly and thousands of pieces of literature have been distributed. The National Committee of Physicians for Extension of Medical Service is an independent organization financed by physician members and designed for purposes of public education in the accomplishments and future needs of medicine. It is not affiliated in any way with the American Medical Association except as members of the committee are also members of the national medical organization.

Appeal for Contributions

The following paragraph from the *Pittsburgh Medical Bulletin*, May 18, 1940, is worthy of note:

"The National Committee of Physicians for the Extension of Medical Service will have a two-page advertisement in the *Saturday Evening Post* for June 22. . . . This form of advertising, believed to be more stable than some other forms, is something physicians have been wishing for and asking for ever since Public Relations Activities were first approved by medical societies. As is well known to all, such advertising is costly. Each contribution will assist, however, in pre-

serving, free from centralized control, for the American People, the highest level of health ever known—a priceless heritage, indeed!"

Members of the Minnesota Branch join with the national organization in an appeal for contributions from every physician to carry on this campaign.

APPROVED BY THE HOUSE

Outstanding among actions taken by the House of Delegates at Rochester, April 21 and 22, were the following (see also complete proceedings of the House of Delegates to be printed in full in an early issue of MINNESOTA MEDICINE):

For Statewide Immunization

An outline for organization of county immunization and vaccination programs was submitted by the Committee on Vaccination and Immunization of which Dr. L. R. Critchfield of St. Paul is Chairman, and it was approved both by the Council and the House of Delegates. The outline is available to any county medical society at the State Office and will stimulate state wide efforts on the part of medical societies, it is hoped, to carry on this essential public health program.

New Tuberculosis Program

Approval of delegates was extended to preliminary plans for an intensive tuberculosis control program under state medical association direction in Minnesota. The tentative plans call for intensive methods including universal tuberculin testing and x-raying in one test county. Methods of organization and financing have yet to be worked out by the Sub-Committee on Tuberculosis of which Dr. J. A. Myers of Minneapolis is Chairman.

No Statewide Insurance

The recommendation made by the Committee on Sickness Insurance, of which Dr. A. W. Adson of Rochester is Chairman, that no statewide plan for sickness insurance be set in motion for the time being in Minnesota was approved by the Delegates. This action does not prevent county medical societies from taking action of this type if they see fit.

In this connection, it is of interest to note, in the report of the Committee on Medical Econom-

ics, of which Dr. W. F. Braasch of Rochester is Chairman, that experiments in voluntary sickness insurance elsewhere do not appear to be working out to the satisfaction of their promoters.

"People who can well afford to pay for care on the old basis are availing themselves of the service," according to the report, "but so far, people in the lower income group for which the service was designed are not being reached."

Recommendations Delayed

Upon recommendation of the Committee to Study Motor Vehicle Accidents of which Dr. J. C. Hultkrans of Minneapolis is chairman, the delegates decided not to approve any specific methods for testing the volume of alcohol in the blood or secretions, nor to name any specific percentage of alcohol which is to be regarded as intoxicating, at this time. The Committee and the Association will continue its studies, however, and will work toward establishment of legislation on this matter when sound methods have been determined.

New Gavel

The delegates accepted the gift of a unique hand-carved gavel from Dr. W. S. Lemon of Rochester, who was present himself at the final meeting of the delegates to explain the symbols he carved into the handle and surfaces.

The handle is a rough hewn bit of Minnesota walnut upon which the artist has carved the rod of Aesculapius and coiled about it is the single snake which formed, with the rod, the original signum of this greatest of the Greek gods of medicine.

The signum of Aesculapius was used throughout the world, according to Dr. Lemon, until the reign of Henry VIII of England, when a confusion occurred and the symbol of Hermes the messenger, king of robbers and god of commerce, was substituted for the rod of Aesculapius. The mistake was later corrected in England but the symbol of Hermes with the wings at the top of the rod to show the speed of the messenger and the two coiled snakes still persists in this country. Hermes had few and slight connections with medicine other than the connection involved in the speed of his service.

On the face of the gavel is a beautifully designed open book and on the opposite surface a Grecian lamp. The gavel was accepted with the

enthusiastic thanks of the delegates by Speaker W. W. Will and will be used at all future sessions of the House.

THE COUNCIL MEETS

Three major insurance companies are writing malpractice insurance in Minnesota. The Council heard representatives of each of them at their first Rochester session and also a report on a comparative study of policies made by Attorney F. Manley Brist. At the recommendation of Mr. Brist and the Medical Advisory Committee it was decided that none of these companies should be singled out for special recommendation but that members should be urged to study all of them and select the policy that protects them best.

Rates for the three companies as reported to the Council are as follows:

Medical Protective Co.

In Ramsey and Hennepin Counties:

\$2,500/7,500	\$5/15,000
Pre. \$21.00	\$25.00

Out-state:

\$2,500/7,500	\$5/15,000
Pre. \$25.00	\$29.00

Lumbermen's Mutual Co.

\$5/15,000	\$10/30,000	\$15/45,000
Pre. \$25.00	\$34.25	\$41.75
Div. 5.00	6.85	8.35
Net \$20.00	\$27.40	\$33.40

Aetna Surety and Casualty Co.

\$10/30,000	\$20/40,000	\$25/50,000
Pre. \$30.00	\$33.47	\$35.31

The Aetna premium rate at \$10/30,000 shows the \$3.00 reduction secured by the Council which went into effect May 1, 1940. Where a partnership exists, Aetna charges an additional \$5.50 for each member of the partnership at \$10/30,000 limits to protect all if one is sued. The fee is somewhat larger at the higher limits. This business liability protection is included in the premium charged by the other two companies.

Surplus—1939

Association finances are in excellent shape in the opinion of Council members who decided to leave it to the Finance Committee of the Council

to determine the disposition of the 1939 surplus of some \$5,000. Finance Committee members may add the 1939 surplus to the investment fund if they see fit.

Figures for the Rochester meeting are not yet available but a profit is assured, the Council was told.

Examination Fees

The question of fees to be charged for physical examinations of applicants for Civil Service positions has been discussed from time to time and was brought for an opinion to the Council at this meeting. In view of the fact that the examinations are by no means complete, it was suggested that the fee might well be in the neighborhood of \$2.00 to \$3.00. The suggestion of the Council was not, however, to be construed as binding upon any individual physician.

Rest Homes

Rest homes, convalescent and nursing homes, so-called, are not licensed by the state nor are they subject to official regulation. The possibility of establishing some kind of official control over these institutions was discussed by the Council and the entire matter was referred for a special study to the Committee on Hospitals and Medical Education. Further action will be taken when the results of this study are reported to the Council.

More Time for Delegates

It will be recommended to next year's Committee on Scientific Assembly that the House of Delegates convene for its first session in the afternoon of the day preceding the opening of scientific sessions instead of in the evening. The delegates will then recess at 4 p. m. to permit reference committees to convene and the entire evening session will be given over to official action on committee reports and other association business.

Insufficient time is available to hear distinguished guests and also to give proper attention to the program of the association under the present plan, Council members believe. They plan to make an effort, also, to see that all delegates report fully to their county medical societies on the proceedings of the House and on economic matters generally.

Literature on the Other Side

Literature and reference materials on sickness insurance and government medicine, generally, will be placed in the principal libraries of the state this year by authorization of the Council.

A great deal of material is available in support of government intervention in the health program of the nation, but students find little in school or municipal libraries on the other side of the picture, it was pointed out. Responsibility for securing the literature and distributing it was placed upon the Executive Committee of the Committee on Medical Economics and the Finance Committee of the Council.

New Child Health Committee

A new committee on Child Health will be appointed this year by the President. This committee will take the place of the former Sub-Committee on Child Health which was part of the Committee on Public Health Education. The change in status and character of the Child Health Committee was made by the Council as a result of a petition from the former committee signed by Chairman R. L. Kennedy of Rochester.

It is the opinion of the Committee, shared by the Council, that the numerous scientific problems relating to Child Health are of sufficient importance to warrant the appointment of a special scientific committee to consider them and that the educational aspect of child health problems can well be handled through the Committee on Public Health Education by making the Chairman of the new Committee a member of the Education Committee. It was recommended that the members of the new committee be selected from chairmen of other committees whose work is related to child health, such as the Committee on Vaccination and Immunization and that the latter committee, especially, might function as a sub-committee of the new Committee on Child Health.

Hospital Insurance Requested

Requests have been received by the Minnesota Hospital Service Association recently for extension of group hospitalization to Owatonna, Red Wing, Winona and Faribault. Following the policy already established by the Council, the hospital service association was asked to take the matter up with each county medical society involved.

Women's Program Endorsed

The program of the Women's Field Army Against Cancer under direction of Mrs. Harlow Hanson of Minneapolis, was again endorsed by the Council and members were urged to co-operate in their own communities with the women's organization.

YOUR INSURANCE POLICY

(Monthly Editorial Prepared by the Medical Advisory Committee)

Recently the writer was asked the following pertinent question: "What points should be covered in a malpractice insurance policy to give complete coverage to a medical man?" This was the answer:

1. The policy should be written in a company organized and conducted on a sound business basis, large enough and old enough to have a reserve ample to take care of all emergencies.

2. The company should have local or state officers who are familiar with local conditions, and local representatives capable of giving the matter quick and thorough investigation; also legal talent who can rapidly scrutinize the findings of the investigation, and then as quickly sense the merits of the case.

3. The premiums should be reasonable and in line with the risk carried. Loss ratio has much to do, as we have lately seen, with cost.

4. To be protected fully, all claims or damages arising out of professional services rendered (not against the law) should be covered, as well as those services performed by a partner, assistant, nurse or any other agent.

5. The ideal policy has a clause in it which states that the policy is non-cancelable for any reason whatsoever, during its term.

6. The limits of the policy should be adequate to protect one fully under the law. The value of a life under the law being set at a known figure should be a criterion as to the lowest limits. The upper limits should be those compensurate with the type of work being done by the purchaser of the policy.

7. The policy should have a provision that no settlement can be made except by consent of the insured.

—B. J. B.

MINNESOTA STATE BOARD OF MEDICAL EXAMINERS

Julian F. Dubois, M.D., Secretary

Belle Plaine Drug Addict Sentenced for Obtaining Narcotic Drugs by Fraud and Deceit

Re. State of Minnesota vs. Merten J. Stratton.

On April 2, 1940, Merten J. Stratton, forty-four years of age, of Belle Plaine, Minnesota, entered a plea of guilty in the District Court of Scott County, to an information charging him with the crime of obtaining narcotic drugs by fraud and deceit. Stratton, after admitting to the Court that he had been a drug addict for over twenty years, was sentenced by the Honorable Joseph J. Moriarty, Judge of

the District Court, to a term of not to exceed five years in the State Prison at Stillwater. Judge Moriarty then ordered the sentence suspended on the condition that Stratton enter the Federal Hospital at Lexington, Kentucky, for treatment for his drug addiction. While Stratton was at liberty on a \$2,500.00 cash bond, awaiting approval of his application to enter this hospital, he again reverted to the use of morphine, and upon this being called to Judge Moriarty's attention by representatives of the Federal Bureau of Narcotics, the Minnesota State Board of Medical Examiners and County Attorney, Irwin, Judge Moriarty made an order cancelling Stratton's bond and ordering him taken into custody by the Sheriff. Stratton was then advised in no uncertain terms by Judge Moriarty, that he could choose between going to Stillwater or being taken, forthwith, to the Government Hospital at Lexington, Kentucky. Stratton chose the latter and Judge Moriarty then made an order that Stratton was to be taken to the Hospital, forthwith, by the Sheriff of Scott County, and all expenses were to be paid by the defendant, Stratton. Sheriff Mesenbrink left with Stratton on May 6, 1940, for Lexington, Kentucky.

Stratton was arrested on March 8, 1940, at Belle Plaine, Minnesota, following the filing of a complaint against him by Mr. Brist on behalf of the Minnesota State Board of Medical Examiners. Stratton was charged with obtaining narcotic drugs by fraud and deceit following a joint investigation made by the Minnesota State Board of Medical Examiners and the Federal Bureau of Narcotics. Stratton had obtained narcotics from at least 3 physicians in that vicinity who, to say the very least, were extremely careless in their prescribing and dispensing of morphine. Stratton has been a drug addict for over 20 years, and has been arrested on numerous occasions, and has served time in the State Reformatory at St. Cloud, Minneapolis Workhouse, and at Los Angeles, California. Despite his admitted drug addiction and his previous bad record, Stratton had no difficulty whatever in obtaining narcotics from several members of the medical profession. It seems a pity that it is necessary for the Federal Government, and the Minnesota State Board of Medical Examiners to take action against physicians who have been warned, time and again, not to prescribe or furnish morphine to drug addicts; nevertheless, there seems to be only one way in which cases of this type can be dealt with. The physician from whom Stratton obtained the largest amount of

morphine, was ordered to appear before the Medical Board on May 10, 1940.

The Medical Board approves, most whole-heartedly, of the manner in which this case was disposed of by Judge Moriarty. It also wishes to acknowledge the splendid cooperation of the Minneapolis Division of the Federal Bureau of Narcotics, County Attorney Irwin, and Sheriff Mesenbrink.

Saint Paul Osteopath and Negress Assistant Given Prison Terms in Abortion Case

Re. State of Minnesota vs. Samuel M. Stern.

Re. State of Minnesota vs. Agnes L. Shanks.

Re. State of Minnesota vs. Evelyn Stern.

On May 13, 1940, Samuel M. Stern, a licensed osteopath, and Agnes L. Shanks, his negress office assistant, entered pleas of guilty in the District Court of Ramsey to an information charging them jointly with the crime of abortion. Stern was sentenced by the Honorable Kenneth G. Brill, Judge of the District Court, to a term of not to exceed four years at hard labor in the State Prison at Stillwater. The defendant Shanks was sentenced to a term of not to exceed four years at hard labor in the Women's Reformatory at Shakopee. A request for a suspended sentence in the case of the defendant Shanks was rejected by Judge Brill, who stated that the Court was unable to grant probation to a woman who had been employed by the defendant Stern seven years, and whose work required her to assist the defendant Stern in the commission of as many as two and three criminal abortions a day, according to the defendant Shank's own statement.

The defendant Stern, who is forty-five years of age, has maintained an office at 512 Hamm Building, Saint Paul, for a number of years. He was licensed to practice osteopathy in Minnesota, March 10, 1926, notwithstanding the fact that he had been previously convicted of a felony in Orange County, California, on January 3, 1922, the felony being the crime of embezzlement, and for which crime Stern was sentenced to a term of not to exceed five years in the San Quentin Prison where he served until January 27, 1923, at which time he was placed on parole. The defendant Shanks, who gave her age as thirty, stated that she had no medical training of any kind and was not a registered nurse. Both defendants were arrested on May 9, 1940, following a raid by the Saint Paul Police Department on Stern's offices in the Hamm Building. A large list of women's names and addresses and giving the date of their last menstrual period, was seized by the police, along with numerous boxes of Leunbach's Paste, a product of Merz & Company Chemical Works, Inc., Newark, New Jersey, which was being used by the defendant Stern in the performing of criminal abortions. The police raid resulted from the death on May 6, 1940, at a Saint Paul Hospital of a twenty-one year old Bemidji girl, upon whom the defendant Stern attempted to perform a criminal abortion earlier that day. The girl was taken critically ill and died that afternoon from embolic pneumonia.

The investigation subsequently made, disclosed that Stern had performed a criminal abortion on a seventeen year old Bemidji girl in November 1939. It was through the performing of this criminal abortion that the Bemidji girl, who died on May 6, 1940, learned of the defendant Stern. Stern was paid \$100.00 for each abortion. Stern and his office assistant decided to plead guilty to the abortion charge rather than face a charge of manslaughter in the first degree in the death case. The defendant Evelyn Stern, a sister-in-law of the defendant Stern, has not been apprehended as yet by the police who hold a warrant for her arrest. It is

claimed that Evelyn Stern took care of a number of these girls at her apartment after they had been aborted by her brother-in-law.

The incarceration of the defendant Stern climaxes several years of most difficult and trying work by the St. Paul Police Department, the Ramsey County Attorney's office, and the Minnesota State Board of Medical Examiners. The defendant Stern was indicted by the grand jury of Hennepin County on March 19, 1935, on a charge of manslaughter in the first degree, the indictment alleging that Stern performed a criminal abortion on a Minneapolis girl who died on March 8, 1935, as the result of that abortion. Stern was also indicted by the grand jury of Hennepin County on April 11, 1935, on a second charge of manslaughter in the first degree, the indictment alleging that Stern performed a criminal abortion on another Minneapolis girl, and that this girl died on March 30, 1935, as a result of the abortion. Stern was indicted on a third charge of manslaughter by the grand jury of Hennepin County on April 30, 1935, the indictment alleging that Stern had performed a criminal abortion on a young Minneapolis girl, and that this girl died on September 7, 1934, from the abortion. In a fourth indictment returned by the grand jury of Hennepin County on April 30, 1935, Stern was indicted on a charge of criminal abortion. Stern was placed on trial on April 27, 1936, on one of the indictments charging him with manslaughter. On May 1, 1936, the jury found him not guilty. The three remaining indictments against the defendant Stern in the District Court of Hennepin County, were nolle on August 19, 1937, upon recommendation of the County Attorney's office of that County.

The present case is the second one in which the state authorities have found Leunbach's Paste, a product of Merz & Company Chemical Works, Inc., Newark, New Jersey, being used by non-medical practitioners in the performing of criminal abortions. In the case of *State of Minnesota v. Herman V. Feenstra*, in August 1938, the Sheriff of McLeod County seized a quantity of Leunbach's Paste in the possession of the defendant who held no license to practice any form of healing in the State of Minnesota, but who claimed to be a South Dakota chiropractor. It would seem that the present case clearly indicates the danger of using this paste, and it is to be hoped that the State and Federal authorities will find a way to deal effectively with the sale of this product in the State of Minnesota.

The Minnesota State Board of Medical Examiners wishes to acknowledge the splendid work done in these cases by the St. Paul Police Department, and particularly by Mr. Charles J. Tierney, Assistant Chief of Police, Lieutenant Thomas Grace and Detective Frank Kennedy. The Medical Board also wishes to mention the splendid work done by Mr. James F. Lynch, County Attorney of Ramsey County, and Mr. Clarence R. Smith, County Attorney of Beltrami County.

Supreme Court of Minnesota Upholds Five-year Suspension of Lake City Physician's License

In re. Revocation of the License of
Gottfried Schmidt, M.D.

On May 17, 1940, the Supreme Court of Minnesota, in a unanimous opinion written by Justice Royal A. Stone, affirmed the District Court of Ramsey County, which Court had previously ruled that the order of the Minnesota State Board of Medical Examiners suspending Dr. Schmidt's license for a period of five years, "was neither arbitrary, oppressive nor unreasonable." The order of the District Court of Ramsey County was made by the Hon. Carlton McNally, Judge of that Court. Dr. Schmidt's license to practice medi-

cine was suspended by the Minnesota State Board of Medical Examiners on December 16, 1938, following a complaint having been made by a former patient to the Medical Board in respect to the manner in which Dr. Schmidt diagnosed and treated various ailments. This hearing brought out the fact that Dr. Schmidt attempted to diagnose ailments, such as, cancer, brain tumors, stomach ulcers and other serious ailments by having the patient moisten a piece of wood pulp paper with saliva. This piece of paper was then placed on the abdomen of the patient, or on the abdomen of a woman subject employed by Dr. Schmidt in his office at Lake City. It was also the claim of Dr. Schmidt that he had a machine in his office with which he could broadcast treatments to absent patients. Dr. Schmidt was twice warned by the Minnesota State Board of Medical Examiners to desist from such practices, but continued nevertheless.

Justice Stone in his opinion, after describing Dr. Schmidt's method of diagnosis, stated:

"That is enough, we think, to show why no judge, or any number of them, could say, judicially or otherwise, that the action of the board was without abundant foundation in the evidence. It cannot be otherwise until the methods of the aboriginal medicine man, the witch doctor, and voodooism are demonstrated to be superior to those of modern science as applied in the field of medicine. The board of seven competent doctors adhered to the notion that the accomplishments of bio-chemistry and microscopy, with their diagnostic disclosures (which, in many cases, go to the point of demonstration) are superior to quackery, ancient and modern. It is just impossible for a court to disagree with them."

Justice Stone's opinion described Dr. Schmidt's diagnostic methods as "so clearly bald quackery, and so much an imposition on his patients, that the testimony of three patients with whom he had good luck would not have helped him."

The records of the Medical Board show that Dr. Schmidt was born in Minnesota in 1871 and graduated in Medicine from the University of Minnesota in 1903. He has practiced at Lake City for the past twenty years.

SEROBACTERINS-MULFORD (SHARP & DOHME) OMITTED FROM N.N.R.

In 1914 and 1915 the Council on Pharmacy and Chemistry accepted certain of the "Serobacterins" which were manufactured by the H. K. Mulford Company, as follows: Acne Serobacterin-Mulford, Cholera Serobacterin-Mulford, Staphylo-Serobacterin-Mulford, Typho-Serobacterin-Mulford and Typho-Serobacterin Mixed-Mulford. At that time the Council did not authorize any claims of superiority over nonsensitized vaccine for these serobacterins. In 1937 Sharp & Dohme presented a booklet, "Advantages of Serobacterins in Bacterial Vaccine Therapy." In general the text gave the impression that "Serobacterins" are better than other well known prophylactic vaccines, that they have a wider field of application and that they offer a "degree of passive immunity during the period of lag or 'negative phase' which precedes the development of active immunity in the use of plain bacterial vaccines." The Council requested the firm to show evidence that the serobacterins were superior to ordinary vaccines and especially to show what clinical evidence existed to establish its claim for recent improvements. The firm requested that the report be held in abeyance pending accumulation of additional evidence. In September, 1938, the firm presented data which it stated would aid in the further evaluation of the usefulness of its serobacterins. The Council reported that the evidence does not favor continued recognition of the preparations by the Council. The Council therefore omitted from New and Nonofficial Remedies Acne Serobacterin-Mulford, Cholera Serobacterin-Mulford, Staphylo-Serobacterin-Mulford, Typho-Serobacterin-Mulford, and Typho-Serobacterin Mixed-Mulford, (Jour. A.M.A., April 13, 1940, p. 1453.)

In Memoriam

George N. Butchart

1872-1940

Dr. G. N. Butchart, a resident of Hibbing, Minnesota, since 1896, died at this home April 7, 1940, at the age of sixty-eight. He had been preceded in death by his wife about three months previously.

Dr. Butchart is survived by his son, Dana, of Hibbing and a daughter, Mrs. Gwenith Waldor of Minneapolis; two brothers, Peter C. Butchart of Edmonton and Robert F. Butchart of Greenburg, North Carolina, and three sisters, who live in western Canada, also survive.

Dr. Butchart received his medical degree from the University of Nebraska Medical College in 1895.

Dr. Butchart was born in County Gray, Canada, December 23, 1872. When four years of age he was taken by his family to North Carolina. Later he lived in Western Canada.

Louis Francis Kelling

1877-1940

Dr. L. F. Kelling, a practitioner at Lakefield, Minnesota, since 1919, died Saturday, April 6, 1940, at the age of sixty-four, after a few months' illness.

Dr. Kelling was born February 15, 1877 at New Liberty, Iowa. He attended high school at Tipton, Iowa, the medical school of the State University of Iowa for two years, and the Saint Louis College of Physicians and Surgeons for a year, where he graduated in 1898.

During the Spanish-American War Dr. Kelling served as a hospital steward with the 49th regiment of Iowa Infantry Volunteers for thirteen months. He practiced for four years at Lowden, Iowa and for fifteen years at Holstein, Iowa, before moving to Lakefield, Minnesota, in 1919.

Dr. Kelling was a member of the Southwestern Minnesota Medical Society, the Minnesota State and American Medical Associations. He was also a member of the Leon C. Brown Camp No. 26, U. S. Spanish war veterans, at Fairmont, Minnesota.

Dr. Kelling is survived by his widow, Jennie Johnson Kelling, and daughter, Betty Jane; also a brother, Dr. George Kelling of Waverly, Missouri, and the latter's son, Dr. Jordan Kelling.

Dennis J. McMahon

1869-1940

Dr. D. J. McMahon of Breckenridge, Minnesota, died on March 12, 1940 at the age of seventy.

Dr. McMahon was born at Prior Lake, March 28, 1869. He graduated from the College of Physicians

and Surgeons of Keokuk, Iowa, in 1894, and began practice in New Richmond, Wisconsin. He also practiced at Waseca and Raymond, Minnesota, before locating in Breckenridge in 1918.

Dr. McMahon was married to Katherine Mulcahy at Waseca in June, 1898.

While practicing at Raymond, Dr. McMahon served as postmaster for eight years. On moving to Breckenridge he began organizing the local Democratic party and served as chairman of the Wilkin County Democratic committee. He was appointed postmaster at Breckenridge by President Roosevelt but was forced to resign because of ill health. At times he served as county coroner and city health officer.

Dr. McMahon is survived by his widow, a son, Dr. Leo H. McMahon of Breckenridge and a daughter, Mildred, of Minneapolis.

Charles J. Plonske

1871-1940

Dr. Charles J. Plonske, president of the Rice County Medical Society and medical specialist in Faribault for twenty-three years, passed away at his home on May 16, 1940.

Dr. Plonske was born in Germany, March 15, 1871, and came to the United States as a child. He received his degree of Doctor of Medicine at the University of Illinois, after which he spent two years in postgraduate work in Vienna, Berlin and London, where he specialized in eye, ear, nose and throat study.

Following his return to this country, Dr. Plonske practiced in Minneapolis until 1917, when he was married to Marion Clarke of Minneapolis, and came to Faribault to establish a practice as specialist. He is survived by his widow and one daughter, Miss Marion Plonske.

At the time of his death, he was a member of the state and national medical associations, and was president of the Rice County Medical Society. He was a member of the staff of the St. Lucas Hospital, a member of the Masonic Lodge No. 9, A.F. and A.M., a member of Zuhrah Temple, Minneapolis, Nobles of the Mystic Shrine and a 32nd degree Mason.

He was the eye, ear, nose and throat specialist for the State School for the Deaf and the State School for the Feeble-minded located at Faribault, Minnesota.

Thomas Tweed Warham

1866-1940

Dr. Thomas Tweed Warham was born August 31, 1866 in Kingston, Ontario, the son of Richard Lee and Agnes Warham. His high school education was obtained in Ontario. Upon coming to Minneapolis he attended the Minneapolis Academy before entering the medical department of Hamline University, where he

was graduated in 1897, receiving the degrees of M.D. and C.M.

He began his medical practice in Vernon Center, Minnesota, coming later to Minneapolis in 1904 where he remained until his death.

Dr. Warham was appointed medical inspector for the Health Department in 1907, a position he held until 1915. He was County Physician for about twenty years, the last period being from 1928 to 1940. He was a member of the staffs of St. Mary's and Asbury Hospitals, which two institutions he served loyally throughout the years. He was a member of the Minnesota State Medical Association, the Hennepin County Medical Society, and the American Medical Association. Fraternally, he was a member of the Sons of Veterans, I.O.O.F., Elks, Eagles, Modern Woodmen, Foresters, Moose, Evergreen Club, and his Masonic affiliations were: first Master of Joppa Lodge, AF&AM, Scottish Rite, and a life member of Zurah Temple of Shriners. He was a Presbyterian by faith.

He was unmarried. He died March 27, 1940 at the age of seventy-four years and is survived by two sisters, Mrs. Maud Hale and Mrs. Jennie Cornish, and a brother, Harry, all of Minneapolis.

Dr. Warham represented the true type of family physician that is frequently lauded in public meetings and not always appreciated in private practice. He examined his patients carefully and gave them an almost brotherly care. Those who were close to him in his professional life appreciated how he gave of himself to his work without stint and regardless of remuneration.

CLAUDE C. KENNEDY

Charles Benjamin Wright

1876-1940

Dr. Charles Benjamin Wright, a trustee of the American Medical Association and for many years one of the outstanding men of Internal Medicine in Minneapolis and Minnesota, died at Northwestern Hospital after an illness of several weeks, on May 31, 1940.

Dr. Wright was born in Kemptville, Ontario, Canada, November 3, 1876. He received his A.B. degree at the University of North Dakota (Phi Beta Kappa) and his M.D. degree at the Johns Hopkins Medical School in 1902. After serving an internship of one year at the Johns Hopkins Hospital he engaged in general practice in Minneapolis for a period of ten years. The years of 1913-1914 were devoted to post-graduate work in Vienna. He then returned to Minne-

apolis and since that time had confined his practice to Internal Medicine.

Dr. Wright had written several important papers. The most recent one on "Hodgkin's Disease" was presented at the eighty-ninth annual session of the American Medical Association at San Francisco, June 14, 1938.

During the First World War he served on the State Advisory Draft Board and afterward on the Medical Advisory Committee of the National Rehabilitation Committee of the American Legion. He was a member of St. Mark's Church, the Minneapolis Club, the Automobile Club, the Six O'clock Club, and the Lake Shore Athletic Club of Chicago.

Dr. Wright was a member of the Alpha Kappa Kappa medical fraternity, the Hennepin County Medical Society, the Minnesota State Medical Association, the American Medical Association, the American Therapeutic Society, the Central Society of Clinical Research, Minnesota Society of Internal Medicine and the Minnesota Pathological Society; a Fellow of the American College of Physicians, the Minnesota Academy of Medicine and a Diplomate of the American Board of Internal Medicine. He was also a member of the staff of Northwestern and Swedish Hospitals and a member of the Executive Committee of the Minnesota Public Health Association.

Dr. Wright contributed in a large way to the advancement of medicine locally and nationally. At the University of Minnesota he served as Clinical Professor of Medicine. He was president of the Hennepin County Medical Society in 1924 and of the Minnesota State Medical Association in 1928. He completed one term, 1933-1938, as a trustee of the American Medical Association and was serving a second term in that capacity at the time of his death. He was appointed member of the Editing and Publishing Committee of MINNESOTA MEDICINE in November, 1935, to fill the vacancy occasioned by the illness of Dr. A. S. Hamilton. He was also a member of the board of trustees of the National Physicians Committee for the Extension of Medical Care. He rendered valuable service as chairman of the Legislative Committee of the Hennepin County Medical Society and in April, 1940, was awarded the distinguished service medal by the Minnesota State Medical Association.

Dr. Wright, by his qualities of leadership, his sincerity of purpose, his unswerving devotion to his clientele and to the cause of medicine, won the sincere admiration of his patients and the medical profession.

Dr. Wright is survived by his wife, Alma Hanson Wright; two sons, Charles B., Jr., and Thomas; and a daughter, Helen, all of Minneapolis.

GEORGE R. DUNN.

OF GENERAL INTEREST

Dr. Royal C. Gray, assistant clinical professor of nervous and mental diseases at the University of Minnesota, has been elected a member of the American Psychiatric Association.

* * *

Attending the meeting of the Association of American Physicians in Atlantic City, May 7 and 8, were Drs. N. M. Keith, C. H. Watkins, W. M. Boothby, E. C. Kendall and W. S. Lemon of Rochester.

* * *

Dr. F. H. Magney, Duluth, was elected president of the State Board of Medical Examiners at the annual meeting of the Board. Dr. Albert Fritsche of New Ulm is the new vice president and Dr. J. F. Du Bois of Sauk Center was re-elected as secretary.

* * *

Dr. Charles E. Rea, assistant professor of surgery at the University of Minnesota Medical School for the past two years, will enter private practice in Saint Paul, July 1, establishing offices at 917 Lowry Building. He will continue on the University teaching staff.

* * *

Appointment of Dr. Frederick W. Hoffbauer, medical fellow in the University of Minnesota Department of Medicine, as physician on the staff of Health Service, is announced. The appointment will be in effect September 16, 1940.

* * *

Dr. Russell Heim has been named Hennepin County physician by the county commissioners. He fills the vacancy created by the death of Dr. Thomas T. Warham. As county physician, he is the medical officer of all county institutions except Glen Lake Sanatorium.

* * *

Dr. Joseph Berkson of Rochester attended a conference of consultants of the United States Public Health Service in Washington, D. C., on May 15 and 16. The conference was concerned with the forthcoming National List for Morbidity Reporting.

* * *

Dr. Walter M. Boothby of Rochester visited hospitals in Toronto and London, Ontario, Canada during the week of May 13. He also took part in the post-graduate course sponsored by the medical faculty of the University of Western Ontario.

* * *

The Society of Neurological Surgery re-elected Dr. Winchell McK. Craig of Rochester as secretary-treasury at its national meeting in St. Louis, May 9. Dr. Craig is also vice president of the Harvey Cushing Society which met recently in Kansas City.

* * *

Dr. J. T. Priestley of Rochester addressed the Medical Society of the State of New York in New York City, May 8. Dr. Frank J. Heck of Rochester spoke at the Texas State Medical Association meeting held in Dallas, May 14-16.

In Kansas City, May 16-18, for a regional meeting of the American Academy of Pediatrics were Drs. L. F. Richdort, C. A. Stewart, E. J. Huenekens, D. M. Siperstein, A. Moss, F. C. Rodda and R. L. Wilder of Minneapolis.

* * *

The faculty of the University of Minnesota Medical School had a good time lampooning itself at the annual meeting of the Medical Six-O'Clock Club recently. The club is an old institution on the campus, which has been under the wing of Incas, honorary medical society.

* * *

An imposter using the name of Dr. Youbert Theodore Johnson of Minneapolis is reported to be calling on southern Minnesota physicians in an attempt to float personal loans. Physicians are asked to be on the watch-out for the man who presents a business card bearing the name of Dr. Johnson.

* * *

Dr. Harold S. Diehl, dean of Medical Sciences at the University of Minnesota, and Dr. Gaylord W. Anderson, also of the University medical faculty, participated in Surgeon-General Thomas Parran's annual public health conference in Washington, D. C. during the week of May 6.

* * *

To provide a more adequate teaching staff for laboratory work, the University of Minnesota has increased the fees for the medical technology course in the Medical School. Fees for resident students are now \$40 a quarter, instead of \$30; for non-resident students, \$60 instead of \$45.

* * *

Dr. Frank Adair, Saint Paul, was married May 1, 1940, to Miss Dorothy Andrews of Grand Rapids, Minnesota. Dr. James McMillan of New York acted as best man at the wedding and among the ushers were Dr. Thomas Thompson of Nashville and Dr. James Hammermill of Saint Paul.

* * *

Dr. Charles E. McLennan of the Department of Obstetrics and Gynecology, University of Minnesota Medical School, has been awarded a Fellowship by the Commonwealth Fund for a year's study with Dr. E. M. Landis of the University of Virginia on problems concerning the toxemias of pregnancy.

* * *

Dr. A. E. Osterberg of Rochester attended a meeting of the Committee for Chemical Service to Medicine of the American Chemical Society in New York, May 8. He also attended the Convention for the Revision of the Pharmacopœia of the United States of America as delegate from the Minnesota State Medical Association.

Seventy-nine persons from fifty-seven institutions attended the course in Health Problems of College Students held at the Center for Continuation Study, University of Minnesota, May 2, 3 and 4. Twelve states were represented—Colorado, Illinois, Iowa, Kansas, Minnesota, Missouri, Montana, New Hampshire, North Dakota, South Dakota, Utah, and Wisconsin.

* * *

A pictorial feature on the new laboratories of physiological hygiene at the University of Minnesota appeared in the May 13 issue of *Life* magazine. The article described the work of Dr. Ancel Keys in measurements of chemistry and physics of athletes' bodies in action. There were several pictures of the exercise laboratory.

* * *

Dr. A. G. Liedloff was re-named chairman of the Public Health Nursing Association of Blue Earth County at its annual meeting, May 14, in Mankato. Speakers at the annual meeting included Dr. Eric K. Clarke of Minneapolis, director of the University Psychiatric Clinic for Children, and Dr. Robert Barr of the State Department of Health.

* * *

Among the thirteen new fellows in the Mayo Foundation are Dr. Rolf M. Iverson of Houston, Minnesota; Dr. H. Penn Harper of Detroit, Michigan who received his M.D. from the University of Minnesota in 1936; and Dr. William W. Wood Jr. of Jamestown, North Dakota, who received his M.D. from the University of Minnesota in 1937.

* * *

The annual dinner of the Minnesota Medical Alumni Association at the A.M.A. meeting in New York will be held at 6 p. m. Wednesday, June 12, at the Brauhaus Restaurant, 207 E. 54th Street. Price of the dinner will be two dollars. Reservations may be sent to Dr. Louis A. Hauser, chairman of arrangements. He is being assisted by Drs. Orville Chancellor, Ernest W. Lampe, John A. Timm and L. S. Ylvisaker.

* * *

Notes from the University of Minnesota department of obstetrics and gynecology: As a coöperative project with the Minnesota Department of Health, the department is conducting a teaching Home Delivery services, to give medical students experience in home deliveries. . . . The department has a new map showing the residence of patients in Minnesota with carcinoma of the cervix.

* * *

Among physicians included on the program for the three-day Medical, Hospital and Institutional Library Service conference at the University of Minnesota Center for Continuation Study, May 22, 23 and 24, were: Dr. Carl C. Chatterton of the Gillette State Hospital for Crippled Children; Dr. Gordon R. Kamman of St. Paul, and Dr. Frank J. Hirschboeck of Duluth.

* * *

Three men closely associated with medicine are members of committees concerned with the selection of a president of the University of Minnesota. On

the Board of Regents' selection committee are Dr. E. E. Novak of New Prague and Albert J. Lobb, Mayo Clinic executive staff. On the faculty committee to advise and consult with the regents' committee is Dr. J. Charnley McKinley of Minneapolis.

* * *

A group of members of the Minnesota State Medical Association spoke before the recent Minnesota Conference of Social Workers in Minneapolis. They were Dr. H. E. Hilleboe and Dr. George Earl of Saint Paul, Dr. W. W. Will of Bertha, Dr. E. J. Simons of Swanville, Dr. W. A. O'Brien of Minneapolis. Raymond M. Amberg, superintendent of the University Hospitals, also spoke.

* * *

Dr. L. A. Buie of Rochester spoke at a meeting of the Missouri State Medical Association in Joplin, April 29, and at a meeting of the South Carolina Medical Association in Charleston, May 2. His topic for these meetings was "Office and Hospital Management of Some Anorectal Disorders." On May 3, he delivered an address at the University of South Carolina in Columbia on "Unceasing world war—the outline of man's struggle against disease."

* * *

Dr. Theodore C. Blegen has been named dean of the University of Minnesota Graduate School. Now on leave of absence from the University where he is professor of history, Dr. Blegen is engaged in research on a fellowship of the Norwegian-American Historical Association. He was formerly superintendent of the Minnesota State Historical Society. The post of dean of the graduate school has been vacant since the death of Dr. Royal C. Chapman last winter.

* * *

To report for war-time medical service in their countries, three physicians, who recently began their fellowships in the Mayo Foundation, have taken leaves of absence.

Dr. H. B. Alexander of Dunedin, New Zealand, and Dr. A. Y. Mason of Johannesburg, South Africa, have gone to England. Both are reserve officers.

Dr. T. Guthe, a native of Oslo, Norway, also sailed for England about the first of May. Mrs. Guthe will remain in the United States.

* * *

Eleven Minnesota men took part in the program of the fifty-ninth annual session of the South Dakota State Medical association in Watertown, May 20, 21 and 22.

They were Dr. Russell J. Moe of Duluth; Drs. Robert G. Allison, Raymond N. Bieter, William A. O'Brien, Charles Spratt, Albert V. Stoesser and L. H. Winer of Minneapolis; Drs. Louis A. Brunsting, William F. Braasch, John M. Waugh, and Ralph K. Ghormley of Rochester.

* * *

Dr. L. G. Rigler, professor of radiology in the University of Minnesota Medical School, addressed the American Society of X-Ray Technicians, May 30,

at its meeting in Memphis. His topic was "The American Registry of X-Ray Technicians."

He also spoke at the Meharry Medical College in Nashville, June 1, before attending meetings of the National Tuberculosis Association and the American Association for Thoracic Surgery in Cleveland, and the American Medical Association in New York City.

* * *

The St. Louis County Sanatorium Commission dedicated its new unit at Nopeming, Sunday, May 12. Speaker was Dr. Malcolm T. MacEachern, associate director of the American College of Surgeons.

Other Duluth hospitals coöperating in the celebration were St. Luke's, St. Mary's, Miller, Webber and Heard.

The new unit at Nopeming has been finished under the direction of Paul H. Fesler, former University of Minnesota Hospitals superintendent.

* * *

Among speakers at the eleventh annual Vocational Guidance Conference of Carleton College in Northfield, April 10, was Dr. Paul C. Benton of Gibbon. In a panel discussion for the professional group, Dr. Benton discussed opportunities offered by the various branches of the medical sciences, and the qualifications necessary for success in each of these fields. This was followed by a round-table discussion on medicine, in which Dr. Benton reviewed problems confronting the graduate who chooses the general practice of medicine as a career, and the rewards, moral and financial, awaiting those who succeed.

* * *

Dr. Nellie N. Barsness of Saint Paul is the new president of the Minnesota Medical Women's Association, succeeding Dr. Della G. Drips of Rochester who was hostess to the group at a luncheon during the recent meeting of the Minnesota State Medical Association.

Dr. Elizabeth Woodworth of Minneapolis is secretary-treasurer of the organization.

Dr. Barsness will attend the national convention of the American Medical Women's Association to be held in New York City, June 9 and 10, in conjunction with the meeting of the American Medical Association. Dr. Barsness, as a branch president, will be among the honored guests at a luncheon, June 9.

* * *

When the American Board of Pediatrics and the Society for Pediatric Research met in Skytop, Pennsylvania, during the first week of May, there were several papers by Minnesota Men. Dr. Arild E. Hansen of the University of Minnesota Medical School gave a paper on "The Study of Serums and Tissue Lipids in Generalized Lipodystrophy (Lipohistioidi-*resis*)," prepared by himself and Dr. Irvine McQuarrie. Dr. H. F. Helmholz of Rochester had for the subject of his address before the board, "Differential bactericidal effects of various urinary antiseptics."

Addressing the Society for Pediatrics Research were Dr. John A. Anderson and Dr. A. V. Stoesser of the University of Minnesota, and Dr. R. L. J. Kennedy of Rochester.

Dr. Hansen was elected vice president of the Society.

Several Minnesota physicians were among the speakers at the fifty-third annual meeting of the North Dakota State Medical Association held in Minot, May 6, 7 and 8.

Taking part in a symposium on "Essential Hypertension" were Dr. Walter Camp of the University Medical School and Dr. Charles N. Hensel of St. Paul.

Dr. R. C. Webb of the University Medical school spoke on "Hernia"; Dr. Paul A. O'Leary of Rochester on "The Eczemas"; Dr. Chester A. Stewart of the Medical school on "Convulsive Disorders in Children"; Dr. M. C. Piper of Rochester on "Chronic Infections of External Genitalia"; Dr. A. W. Adson of Rochester on "Early Skull Fractures"; Dr. John L. McKelvey on "Vascular Disease as Related to the Pregnancy Toxemias," and Dr. F. E. Foley on "The Choice of Operation for Bladder Neck Obstruction." The latter two are also associated with the University of Minnesota Medical School.

* * *

University of Minnesota medical school administrators with medical school heads throughout the country, have plunged into the task of organizing the nation's medical resources for a "national emergency."

Dr. Harold S. Diehl, dean of medical sciences at the University of Minnesota, has been authorized to form "United States General Hospital No. 26" at the University. This is the same number the Minnesota base hospital unit had during the World War. The hospital unit, in event of war, would be under orders from the United States surgeon general for service in any zone he might designate.

A typical unit, such as to be organized at the University, would have a basic personnel of about 40 persons, including 20 surgeons, seven medical service physicians, two dentistry service physicians, an x-ray specialist, a laboratory man, commanding officer, executive officer, quartermaster, and six men from the army's administrative reserve. In addition, the staff would be supplemented by several hundred enlisted men and nurses.

* * *

Dr. C. L. Scofield of Benson recently marked two major anniversaries. One was his 75th birth anniversary (April 16); the other, the fiftieth (March 1) of his coming to Benson to start a medical practice which has taken him into important work in public health and civic leadership.

With many years of practice as a family doctor, Dr. Scofield first stepped into state-wide medical activity in 1906, as one of the organizers of the state sanitary conference. A year later he became a member of the society for the study of prevention of tuberculosis, subsequently the Minnesota Public Health association of which he was president from 1919-1923.

He has served twelve years on the state board of health, four years as president; has been a member of the state tuberculosis advisory commission, and chairman of the Swift County Public Health association.

Long active in Benson civic affairs, Dr. Scofield was president of the village council in 1897, and is known as the father of the Benson park system.

The Scientific Exhibit at the A.M.A. meeting will include the work of several Minnesotans.

Dr. V. L. Hart of Minneapolis will take part in the demonstration of an exhibit on fractures.

In connection with the exhibits of the section on dermatology and syphilology, there will be motion pictures by Dr. L. A. Brunsting of Rochester, and also by Dr. C. W. Laymon of Minneapolis.

Other exhibits in the various sections will be by: Drs. R. K. Ghormley, E. F. Rosenberg and P. S. Hench of Rochester, section on orthopedic surgery; Drs. Lundy, Mousel, R. C. Adams and E. B. Tuohy of Rochester, anesthesia; Dr. L. E. Prickman and Dr. H. J. Moersch, section on practice of medicine; Dr. Comfort and Dr. Arnold E. Osterberg, section on practice of medicine; Dr. S. W. Harrington, section on surgery; Dr. A. H. Bulbulian, section on surgery.

Drs. Wakefield and Friedell will have an exhibit in the section on gastro-enterology and proctology, as will Drs. A. H. Logan, P. W. Brown, J. A. Bargaen, H. M. Weber, L. A. Buie, H. H. Bowing, A. H. Baggenstoss, C. F. Dixon, J. de J. Pemberton and C. W. Mayo.

Motion pictures will be shown in the section on nervous and mental diseases by Dr. B. T. Horton and Dr. G. M. Roth; and by Dr. C. H. Sheldon and Henry W. Woltman.

* * *

When the American Psychiatric Association held its ninety-sixth annual meeting in Cincinnati, May 20-24, Dr. Reynold A. Jensen of the University of Minnesota Psychiatric Clinic for Children read a paper prepared by himself and Dr. Eric K. Clarke, director, entitled "The Integration of Psychiatric Teaching with Pediatrics."

Participating in the meeting besides Drs. Jensen and Clarke were Dr. Burtrum C. Schiele, also of the University of Minnesota, who presented a paper, "A Clinical Study of Sleep Disturbances"; Dr. Nathaniel J. Berkwitz of Minneapolis who discussed "New Developments in Pharmacological Shock Therapy"; Dr. Herman E. Hilleboe of Saint Paul who discussed a paper on clinical tuberculosis in light of a recent survey of tuberculosis patients in Minnesota state hospitals.

* * *

With the close of the spring quarter, the staff of the Hospitals of the University of Minnesota completes its eleventh year of weekly staff meetings.

Held each Friday noon during the school year, the meetings are attended by members of the staff, fellows and internes. Attendance averages approximately 150 persons. Luncheon at 11:45 a.m. (sandwiches, pie and beverage served "on the house") is followed at 12:15 p.m. by an entertaining non-medical film, and that by the weekly scientific paper and discussion. The program is arranged so that each department contributes a paper to the scientific program during the year.

These papers are published in full in a mimeographed bulletin, prepared under the direction of Dr. W. A. O'Brien, chairman of the staff meetings. The bulletin is distributed at the close of the meeting. A page of

announcements and a much-read gossip column are included each week in this staff meeting bulletin.

* * *

Scheduled to appear on the program of the American Medical Association meeting in New York City, June 10-14, are a large number of Minnesota physicians.

Two will serve as chairmen of sections. Dr. Harold S. Diehl, dean of Medical Sciences at the University of Minnesota, will be chairman of the section of preventive and industrial medicine and public health, and Dr. Frederic E. B. Foley of Saint Paul will serve as chairman of the section on urology. Both will give papers.

Others from the Twin Cities who will present papers are Dr. Erling S. Platou, Dr. J. Arthur Myers, Dr. Ruth E. Boynton and Dr. L. H. Winer of Minneapolis and Dr. John F. Madden of St. Paul. Taking part in the discussion of the section on orthopedic surgery will be Dr. Myron O. Henry of Minneapolis.

Dr. F. T. Becker of Duluth will deliver a talk before the section on dermatology and syphilology.

Two Rochester men are secretaries of sections: Dr. J. A. Bargaen, section on gastro-enterology and proctology, and Dr. Edgar V. Allen, section on pharmacology and therapeutics.

Others from Rochester scheduled to give scientific lectures are Drs. Walter C. Alvarez, B. T. Horton, F. A. Willius, J. P. English, W. E. Herrell, Harold I. Lillie, F. P. Moersch, A. E. Brown, Howard K. Gray, W. L. Benedict, F. A. Figi, A. R. MacLean, H. E. Robertson, J. L. Bollman, W. F. Braasch, V. S. Counsellor, E. N. Cook, M. S. Henderson, E. G. Wakefield, M. T. Friedell, M. W. Comfort, E. T. Leddy, H. J. Moersch and Lloyd H. Mousel.

Programmed to take part in discussions are Drs. Allen, L. M. Randall, Gordon B. New, Paul O'Leary, E. J. Keppler, Hamilton Montgomery, Ralph K. Ghormley, C. Allen Good, Jr. and John S. Lundy.

MINNESOTA HOSPITAL ASSOCIATION

Miss Esther Wolfe, superintendent of St. Andrews Hospital in Minneapolis, was named president-elect of the Minnesota Hospital Association when that group conducted its seventeenth annual convention in Minneapolis, May 23-25.

Others elected to take office next year are Dr. Walter P. Gardner of Anoka, first vice president; Miss Eda Kamrath of Hutchinson, second vice president; Emil M. Hauge, Fairview Hospital in Minneapolis, treasurer.

Dr. A. F. Branton of Willmar, administrator of the Willmar hospital, is the association's executive secretary.

There were more than 400 registrations for the 3-day convention, at which Dr. Fred Carter of St. Luke's hospital in Cleveland was principal speaker.

A. G. Stasel, Eitel hospital in Minneapolis, retiring president, presided at the sessions. Raymond Amberg, University of Minnesota Hospital, who was named president-elect a year ago, assumed his duties as head of the association.

MEDICAL BROADCAST FOR JUNE

The Minnesota State Medical Association Morning Health Service

The Minnesota State Medical Association broadcasts weekly at 11:00 o'clock every Saturday morning over Station WCCO, Minneapolis (810 kilocycles or 370.2 meters), and Station WLB, University of Minnesota (760 kilocycles or 395 meters).

Speaker: William A. O'Brien, M.D., Associate Professor of Pathology and Preventive Medicine, Medical School, University of Minnesota. The program for the month will be as follows:

- June 1—What is Diabetes?
- June 8—Management of Diabetes in Children.
- June 15—Management of Diabetes in Adults.
- June 22—The Outlook in Diabetes.
- June 29—Stomatitis.

ABBOTT LABORATORIES FELLOWSHIPS IN CHEMISTRY

For the academic year 1940-41, Abbott Laboratories has established fellowships in several universities with important departments of organic chemistry and biochemistry. The fellowships, carrying stipends of \$650 per year, will be available to graduated students in the last or next to last years of graduate work leading to the doctorate degree. The recipients, who are to be selected by the universities in which their work is being done, are not limited as to the subjects on which they will work.

The object of the fellowships is to provide means for the carrying on of additional scientific work in American universities. The future progress of chemical developments in this country will depend upon the availability of well-trained and qualified men, and it is the intent of Abbott Laboratories in establishing these fellowships to lend encouragement in these general fields.

Grants will be made in organic chemistry to Cornell, Harvard, Illinois, and Michigan; in biochemistry to California, Columbia, and Cornell.

DEDICATION OF OSLER MEMORIAL TO BE HELD AT BLOCKLEY

The old autopsy house where Osler worked at Blockley has been restored as the Osler Memorial Building, and will be dedicated on the grounds of the Philadelphia General Hospital, at Curie Avenue, near 34th and Pine Streets, Philadelphia, Pa., at 2 P.M. on June 8, 1940.

Original furnishings, including the necropsy table, have been collected. The painting by Dean Cornwell, N.A., of New York, entitled "Osler at Old Blockley," later to be hung in the building will be on exhibition during the celebration.

There are facilities in the building for the housing and preservation of relics of old Blockley, as well as

Osleriana. The Committee would welcome any additions to this collection.

A cordial invitation is extended to those who are interested, and especially those who are planning to attend the American Medical Association Convention in New York City June 10th to 14th.

AMERICAN CONGRESS OF PHYSICAL THERAPY

The 19th annual scientific and clinical session of the American Congress of Physical Therapy will be held September 2, 3, 4, 5, and 6, 1940, at the Hotel Statler, Cleveland, Ohio.

The mornings will be devoted to the annual instruction course, enabling attendance at both the course and scientific sessions which will be given in the afternoons and evenings. This will minimize the time element and permit attendance at both functions during the same week. The seminar and convention proper will be open to physicians and qualified technicians.

For information concerning the seminar and preliminary program of the convention proper, address American Congress of Physical Therapy, 30 North Michigan Avenue, Chicago.

HENNEPIN COUNTY SOCIETY

Dr. Russell W. Morse is the newly elected president of the Hennepin County Medical Society. With other recently named officers, he will take office at the annual meeting of the organization next October.

Dr. C. A. McKinlay was chosen first vice president, and Dr. Kenneth Phelps, second vice president. Dr. James K. Anderson and Dr. Paul F. Dwan were elected to the executive committee. Dr. James A. Johnson will retire as president next autumn to become chairman of this committee.

Named on various elective committees and boards were: Board of Censors, Dr. Donald McCarthy and Ivar Sivertsen; Board of Trustees, Drs. Martin Nordland and James S. Reynolds; Ethics Committee, Drs. R. R. Cranmer and Willard D. White.

Delegates to the Minnesota State Medical Association are: three-year term, Drs. H. F. Bayard, J. M. Hayes, Douglas P. Head and C. O. Maland; two-year term, Drs. S. H. Baxter and H. B. Sweetser, Jr.; one-year term, Dr. John E. Hynes.

MINNESOTA SOCIETY OF NEUROLOGY AND PSYCHIATRY

Twenty-five members of the Minnesota Society of Neurology and Psychiatry attended a scientific program in Rochester, May 11.

The morning program at St. Mary's hospital was followed by a luncheon at the Mayo Foundation House, the guest speaker being Dr. Peter Bassoe of Chicago. His topic was "Some Neuropsychiatric Observations in Mexico, Puerto-Rico and the Virgin Islands."

NORTHERN MINNESOTA MEDICAL ASSOCIATION

Arrangements for the meeting of the Northern Minnesota Medical Society to be held in Duluth, July 19 and 20, are being completed under the direction of the following committee chairmen:

General ChairmanDr. F. J. Elias
Place of Meeting.....Drs. Richard Bardon and E. Barrett
RegistrationDr. Gordon MacRae
BanquetDrs. F. H. Magney and Phil Bray
Entertainment.....Drs. R. J. Moe, W. Graves, and A. J. Spang
Hotel and Transportation.....Dr. T. G. Clement

The committees appointed by Mrs. Thomas O. Young, president of the St. Louis County Auxiliary, are as follows:

Transportation.....Mrs. P. S. Rudie
Entertainment.....Mrs. R. S. Forbes
Registration.....Mrs. W. A. Coventry

The papers obtained so far for the meeting include the following:

Disturbances of Peripheral Circulation—
E. V. Allen, Rochester
Coronary Disease—
Jay Davis, Minneapolis
Gout, the Forgotten Disease—
E. L. Tuohy, Duluth
Subject not yet announced—
L. A. Buie, Rochester
Treatment and Results in Appendicitis—
R. H. Mueller, Two Harbors
A Report on Progress in Adrenal Therapy—
J. L. McLeod, Grand Rapids
Practical Points in Female Sex Hormone Therapy—
J. R. Manley, Duluth
Presentation of two Unusual Cases, (1) Amyloidosis
(2) Hypoparathyroidism with Bone Changes—
R. O. Sather, Crookston
Pathology in the Bronchi and Esophagus: A Clinical
and Endoscopic Study of Recent Cases—
Virgil J. Schwartz, Minneapolis

Papers accepted, but title not yet presented include one by H. A. Chesley, Health Department, University of Minnesota and another on a urologic subject by Wm. Elliott, Virginia, Minnesota.

On July 19, the following physicians will present cases in the form of clinical presentations under the direction of Drs. W. D. Coventry and S. H. Boyer, Jr.:

Karl W. Emanuel—Congenital Hemolytic Icterus.
J. R. Kuth—Report of a Case of Spinal Block.
W. E. Hatch—Urological Demonstration.
M. G. Gillespie—A Case Report of a Carcinomatous Ulcer of the Stomach.
D. W. Wheeler—Chronic Fibrosing Pneumonia.
Chas. Mcad—Abscess of the Tongue.
Anderson Hilding—Experimental Sinus Surgery and its Significance.

R. E. Nutting—Some of the Newer Therapeutic Procedures in Pediatrics.

P. N. Bray—Roentgenographic Diagnosis of Pregnancy.
P. G. Boman—Acute Suprarenal Failure.

Dr. C. H. Schroder will be toastmaster for the banquet. Dr. O. W. Parker will give an address, and one other speaker not yet engaged.

Dr. F. J. Hirschboeck is Program Chairman.

MINNEAPOLIS SURGICAL SOCIETY

Dr. James A. Johnson is the new president of the Minneapolis Surgical Society. Other officers named recently are Dr. Arthur Bratrud, vice president; Dr. R. F. McGandy, secretary-treasurer.

Others on the Council besides the officers are Dr. Willard D. White, retiring president; Dr. William Hanson, Dr. H. O. McPheeters, Dr. Daniel McDonald, Dr. R. C. Webb and Dr. Richard Cranmer.

The Society has recessed for the summer and will resume its meetings next October.

MINNESOTA MENTAL HYGIENE SOCIETY

The first annual meeting of the Minnesota Mental Hygiene Society was conducted in Minneapolis, May 8, with Dr. David Slight, professor of psychiatry at the University of Chicago, as principal speaker.

Directors were elected, Dr. H. M. Keith of Rochester, Mrs. Stella Amass of Saint Paul, Miss Elizabeth Glynn and Dr. Alex Blumstein of Minneapolis being renamed. Others elected were Mrs. Angus Morrison of Wayzata, Dr. L. R. Gowan of Duluth, Miss Ruth Ferguson of Stillwater and Ralph Helstein of Minneapolis.

These directors, together with other members of the Board, will meet June 5 to elect officers. Present officers are Dr. Keith, president; Mrs. Amaas, vice president; Miss Glynn, secretary; Stanley Hedstrom of Saint Paul, treasurer.

OLMSTED-HOUSTON- FILLMORE-DODGE SOCIETY

Twenty-one new members were elected to the Olmsted-Houston-Fillmore-Dodge County Medical Society at a meeting in Rochester, May 1.

Held in conjunction with a meeting of the Mayo Clinic general staff, the session included a scientific program, over which Dr. C. E. Bigelow of Dodge Center, vice president, presided.

New members elected to membership are: Drs. Bruce M. Anderson, William J. Brackwell, J. W. Burks, Joseph R. Campbell, Franklin F. Ferguson, Robert F. Golden, J. M. Ivie, Charles E. Jacobson, Jr., M. P. Kelsey, Robert M. Kent, Henry J. Lehnhoff, Jr., C. H. McCall, William C. MacCarty, Jr., J. R. Miller, Jr., R. M. Meale, E. D. Quick, George P. Sayre, Richard M. Shick, Gordon W. Strom, R. E. Van Demark and Wilson Weisel.

REDWOOD-BROWN COUNTY SOCIETY

The annual meeting of the Redwood-Brown County Medical Society was held Tuesday evening, May 14, at New Ulm, preceded by a joint dinner with the Auxiliary. Dr. Francis Lynch of Saint Paul talked on "Fungus Infection."

The following officers were elected: President, Dr. H. E. Mortensbach, Hanska; Vice President, Dr. E. J. Wohlrabe, Springfield; Secretary-Treasurer, Dr. O. B. Fesenmaier, New Ulm; Censor to 1943, Dr. F. J. Pelant, New Ulm; Delegate, Dr. O. J. Seifert, New Ulm.

SOCIETY FOR RESEARCH ON CONVULSIVE DISORDERS

A Society for Research on Convulsive Disorders has been organized with the approval of the executive board of the Minnesota State Medical Association. Goal of the Society is primarily one of creating interest and of collecting funds for the advancement of research in this field. It is planned that funds collected by the society will be given to the Minnesota Medical Foundation to be devoted to specified research projects.

There are four classes of membership: active (\$5 a year), contributing (at least \$1.50 a year), sustaining (trust fund in any amount in excess of annual dues of active members), and honorary.

Mrs. H. H. Creamer of Minneapolis is president of the Society; W. A. Gordon of Saint Paul, vice president. James Norton, 823 22nd Avenue South, Minneapolis, is secretary.

The Board includes M. E. Souther and Dr. Gordon R. Kamman of Saint Paul; Dr. H. W. Woltman of Rochester; Dr. D. E. McBroom of Cambridge; Dr. Charles G. Ferrari, Dr. W. A. O'Brien, Dr. Irvine McQuarrie and Vincent Johnson of Minneapolis.

WASHINGTON COUNTY SOCIETY

The regular monthly meeting of the Washington County Medical Society was held at the Stillwater Club rooms on May 14, 1940. The special feature was a dinner given by the Society to the doctors who had lectured to the society during the year and in appreciation thereof. As the weather was pretty soggy none of the guests tore up the turf on the fine and beautifully located Stillwater Golf Course; golf was to have been the feature and bait of the entertainment.

After the dinner, stories and gossiping, members and guests returned to the realities of this mundane sphere, and Dr. Frank Savage gave a résumé of the activities of the Minute-men of American Medicine and of the National Physicians' Committee for the Extension of Medical Service and Free Enterprise in Medicine. This was illustrated by lantern slides. As the time became limited, Dr. E. V. Strand's report on the Obstetrics Course given at the University of Minnesota (which he had reviewed before the staff of the Lakeview Memorial Hospital on May 3) was put off until the September meeting. Dr. E. M. Jones spoke on some features of the Rochester meeting, as did Dr. Humphrey, who also reported on the Milk Ordinance before the City Council. The second reading of this was put off until June, as the opposition is quite strong, and the Council wanted more time for study of the several objections.

Dr. E. S. Boleyn reported that the State Society requested, through its proper committee, greater activities in immunization, which should be pushed effectively now and in the future without any let-up. A committee was appointed to establish inter-professional contacts and to arrange for a meeting or meetings as soon as practical.

E. SYDNEY BOLEYN, M.D., *Secretary*.

WOMEN'S AUXILIARY

MRS. A. C. BAKER, Fergus Falls, *President*

MRS. E. V. GOLTZ, 2259 Summit Avenue,
Saint Paul, *Publicity Chairman*

State Meeting

The 18th annual meeting of the Women's Auxiliary to the Minnesota State Medical Association was held in Rochester, Minnesota, April 22, 23 and 24. It was not only exceedingly well attended but was most successful from every point of view. The wonderful hospitality of the Rochester members made every minute's stay in the city most enjoyable and the pleasant memories will linger long with those who had the opportunity of attending. The various reports showed well that the past year has found the Women's Auxiliary throughout the state actively engaged in various health projects and in promoting better understanding between other organizations and groups.

It was most inspiring to have the national president, Mrs. Rollo Packard, at the opening meeting which took place Monday, April 22, at 10:30 at the Mayo Foundation House. Her talk, which was given at the luncheon following this board meeting, gave us a splendid picture of what physicians' wives could do in the future, and the need for continued study and work in carrying out the aims of the Medical Association. A delightful tea was given that afternoon at Mayowood with Mrs. Charles W. Mayo the hostess. Assisting Mrs. Mayo in receiving were Mrs. Rollo Packard, Mrs. A. C. Baker, and Mrs. M. A. Nicholson. Monday closed with "Open House" at the Mayo Civic Auditorium.

Tuesday, April 23, was devoted to the annual meeting which was held at the Rochester Country Club at 10 A.M. Mrs. A. C. Baker presided. Mrs. L. P. Howell of Rochester gave a cordial address of welcome which was followed by a response by Mrs. T. N. Fleming of St. Cloud. A memorial service was read by Mrs. E. M. Hammes of Saint Paul. A most interesting part of the program was the Demonstration Broadcast of the High School Radio Contest program which was introduced by Mrs. Marguerite Breen of the Minnesota Public Health Association and included talks by the high school contestants: Barbara Zeches, St. Charles High School, St. Charles, Minnesota; and Carl Baumgartner of St. Thomas Military Academy, Saint Paul. Mrs. A. C. Baker presented pins to each student and also presented the Auxiliary Trophy. Reports from the various officers, chairmen and county presidents were heard, and Election of officers followed. A luncheon was served at the Country Club when the newly elected officers were presented. Mrs. W. B. Roberts of Minneapolis awarded the President's Pin to the newly elected president, Mrs. M. A. Nicholson of Duluth, who responded with greetings. Malcolm McLean, Ph.D., Director of the General College of the University of Minnesota gave an address, "Are the Schools on Trial?" Following the luncheon the

Post Convention Board Meeting was held when various chairmen were named for the coming year. At 6:30 P.M. the annual banquet was held at the Rochester State Hospital with Dr. Bertram S. Adams, president of the Minnesota State Medical Association, as toastmaster. Dr. John DeJ. Pemberton, president of the Olmsted-Houston-Fillmore-Dodge County Medical Society, gave the address of welcome which was followed by the introduction of Mrs. M. A. Nicholson of Duluth, newly elected president of the Women's Auxiliary. The Southern Minnesota Medical Association Medal was presented to Dr. Carl W. Waldron and this was followed by an address by the Honorable Harold E. Stassen, Governor of the State of Minnesota. An interesting talk was given by Mr. Bernard H. Ridder, Publisher of the *Saint Paul Dispatch and Pioneer Press* on "How the Peace of the World was Lost."

Many visiting women remained for the Wednesday informal program and were graciously entertained at a coffee at 10:30 A.M. at the home of Mrs. D. C. Balfour. Mrs. M. S. Henderson assisted. This was followed by informal luncheons at the homes of local members and the close of a most interesting and profitable convention.

Newly elected officers for the coming year are: Mrs. John James Ryan, Saint Paul, president-elect; Mrs. R. J. Josewski, Stillwater, first vice-president; Mrs. R. H. Wilson, Winona, second vice-president; Mrs. W. F. Braasch, Rochester, third vice-president; Mrs. B. J. Branton, Stillmar, fourth vice-president; Mrs. T. N. Fleming, St. Cloud, recording secretary; Mrs. H. F. Wahlquist, Minneapolis, treasurer; Mrs. John Dordall, Sacred Heart, auditor.

Those in charge of the convention were as follows:

General Arrangements.—Mrs. G. B. Eusterman and Mrs. M. S. Henderson.

Registration.—Mrs. T. B. Magath, chairman, assisted by Mrs. J. E. Crewe, Mrs. H. C. Habein, Mrs. F. J. Heck, Mrs. L. M. Randall and Mrs. H. M. Weber.

Reservations.—Mrs. F. J. Moersch, chairman, assisted by Mrs. F. A. Figi, Mrs. B. T. Horton, Mrs. M. C. Piper, Mrs. B. F. Smith.

Transportation.—Mrs. S. W. Harrington, chairman, assisted by Mrs. M. W. Binger, Mrs. F. W. Gaarde, Mrs. D. F. Hallenbeck, Mrs. B. R. Kirklin, Mrs. L. E. Prickman and Mrs. E. C. Rosenow.

Exhibits.—Mrs. M. S. Henderson, chairman, assisted by Mrs. L. M. Eaton, Mrs. George Edward, Mrs. W. G. Grinnell, Mrs. B. E. Hall, Mrs. M. M. Hargraves, Mrs. P. H. Heersema, Mrs. E. A. Hines and Mrs. H. Paul Johnson.

Executive Luncheon.—Mrs. V. S. Counseller, Mrs. W. F. Braasch and Mrs. R. K. Ghornley.

Annual Luncheon.—Mrs. J. deJ. Pemberton, Mrs. Waltman Walters, Mrs. A. W. Adson.

Assisting hostesses at the tea at Mayowood included Mrs. M. J. Anderson, Mrs. N. W. Barker, Mrs. C. E. Bigelow, Mrs. A. U. Desjardins, Mrs. C. E. Dixon, Mrs. H. K. Gray, Mrs. W. C. McCarty, Mrs. H. B. Macey, Mrs. F. C. Mann, Mrs. Hamilton Montgomery, Mrs. J. T. Priestly, Mrs. A. B. Rivers, Mrs. A. M. Snell, Mrs. C. H. Watkins and Mrs. J. M. Waugh.

District Meeting

May 4 was the date chosen for the spring business meeting of the District Medical Auxiliary at the home of Mrs. O. K. Behr, Crookston, Minn. There were nineteen members present and before the meeting the group attended the dinner meeting with the District Medical Society at the Crookston Hotel. Mrs. S. H. Stuurmans, president, presided, and a paper which had been prepared by Mrs. J. F. Norman, was read. A report was given on the social events of the annual state meeting by Mrs. M. O. Oppegard. Mrs. A. R. Reff, Polk County chairman of the Red Cross knitting and sewing project for the war refugees, told the group of the success of the work in Crookston and urged more help for the project in the outlying districts.

The following officers were elected for the new year: president, Mrs. W. H. Hollands, Fisher; vice president, Mrs. J. L. Delmore, Sr., Roseau; Secretary, Mrs. G. W. Bohl, Ada; corresponding secretary, Mrs. H. H. Hedemark, Thief River Falls; treasurer, Mrs. C. L. Oppegard, Crookston. A program of fun entitled, "Information Please," was conducted by Mrs. H. H. Hodgson. Mrs. Behr served a late luncheon following a short session of bridge.

Those attending from out of town included Mrs. Delmore, Mrs. Anderson and Mrs. C. M. Adkins of Thief River Falls, Mrs. Stuurmans and Mrs. W. B. Torgeson of Oklee; Mrs. G. A. Sathiers of Fosston; and Mrs. Clark of Clearbrook. Mrs. O. O. Larson of Detroit Lakes was a visitor.

PROPAGANDA FOR REFORM

The Effect of Quick Freezing on the Nutritive Values of Foods.—At the request of the Council on Foods of the American Medical Association, Dr. Mary Swartz Rose has prepared a review of available evidence on the nutritive value of quick-frozen foods. Dr. Rose reports that quick freezing is a mode of food preservation which affords the consumer fresh material, free from inedible waste and held in cold storage until delivery. The number of micro-organisms in foods is greatly reduced by quick freezing. Extensive studies indicate that there is little danger from foods frozen and held in storage at temperatures below 32° F., but refreezing of products once defrosted is not a safe practice. Vitamin A values in foods are conserved by quick freezing. Vitamin B₁ (thiamin) is not affected by the freezing but considerable loss may occur in the processes of preparing food for quick freezing such as blanching of vegetables. To conserve vitamin B₁, the blanching time should be as short as is compatible with a product satisfactory in other respects. Little if any loss of vitamin G (riboflavin) has been observed in the quick-frozen vegetables investigated. Vitamin C (ascorbic acid) in fruits appears to be conserved by quick freezing and storage at low temperatures. Loss of vitamin C in vegetables depends partly on the completeness of the destruction of the ascorbic acid oxidase in the blanching process and partly on the conditions under which the vegetable is allowed to thaw. Loss in thawing can be avoided by cooking without defrosting. Partly on the basis of Dr. Rose's report the Council has voted to give consideration to quick-frozen vegetables and fruits with a view to inclusion in the list of accepted foods. (Jour. A.M.A., April 6, 1940, p. 1356.)

BOOK REVIEWS

Books listed here become the property of the Ramsey, Hennepin and St. Louis County Medical libraries when reviewed. Members, however, are urged to write reviews of any or every recent book which may be of interest to physicians.

Books Received for Review

CHEMISTRY AND MEDICINE. Papers presented at the Fiftieth Anniversary of the Founding of the Medical School of the University of Minnesota. Edited by Mruaice B. Visscher, M.D., Professor of Physiology at the University of Minnesota. 296 pages. Illus. Price, \$4.50, cloth. Minneapolis: University of Minnesota Press, 1940.

DIABETES. Practical Suggestions for Doctor and Patient. Second Edition. Edward L. Bortz, A.G., M.D., F.A.C.P. Associate Professor of Medicine, Graduate School of Medicine, University of Pennsylvania; Chief of Medical Service B., the Lankenau Hospital, Philadelphia; Assistant Editor The Cyclopedia of Medicine. Foreword by George Morris Piersol, B.S., M.D., F.A.C.P. Professor of Medicine, Graduate School of Medicine, University of Pennsylvania and Editor in Chief, The Cyclopedia of Medicine. 296 pages. Illus. Price, \$2.50, cloth. Philadelphia: F. A. Davis Co., 1940.

THE COMPLETE PEDIATRICIAN. Practical, Diagnostic Therapeutic and Preventive Pediatrics. Third Edition. Wilburt C. Davison, M.A., D.Sc., M.D. Professor of Pediatrics, Duke University School of Medicine and Pediatrics, Duke University School of Medicine and Department of Pediatrics, Johns Hopkins University School of Medicine, Acting Pediatrician in Charge, The Johns Hopkins Hospital, and member American Board of Pediatrics, etc. 256 pages. Price, \$3.75, cloth. Durham, N. Car.: Duke University Press, 1940.

MANUAL OF FRACTURES, DISLOCATIONS AND EPIPHYSEAL SEPARATIONS. Harry C. W. S. deBrun, M.D., F.A.C.S. Adjunct Professor of Surgery, New York Polyclinic Medical School and Hospital; Associate Visiting Surgeon, Swedish Hospital, Brooklyn, N. Y.; Consulting Skeletal Surgeon, New York Police Department; Late Chief of Clinic, Reconstruction Hospital, N.Y.C.; Late Chief of Compensation Clinic, Beekman St. Hospital, N.Y.C.; Member, Association française de Chirurgie. Illus. Price, \$3.00, postpaid. 468 Pages. Chicago: Year Book Publishers, 1939.

The author of this volume has attempted to set down from his own experience the practical and helpful points found useful in the management of fractures. Of necessity, because of the size of the Manual, the result turns out to be largely a summary and tabulation of the means and methods employed in the present-day treatment of fractures. This is borne out by the fact that of the 150 illustrations practically one-sixth are reproductions from the catalogs of surgical supply houses.

This type of book presupposes a working knowledge of the subject. One who attempted to learn to treat fractures by consulting the Manual would be disappointed because of the lack of detailed information on the application of any one particular method, and by

the paucity of illustrations. This criticism could have been forestalled by including references to reliable articles dealing at greater length with problems in individual fractures.

It is interesting that a book on fractures could have been written with but a bare half-dozen illustrations from radiographs of actual fractures. The intention may have been to attempt to cover this subject in the special chapter written by a collaborating roentgenologist. This chapter, however, contains no illustrations of fractures. An opportunity was missed in not using this chapter to attempt to depict the methods and positions used in taking radiographs of patient with fractures, in and out of equipment, and the essential points in interpreting such pictures made under difficulties.

In spite of its shortcomings, the book is of value in furnishing a ready reference in refreshing oneself on the various methods applicable to any given fracture.

—JOHN F. POHL, M.D.

CANCER IN CHILDHOOD and a Discussion of Certain Benign Tumors. Harold W. Dargeon, M.D., F.A.A.P., Attending Pediatrician, Memorial Hospital for Cancer and Allied Diseases, New York; Associate Pediatrician, St. Luke's Hospital, New York; Associate Pediatrician, New York Foundling Hospital; Instructor in Pediatrics, College of Physicians & Surgeons, Columbia University. 114 pages. Illus. Price, \$3.00, cloth. St. Louis: C. V. Mosby Co., 1940.

This volume represents a group of collected papers which originally appeared in the *Journal of Pediatrics*, the compilation being done by different staff men at Memorial Hospital, New York. All the articles emphasize the importance of cancer in the field of children's diseases.

Ewing's chapter on "A Survey of Cancer in Childhood" gives a comprehensive review of the literature and, I believe, is the best chapter in the book.

The symptoms, diagnosis, and treatment of the different malignancies is discussed in each chapter. The different conditions are fairly well illustrated.

Many references are given at the end of each chapter which no doubt include the outstanding articles referable to the particular discussion.

I believe the book will make us more conscious of childhood malignancies, leading perhaps to earlier diagnosis and a larger percentage of cures.

O. S. WYATT, M.D.

GOOD HEALTH AND BAD MEDICINE. Harold Aaron, M.D. A Consumer's Union Publication. 328 Pages. \$3.00. New York: Robt. M. McBride & Co., 1940.

Here's a readable, sensible book dealing with the common problems of everyday health. It is particularly directed to the gullible, misinformed millions who receive their medical advice from the nostrum-ads and commercial radio announcements. As such it deserves a place in every physician's reception room. It explodes the wealth of superstitions and delusions, which prevail over such subjects as colds, coughs, and constipation, and the abuses of the various analgesics and

antiseptics which often prove dangerous through their toxicity, as well as not seldom by their inadequacy.

Interesting chapters on diet fallacies, and on the vitamin racket are most timely. Some valuable observations on the care of teeth, and on the comparative value of the various brands of tooth pastes and tooth powders are noteworthy. The place of stimulants in the daily regime is sensibly treated. The discussion of the abuse of, and false claims for, the various types of physical therapy in the home is well handled.

Each chapter is followed by a list of acceptable and non-acceptable products which renders the volume of added value to the reader. The physician may also read this with benefit, and find some valuable suggestions and formulæ in the text.

THOMAS MYERS, M.D.

HERNIA; ANATOMY, ETIOLOGY, SYMPTOMS, DIAGNOSIS, DIFFERENTIAL DIAGNOSIS, PROGNOSIS, AND THE OPERATIVE AND INJECTION TREATMENT. Leigh F. Watson, M.D., Member Staff California Lutheran Hospital and Methodist Hospital of Southern California. 591 pages. Illus. 2d ed. \$7.50. St. Louis: C. V. Mosby Co., 1938.

Watson's second edition of his monograph on hernia has taken into account the modern trend for the injection treatment of well selected cases. His chapters on this phase of hernial treatment are very well written, especially as they come from a surgeon with extensive experience in the operative work as well. The entire work has been brought up to date and there is no finer monograph on the treatment of all forms of hernia.

The small chapter on medico-legal aspects of hernia could well be studied by any physician who treats hernias.

This monograph is valuable mostly as a review volume covering all phases of this very important subject.

EUGENE E. SCOTT, M.D.

DIAGNOSTIC STANDARDS AND CLASSIFICATION OF TUBERCULOSIS. Committee on Diagnostic Standards, Fred H. Heise, M.D., Chairman. 32 pages. New York: National Tuberculosis Association, 1940.

Currently accepted standards in diagnosis, treatment and prevention of tuberculosis are given in the new edition of "Diagnostic Standards and Classification of Tuberculosis" issued by the National Tuberculosis Association.

The new edition of the publication incorporates many ideas of physicians who gave the Standards in the tentative edition, published in 1938, a practical trial during the last two years, according to Dr. Fred H. Heise, medical director, Trudeau Sanatorium, Saranac Lake, N. Y., who is chairman of the Committee on Diagnostic Standards.

Some of the changes in the new edition are in terminology. The terms "primary" and "reinfection phases," are used to replace the terms "childhood type" and "adult type," respectively. This change is due to the fact that primary infections occur in adult life more frequently than formerly simply because fewer children become infected.

The term, "frankly active," is now employed to in-

SILVER PICRATE

Wyeth

HAS SHOWN A CONVINCING RECORD* OF EFFECTIVENESS IN ACUTE ANTERIOR URETHRITIS

**due to Neisseria gonorrhoeae • Trichomonas vaginalis
Monilia albicans**

Silver Picrate is a crystalline compound of silver in definite chemical combination with picric acid. Dosage form for use in anterior urethritis: Wyeth's Silver Picrate Crystals in an aqueous solution of 0.5 percent.

Supplied at all pharmacies in vials of 2 grams

Complete literature on Silver Picrate as used in genitourinary and gynecological practice will be mailed on request.

*"Treatment of Acute Anterior Urethritis with Silver Picrate," Knight and Shelanski, **AMERICAN JOURNAL OF SYPHILIS, GONORRHEA AND VENEREAL DISEASES**, Vol. 23, No. 2, pages 201-206, March, 1939.

JOHN WYETH & BROTHER, INCORPORATED, PHILADELPHIA, PA.

clude the cases formerly classified as "improved and unimproved," though these terms are retained as subdivisions.

The section presenting the pathogenetic development of pulmonary tuberculosis discusses fully the primary and reinfection phases of tuberculosis, initial lesions, prevalent types of retrogression and progression, and the histologic characteristics of the two phases of the disease.

The necessary correlation of the clinical symptoms of tuberculosis with the pathologic course of the disease is emphasized and many such correlations are given as illustrations.

The diagnosis of tuberculosis is discussed from the standpoints of pulmonary tuberculosis with and without symptoms, the primary phase of the disease, non-pulmonary tuberculosis and differential diagnosis.

The technical procedures in the diagnosis of tuberculosis are fully presented. The methods and the interpretations of the intracutaneous tuberculin test are discussed, as well as the demonstration of the tubercle bacilli in the sputum, stomach washing and other body fluids.

Many factors involved in the taking of the radiograph and its interpretation are evaluated.

This publication is available to Minnesota physicians on request to the state and local Christmas Seal organizations. Requests can be made to the Minnesota Public Health Association, 11 West Summit Avenue, Saint Paul, Minnesota.

HEIL HUNGER! Health Under Hitler. Dr. Martin Gumpert. Translated from the German by Maurice Samuels. 128 pages. New York and Toronto: Alliance Book Corporation—Longmans, Green and Co., 1940. Price \$1.75.

The author effectively destroys the myths created by Nazi sympathizers that Hitler transformed a sick, degraded people into a healthy, vigorous nation. The findings of the author to the contrary are the more convincing, because they are based on original German scientific sources, plus numerous reports on health conditions in Germany which appeared in the *Journal of the American Medical Association*.

On the strength of these documents, an entirely different picture emerges. In Germany today, there is no specific state of hunger, but rather, a treacherous chronic state of undernourishment. This is the more ruinous because of the great physical strain to which the population is subjected. Labor is forced with no regard as to fitness and experience; hours are long, wages small, and vacations infrequent. Child labor is exploited; women are driven into industry in a proportion far exceeding that of any other country. Athletics of a strenuous character and military exercises are compulsory. At the same time, medical science and its practice is undermined through mass expulsion of non-

Aryan physicians, by curtailing medical courses and hospital training, by licensing quacks, and by rigid governmental control.

Lack of medicaments to an extent where such staples as cod liver oil, boric acid and iodine are unobtainable is also a great detriment to health. The results are disastrous indeed. Diseases of malnutrition such as scurvy and rickets, long forgotten in Germany, have reappeared. Tuberculosis of men and cattle alike has increased tremendously. Venereal diseases are widespread. Insanity is in the ascendance. The birth rate, contrary to expectation, is falling while the death rate is mounting.

Because of the physical and nervous strain, and also due to increase in the consumption of alcohol encouraged by the government for fiscal reasons, suicide has become a frequent occurrence. That the unfortunate non-Aryans seek in death an escape from their misery is a factor overlooked by the author. However, be that as it may, the number of suicides in Germany for the last four years is almost equal to that of the rest of Europe for the same period.

Ruined health, semi-starvation, and the wholesale sacrifice of the flower of the nation on the altar of the God of War—that is the price of Naziism.

M. L. ZLATOVSKI, M.D.

PHYSICAL DIAGNOSIS, (Elmer and Rose) 8th edition. Revised by Harry Walker, M.D., F.A.C.P. 792 pages, Illus. Price \$8.75. St. Louis. C. V. Mosby Company, 1940.

The present author has undertaken the commendable task of attempting to bring physical diagnosis into present-day perspective. Prejudiced authors have exaggerated their powers of observation and bewailed the blundering dependence of others on laboratory methods and vice versa. The author's sincerity is manifested by his critical treatment of all recognized signs and additional collaboration with men working in neuropsychiatric, endoscopic, pathologic and medical fields.

The difficulty of combining just enough monographic clinical medicine in each section is met by including the bare essentials of physiology of the various systems and etiology and pathology of specific diseases. Illustrations, diagrams, x-ray films and electrocardiograms are used to amplify the text. The synopsis of neuropsychiatric examination impresses me as a valuable inclusion in such a book. In that, as well as in the remainder of the last half of the book, the necessary conciseness precludes expansive detail. Luten's section on the heart is a masterpiece of concise comprehensive and practical coverage.

I feel that the present revisor has achieved his objective, i.e., to impart a practical diagnostic perspective.

MODERN TRENDS*

BERTRAM S. ADAMS, M.D.

Hibbing, Minnesota

THE medical profession is facing a challenge today—a challenge from those who favor government control of medical care, believing it to be more effective. Our critics claim that many persons are forced to go without medical care because it is not offered to them at terms they can meet. We are told that the family doctor era is past and that because medical care has become highly specialized, newer methods of making it available should be developed. They want the Government to collect a small fee from everyone in the lower income brackets. To this will be added a similar amount by the employer. These together will entitle those paying and their families to medical care—the European system.

The challenge also comes from our friends who think that our American system of medical care is in grave danger, and that something should be done to avert such a crisis. They believe that government control will lower standards of medical care, and hinder advancement.

We must not be blind to the facts giving rise to this challenge. Vital adjustments of a socio-economic nature are affecting the character of our people. Our frontiers are gone; our young people no longer look forward to moving west and making a fortune. Instead they are satisfied with salaried positions. Many are unemployed, and some may never again find private employment. Incomes are not high, yet everyone spends money for automobiles, radios, movies, and whatnot. What used to be luxuries are now necessities. Their income is spent by the end of each month. People do not accumulate savings to meet a catastrophe in the form of sickness.

On the other hand, the cost of medical care has increased due to scientific advancement, improved methods of diagnosis and treatment, laboratory and x-ray facilities, surgical and specialized medical treatment calling for hospitalization and for nursing services. The advances in medical science require correspondingly longer periods of study for professional students as well as more frequent periods of postgraduate study for those in active practice. It also necessitates specialization with its increased costs and larger fees. All of these contribute toward making modern medical care the most efficient ever known, but also the most costly.

Another fact is that, while people in the lower income bracket may be content and happy in a humble home with simple clothing and food, when sickness comes they, too, need the best of medical care and service. Hospitalization, laboratory and x-ray services, surgery, blood transfusions, consultations—all these are necessities regardless of financial status.

To be remembered also is the changing character of disease incidence; diseases that were common forty years ago are now rare. Others are assuming greater importance. The degenerative diseases accompanying old age and requiring medical care over a long period of time—care that is frequently of an expensive nature—constitute an important phase of medical care today. "Data from the National Health Survey, based on surveyed persons of all ages, show that chronic diseases, including permanent impairments, alone account for six of the ten days of incapacity due to illness and accident experienced by the average person per year." On the other hand, the infectious diseases are constantly decreasing.

*Presidential address before the House of Delegates at the annual meeting of the Minnesota State Medical Association, Rochester, Minnesota, April 21, 1940.

Our answer to this challenge is that our American system of medical care gives better medical care and better service to the entire population than is given by the European system or any other system yet devised. It respects the personal relationship between the physician and his patient. It maintains his self-respect and encourages him to give to his patient the best that medical science has taught him. The remuneration of the average physician in this country is greater than in any other country, and this provides additional incentive for work of fine quality. Were the European system introduced into this country and the same quality of service maintained as is now given, the costs in taxation would be prohibitive. In preventive medicine, the most important field of medicine and the one in which the most progress is expected in the future, our country leads all others by a wide margin although, theoretically, the European system should be more effective.

As an example, I wish to point out the achievements of American medicine in coöperation with State Boards of Health and the United States Public Health Service. Striking is the reduced incidence of such diseases as typhoid fever, typhus, plague, smallpox, and yellow fever—far below that in any other country. As a result of immunization, diphtheria seldom occurs in this country. Because it is largely a disease of childhood occurring especially among the lower income groups, one should expect it to disappear under the European system of pre-paid medical care; but the facts are otherwise. While diphtheria in this country decreased 88 per cent between 1928 and 1936, the drop in England under the panel system was only 16 per cent. In Germany, which has had sickness insurance under government control longer than any other country, there was even an increase of 17 per cent. If the plans of our State Committee materialize, immunization will soon wipe out diphtheria in Minnesota. The same is true of tuberculosis. During this same period tuberculosis dropped 36.2 per cent in this country as compared with 28 per cent in England, and 22.7 per cent in Germany.² Until recent years this disease was the chief cause of death in the United States; it is now seventh in the causes of death. In 1909 fully one-fourth of the admissions to Gillette Hospital, Saint Paul, were for tuberculosis; today less than 1 per cent have that disease.⁹

Our State Committee on Tuberculosis hopes to see the disease completely eradicated before many years. By testing every individual with tuberculin, by taking annual films of all positive reactors, and by isolating all active cases, the Committee believes this can be done. Venereal diseases are being more and more efficiently controlled, especially in Minnesota. Crownhart quotes the following from an English statement: "The health needs in a country that has had a quarter of a century of sickness insurance are greater than in a country that has not had this legislation." He adds, in comment: "While the theory of sickness insurance indicates its use as a powerful weapon in disease prevention, there is no indication that it has ever occupied that rôle."³

American medicine, assisted by child welfare agencies, has done much in preventing and treating diseases of infancy and childhood. In 1900 it was estimated that one child died for every five births and in 1932 one for every thirty-two.⁸ Using statistics from Duluth as a fairly typical city, we find: Deaths under one year of age have decreased from 24 per cent of all deaths in 1900 to 5 per cent in 1937; during these same years, deaths in people over seventy-five years have increased from 4 per cent to 25 per cent; the average length of life has increased from 26.79 years to 58.65 years, while the number of persons attaining forty-five years or more has increased from 24 to 79 per cent.⁴ But in England, 11.6 babies out of every 1,000 died in the first twenty-four hours in 1906-1910. In 1935 the figure was 10.7.³

Another new field of medical endeavor relates to the work of the new Council on Industrial Diseases, formed by the American Medical Association three years ago. A large number of diseases have been called compensable by the courts. These diseases and their relation to industry are being studied in thirty-four states, annual conferences are being held, and a survey is being made by the Public Health Service. Our new State Committee is studying this subject and plans will be formulated as seem advisable.

We take justifiable pride in the reduction of time lost from work through accidents and disease by industrial workers. The iron and steel industry is fairly representative of all industries. Between 1907 and 1932 there was a 78 per cent decline in the number of accidents in this indus-

try, while the loss in time dropped from 6.9 days to 2.19 days, or 68.3.⁶ In England time lost through accidents and disease has increased 200 per cent since the panel system was introduced in 1911, and in Germany the rise has been 300 per cent since Government control was started in 1883.⁷ Gustav Hartz, an economic writer in Berlin, writes, "Since the sick insurance has been in effect, the number of days of incapacity to work owing to ill health, has risen from five and one-half days to twenty-eight days."⁵

Along this line is an evil which should be corrected, namely, the court procedure in cases in which medical testimony is required. It is unfair to allow the attending physician to testify as an expert witness. The present custom of permitting both the plaintiff and defense to present expert medical testimony is disgraceful to both the medical and legal professions, and fails to give testimony that is unbiased. We hope to initiate a procedure which will be fairer and more scientific.

In every other line of medical endeavor, study and research are being done; progress requires time, but efforts are not being spared.

To meet this challenge of our critics, we must give service that is not only better than any given elsewhere, but care so good that it will sell itself. We must acquaint the public with what has been done and what our goals are.

The challenge brings out another phase, an obligation that devolves upon every member of our organization. Believing as we do that our American system of medical care is better than the European system, and confident that it provides better medical care for the patient, permits full development of preventive aspects of medicine and is more responsive to advancement of medical science, we should do all in our power to retain it. We cannot permit a misguided and badly informed group of political leaders to force the European system of medical care upon the country without our serious protest. We shall indeed be remiss in our duty if we, the medical profession of America, who are informed on medical subjects, do not enlighten the public in regard to what we believe to be best for the health and physical well-being of every American citizen, and for the advancement of medical science.

Government control of medical care involves a great deal more than payment for the costs of

the sickness and injury; it restricts the freedom of those who minister to the physical welfare of the people. Rules and regulations to cover the smallest details will be made here just as they have been made in Europe. Innumerable reports will be required which will occupy the time the doctor should be giving to his patient. Since the doctor will be employed by the government and not by his patient, there will be a loss of the confidential relations between the doctor and the patient. As Crownhart says, "The primary responsibility of the physician is to the Government and not to his patient."³ Again quoting Crownhart, "The tendency of sickness insurance systems is to make the physician the re-insurer of the unknown demands, thus loading him beyond his capacity to render a sound quality of sickness care."³ The quality of goods or the value of service bought depends on the price paid; the European system has always paid a low price to the doctor and the result has been an inferior medical service.

Improved methods of distributing and making available medical care should be developed; several hundred plans have been devised by medical societies based on insurance principles and involving prepayment for medical care by industrial groups. So far these are experimental and untested. California began operation of a plan developed by their State Medical Society last year; the Michigan Medical Service organized by the State Medical Society, started operation last January. A number of contract plans are in use, the oldest probably being that used successfully for three-quarters of a century throughout the Lake Superior mining districts. This is probably the simplest and most economical plan in operation. Whatever the system may be, one important principle must be retained; the medical profession must be given freedom to act; the physician must be allowed to use his judgment, ruled by his own Code of Medical Ethics which is as important a guide to upright conduct today as it was in the period of Hippocrates.

The medical profession is earnestly trying to give the best possible service to the public. Its members are working steadily to keep abreast of new developments and improvements in medical care. Preventive medicine offers the greatest hope for ameliorating sickness, suffering, and invalidism, and needs our most serious efforts. If, unhampered by restricting regulations, we can be

allowed to continue our efforts along these lines, encouraged by public sentiment, stimulated by energetic efforts of public health activities, and aided by new improvements and discoveries in chemistry, physics, and engineering, the progress already made should be but the entrance to an era of medical achievement unrecorded in history.

MEDICAL SYMBOLISM IN THE MYTHOLOGY OF ANCIENT GREECE*

WILLIS S. LEMON, M.D.

Rochester, Minnesota

STUDENTS of Homer have in the *Iliad* and *the Odyssey* a storehouse of Greek myths, of legend and of symbolism. No attempt will be made to cover all of the myths relating to the snake, much less to report those concerned with other animals or with gods where insignia do not specifically include the serpent. Only the life and deeds of Æsculapius, the "blameless physician" of Homer, and some of the lore concerning Hermes, self-confessed king of robbers, will be considered.

A number of legends are connected with the birth of Æsculapius. The one most appealing to a physician is that in which his mother, Koronis, with child by Apollo, is related to have fallen in love with Ischys. Because of her unchaste deed Apollo sent his sister to punish her. While Koronis lay on her funeral pyre Apollo relented, "seized the babe from its mother's womb" and hastened to Cheiron, the centaur, so that the babe might be educated in medicine and learn to assuage the pains and cure the diseases of mortals.

In the Epidaurian legends it is stated that Æsculapius was nursed by a goat and guarded by the shepherd's dog. When the babe was discovered by Aristhanas, the shepherd, the babe shed a radiance about itself which proclaimed it to be of divine origin. Perhaps this legend accounts for the fact that the dog was often associated with the serpent in ancient carvings of the god Æsculapius. As a child, he learned all

the uses of drugs and much of hygienic treatment from Cheiron, and even while still a lad he is reputed to have cured the sick and raised the dead. He went with the Argonauts on their voyage to Kolchis, and proved himself the best of the students of Cheiron. He trained his sons to be physicians, and they became proficient and distinguished themselves as healers during the long years of the Trojan wars.

The followers of Æsculapius were the earliest to develop and record clinical observations and to establish the practice of medicine on a reasonable basis. In the sixth century B.C., a shrine was established at Epidarus and this sanctuary became the chief center of the cult; ruins may be visited to this day. From this center, the teaching of Æsculapius and his practice of medicine spread throughout the world and more than 400 shrines or sanatoria were set up. Serpents were always found at the shrines, and legend records that many of the shrines throughout the world were located where snakes took up their abode. Sometimes, the snake was sent with the priest to represent the god, as was the case during the terrible pestilence of 293 B.C. that afflicted the city of Rome "with prodigious mortality."

It is stated that Æsculapius retained his supremacy as a healer until the Christian Era. An interesting legend records the circumstances of his death. It was claimed by Hades that Æsculapius was prompted by avarice and an improper desire for gold, and that he imparted his art to mortals, which was contrary to the will of the

*From the Division of Medicine, The Mayo Clinic, Rochester, Minnesota. Remarks before the House of Delegates of the Minnesota State Medical Association, April 22, 1940, on presentation to the Speaker of a gavel designed and carved in Minnesota black walnut by Dr. Lemon.

gods. Hades further complained to Zeus that the success of the medical care given by Æsculapius had averted too many deaths and consequently threatened to depopulate his realm. Zeus was angered and sent a flaming thunderbolt from Olympus and slew Æsculapius, thus making the Olympian immortal. "Incineration by a thunderbolt implied celestial or Olympian immortality."

It is particularly appropriate that Æsculapius should have the serpent for his emblem. The snake was the symbol of life and sagacity and was known to the Greeks as a sacred and mystic being whose magic powers were associated with dreams, prophecy and healing. In sculpture, the snake is always represented as coiled about a staff which the god Æsculapius carries (Fig. 1), or about his body and lower limbs. The snake's habit of sloughing its skin is one of the reasons for its reputation as a healer. Tyson quoted from Ovid: "It was natural to suppose that a creature which could renovate itself could also renew the energies and prolong the life of the sick and the suffering," and he pointed out that both the Latin and the Greek word for old age was also applied to the slough of serpents.

Snakes and dogs were found at all the temples, and snakes are pictured in drawings of the abaton where sick people came and slept while undergoing treatment. It was thought that the divine healing power was transmitted to these animals. Lacerations were healed when licked by cult reptiles, and the blind were made to see when the eyes had been licked by the sacred dogs. It is also recorded that baldness, as well as blindness, was cured by the touch of the hand of Æsculapius, who came to the afflicted while they slept. Sometimes Æsculapius came to the sleeping patient in the form of a serpent.

Today, the signum of Æsculapius is a single snake coiled about a rough olive branch. In earlier times, the shoots of the branch were adorned with ribbons or garlands.

The God Hermes

The Greek god Hermes, sometimes said to be the half brother of Æsculapius, is identified by the Romans with Mercury. He was the son of Zeus and Maia, and Mount Cyllene in Greece was reputed to be his birthplace. His reputation as the master thief among the gods began while he was still an infant. He was a precocious child and while yet a newborn babe began his

life of thievery by stealing the cows of Apollo. He became lord of those who swindle, house-break, sheep-steal and shoplift. He was represented as the god of thieves, of travelers and of shepherds. He was called crafty and tricky,

Fig. 1 (Left). The seal on a doctor's diploma of the medical faculty of Montpellier (1605). Æsculapius is shown seated on a hillock on which medicinal plants are growing; also the coats-of-arms of France and Montpellier. Engraved by the sculptor Jean Leblanc, Montpellier. Reproduced by permission of Ciba Symposia.

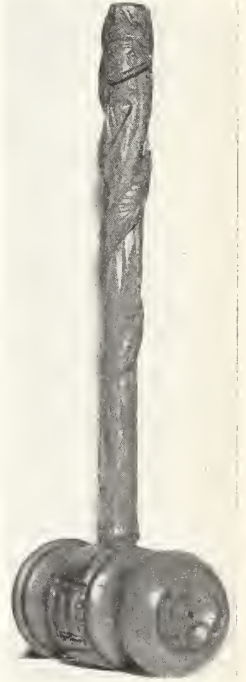

Fig. 2 (Right). The gavel which was presented to the Speaker of the House of Delegates of the Minnesota State Medical Association at the Rochester meeting in April, 1940.

and was often referred to as the giver of fertility. According to Plutarch, the ancients set Hermes by the side of Aphrodite, that is, the god and goddess represented, respectively, the male and the female principles of generation, and the two deities were worshipped together. Aphrodite was known as the goddess of love and the reproductive powers of nature. Our word, "hermaphrodite," a combination of "Hermes" and "Aphrodite," recalls the myth of their son, Hermaphroditus, who grew together with the nymph of the fountain of Salmacis while bathing and thus combined male and female characteristics: a creature half man, half woman.

As a messenger, Hermes became the god of roads and doorways and the protector of travelers. Treasure found on the road was spoken of as a gift of Hermes, and he became the god

of good luck. He became the deity of gain and commerce and, like Mercury, was known as the god of trade. His office as god of trade is reflected in words of common use today. In 1756, Rolt described the hermetic seal as used in trade, which consists of airtight closure of a vessel by fusion, soldering or welding. In a surgical sense, the hermetic seal of wounds refers to a method of dressing penetrating wounds, especially of the thorax and abdomen.

Hermes appears to have had admirable qualities, too. He was worshipped by farmers because he brought luck, probably by insuring fertility and adding increase to the herds. He became the sponsor of games, and his statues were common in Greek gymnasia and stadia. As such, he came to impersonate the ideal Greek youth, who was graceful and dexterous as well as strong, courageous and eloquent. He was the giver of grace, rather than strength, which was the province of Hercules. Because of the influence of Praxiteles, he is commonly represented as a youth with caduceus or rod, petasus or brimmed hat and talaria or winged shoes.

He was a patron of music, and invented the cithara which he played so beautifully and so pleased Apollo that, in exchange for the instrument, Apollo gave him a herald's wand and made him a messenger between the gods and man. It is stated in another legend that he evolved a lyre with great ingenuity from the shell of a tortoise, and played so divinely that the enchanted Apollo gave him the wand. In his office as messenger of the gods, he conducted the souls of the dead to the world below. It was said that his caduceus or magic wand exercised an influence over the living and the dead, bestowed wealth and prosperity, and turned everything it touched to gold.

He is supposed to have been one of the gods of healing, but he, whose caduceus we sometimes use as the insignia of medicine, seems to have had but few contacts with healing. He is reported to have performed one of the earliest Cesarean sections when he delivered Semele of Dionysus. The account of this is not dissimilar to the delivery by Apollo of Æsculapius, whom he tore from the body of the beautiful Koronis. Hermes also stopped a plague at Tangara by carrying a

ram on his shoulders around the walls of that city. But there Hermes' connection with medicine comes to an end.

The Caduceus

The caduceus, or herald's wand, was given to Hermes by Apollo. In the *Encyclopædia Britannica*, the author says: "In its oldest form it was a rod ending in two prongs twined into a knot (probably an olive branch with two shoots adorned with ribbons or garlands) for which, later, two serpents with heads meeting at the top were substituted. The mythologists explained this by the story of Hermes finding two serpents thus knotted together while fighting; he separated them with his wand which, crowned by the serpents, became the symbol of the settlement of quarrels. A pair of wings was sometimes attached to the top of the staff in token of the speed of Hermes as a messenger. In historical times, the caduceus was the attribute of Hermes as the god of commerce and peace, and among the Greeks it was the distinctive mark of heralds and ambassadors whose persons it rendered inviolable."

It would appear that the caduceus has scant claim to medical importance and should not be used as the symbol of medicine. That right should be given to the signum of Æsculapius* and this should always be represented as a single snake coiled around a knotted staff.

Presentation

Mr. Speaker: I have designed and made a gavel for the use of the Minnesota State Medical Association (Fig. 2). It has for its handle a roughly carved rod ending in two prongs, and coiled about it I have represented a snake. It is intended to resemble the signum of Æsculapius. On one face of the hammer there is an open book, and on the other a Grecian lamp. I hope you will accept the gavel in the name of the Association and that it may be used whenever the members are called together.

*The signum of Æsculapius was the accepted symbol of medicine until the reign of Henry VIII. Then, Sir William Butts, the King's physician, confused it with the caduceus of Hermes. A few years later, Dr. John Caius presented to Gonville and Caius College, Cambridge, a silver caduceus. This form of symbol is used only in the United States.

TUBERCULOSIS CASE FINDING AMONG AMERICAN COLLEGE STUDENTS*

CHARLES E. LYGT, M.D., F.A.C.P.

Director, College Health Service, Carleton College
Northfield, Minnesota

THE battle for the control and eventual elimination of tuberculosis is being waged along many fronts. One of the most important and promising is that occupied by our colleges and universities. The educational environment lends itself ideally to the formulation and direction of an effective system of health supervision, as well as offering opportunity for lasting imprint on the minds of those soon to succeed to leadership of American enterprises. More practical is the fact that during the years normally spent in colleges and graduate schools, tuberculosis remains, in its very essence, the prime threat to life and health. This arises from no particular hazard of undergraduate existence, nor from some perverse process of selection which would act to fill colleges and universities with young men and women possessing poorer than average health. It is due rather to the well recognized phenomenon of tuberculosis' heightened morbidity and mortality during late adolescence and early adult life. Here, then, are the young people. Here, too, is the menace of unrecognized tuberculosis. You may be interested in what is being done to safeguard the first-named from the latter.

It is twenty years since Myers and his co-workers began their student chest clinic at the University of Minnesota, a mere moment in medical history, but a long, fruitful period in the vanquishment of tuberculosis. From that humble beginning evolved a plan of advancing to meet trouble more than half-way, of searching for it constantly, of harrying and badgering tuberculosis, instead of waiting patiently, idly, for the manifestations of advanced disease to appear through the development of signs and symptoms. Other schools have caught the vision, largely due to the leadership, example and enthusiasm of men like Myers, until today there are nearly 200 institutions of higher education in the United States providing some degree of tuberculosis case finding among their students.¹⁷

You shall hear a few of the results reported

by colleges to the Tuberculosis Committee of the American Student Health Association annually, and by the Committee summarized and turned back to the colleges. The Tuberculosis Committee, formed in 1931, is but a recent recruit in the anti-tuberculosis forces. Yet its sphere of influence grows so rapidly, as more schools inaugurate modern tuberculosis control projects, that it is difficult to anticipate, to say nothing of meeting the needs of an expanding horizon bounding the academic field of action. Nevertheless, though recent development of interest has seemed phenomenal, there has been no hint of mushroom growth. Instead, during the years when it appeared that only a few larger universities would or could accept the challenge to embark on a campaign of early diagnosis, early treatment, early arrest, adequate foundations for a thorough-going national collegiate program were being laid. As a result, close and satisfactory working arrangements exist between the Student Health group and the National Tuberculosis Association. Presently, plans are being discussed that should gradually eliminate the early inevitable centralization of effort and direction, substituting for it an enlistment of sectional Student Health organizations and local tuberculosis agencies. Thus, each year, the activities of the Tuberculosis Committee promise to grow more preceptual and advisory, its annual Report a clearing house for mutually helpful data. Our replies to future appeals from colleges struggling with new programs will take the shape of notifying the nearest tuberculosis associations, giving them the facts, and asking them to render all possible aid. One of our chief responsibilities will continue to be the discriminating selection and dissemination of proved new methods by which student tuberculosis case finding may be strengthened, accelerated, reduced in cost, augmented in effectiveness.

Having reviewed the popular growth of tuberculosis control in American colleges (57 per cent increase during the last two years), and hinted at future needs (over three-quarters of the in-

*Address delivered before the Minnesota Trudeau Medical Society, Hotel Nicollet, Minneapolis, February 23, 1940.

stitutions still with no programs), let us examine the facts deducible from the data concerning current action. It will be unnecessary to employ the arguments to which we must have recourse when bidding for the interest and support of such laymen as college deans or presidents. Nor will it be necessary to stress the importance of student tuberculosis as when we address partially convinced student health administrators and physicians. You are daily in contact with tuberculosis, more often than not in a stage you would gladly exchange for an earlier and more hopeful one. Accordingly, though you may not all agree with everything presented, all should admit the problem of student-age tuberculosis, the need for adequate means of solving it, and the advisability of reasonably uniform methods of approach toward its solution.

Whether we consider national figures, or those from individual institutions such as the University of Pennsylvania or our own University of Minnesota, or such regional reports as the detailed analysis recently made in the Pacific Northwest,¹⁵ comparable facts emerge and similar lessons are to be learned. Most of the facts are so well known to tuberculosis workers that it seems banal to reiterate them. The value of the tuberculin test,⁸ the need for adequate dosage whenever the test is employed, the diagnostic aid of the roentgenogram along with its limitations,⁹ the necessity of painstaking follow-up and evaluation of the status of every suspected case, the importance of crowning early diagnosis with effective treatment, the demand for a program that traces contacts and hunts sources, are all points so self-evident that they call for dismissal without elaboration. Experience teaches, on the contrary, that these may be the very facts whose familiarity has acted to disarm us, and to breed in initiated minds a certain amount of forgetfulness, if not contempt.

Our Report for 1938-39 lists 282 replies to the Committee's questionnaire from colleges and universities, of which 165 reported some form of tuberculosis program in operation. Tardy returns, plus new programs known to have started last fall, to say nothing of several programs in progress at negro colleges, would swell the total until, as stated earlier, there are close to 200 schools with case finding in effect. The institutions replying were of all sizes and types, ranging from ninety small schools with enrollment below

500, through 150 middle-sized colleges, to thirty-five large institutions having 4,000 to 16,000 students apiece. Among those with tuberculosis work under way, seventy-eight represented privately endowed colleges and universities, forty-three were in the category of State universities, colleges or institutes, thirty-seven were State teacher's colleges and normal schools, and seven were civic institutions. All sections of the country were represented in the honor roll of schools with programs, including eighteen in New England, thirty-one in the Middle Atlantic and eight in the Southern Atlantic areas, twelve in the deep South, nine in the Plateau and Mountain region, twelve in Pacific coast States, and seventy-five in the States of the Northern Mississippi basin. The initial leadership provided by our own district is again evidenced both in the volume and quality of work recorded in the last-named portion of the nation.

Analyzing the figures from the 165 institutions possessing a tuberculosis set-up, we find 143 testing with tuberculin, while twenty-two resort to x-ray as the first step in their screening procedure. We are aware of the difficulties at various schools which have led to adoption of this latter method, including real or fancied student distaste for the tuberculin test, a high incidence of positive reactors as in most Eastern colleges, and the time, energy and expense demanded by careful tuberculin testing. None the less, we have campaigned for and will continue to advocate prior tuberculin testing, since it provides the only sure way of discovering better than 90 per cent of the presently infected individuals. Moreover, the retesting of negative reactors at appropriate intervals, preferably annually, gives definite indication of tuberculo-protein allergy very shortly after its development, on the one hand, or its resumption by those few who may have achieved anergy for a time, only to revert to positivity through reactivation of once inactive, apparently well-calcified lesions.^{3,7} The benefits of tuberculin testing so far outweigh the admitted bother and the negligible expense that we feel the method should be preserved intact, its use spread rather than abandoned for what may be a questionable shortcut. At the same time, we admit the advantages of *any* intelligently conceived and directed system of tuberculosis control as contrasted with none. Our thesis is that tuberculosis *control* in its very essence depends on case

finding, that is, discovering as many infected humans as possible with the means available. If this contention be accepted, then tuberculin testing becomes an initial procedure for which, up-to-date, there is no substitute.

Last year the vast majority of tuberculin testing colleges used the Mantoux intradermal technique, 136 in all, while three employed von Pirquet, and four experimented with the Vollmer patch test. Here, again, we have maintained a conservative attitude but an open mind, pointing out that where the Mantoux method is used, the clinician is sure at least that tuberculin of measured quantity and reasonably standard potency actually entered the skin layers, and that premature removal of a patch, dilution of tuberculin by water or perspiration, side effects of air due to imperfect seal, or non-specific skin reactions to adhesive substances are not possible. We have urged colleges to give the patch test a thorough, controlled trial, comparing it as several pediatricians have done,^{10,16} with the Mantoux or von Pirquet results, and checking all tested persons with searching roentgenographic studies. Where this has been done, we learn the patch test is roughly comparable to a first-strength dose of Purified Protein Derivative administered intracutaneously. This would indicate that patch test negatives should have benefit of a further test with 0.005 mg. P.P.D. or 1.0 mg. O.T. Further investigation may even lead to combining the two methods if such a departure proves reliable and economically advantageous.

P.P.D. was the testing material of choice in seventy-nine colleges; fifty-five others used O.T.; five failed to specify, and four employed the patch test. It seemed to matter little which of the first two products was used, so long as an adequate dosage was reached before students were classified as negative reactors. There were 33,355 students tested with the standard maximum of 0.005 mg. P.P.D. in forty-eight colleges, and 30.5 per cent reacted positively, while in thirty-four other schools where the dosage of O.T. ran to 1.0 mg. and where 21,516 students were tested, 30.1 per cent gave positive reactions. Thus, although the Committee has recommended use of P.P.D. for reasons of uniformity and standardization, it is much more concerned with the selection of potent products and the carrying of the dosage to a point where no significant proportion of truly positive reactors will be

overlooked. Though many observers have maintained the lower dosage to be capable of identifying most cases with clinically significant lesions, we have personal experience and receive further reports from others to support the contention that many instances occur where cases of active tuberculosis showed negative or equivocal reactions to the usual first strength dose of 0.00002 mg. P.P.D., or 0.01 or even 0.1 mg. O.T.¹⁴ Therefore, we prefer to advocate retention of a highly dilute first dose, or, perhaps, in areas with low infection rates, an intermediately-sized dose, so that persons with marked allergy may be spared violent reactions, and to urge the use of a much concentrated second dose in order to locate positive reactors who otherwise would be missed. In each of the past two years eighty-two colleges followed the recommended procedure, reporting a positivity of approximately 29 to 30 per cent. A lesser number of schools, annually testing up to 20,000 students with what we, at least, term below an adequate dosage, succeeded in finding only about 15 per cent positive reactors. Admittedly, we are averaging results from scattered institutions, so that these figures are presented not as exact computations, but merely to indicate general truths. The basic moral to the story, namely that adequate dosage is imperative, is in no wise disturbed, especially as the sampling is nationwide and includes a generous number of tuberculin tests. Furthermore, where the two methods have been tried out under ideal conditions, that is, concurrently within the same institution, as investigated by Canuteson at the University of Kansas over a three-year period,² the discrepancy in results caused by testing with unduly small doses of tuberculin was quite as marked as in the quoted figures collected from well distributed national experience.

That our harping on the necessity for unceasing prosecution of case finding is bearing fruits is borne out by a steady increase in the percentage of colleges providing annual retest for their previously negative reactors. Others, not yet equipped to go this far, preliminarily test new students, retest seniors. Still others make the test available annually to any student electing it. The entire movement seems to be toward increasing the scope and effectiveness of existing programs, as well as toward establishing new ones. Seldom do we hear of one being

abandoned, and very infrequently of any that stand still or regress. This heartening improvement is further underscored by such advances as a total of seventy-one colleges requiring tuberculin testing and roentgenograms of all their food handlers. Two years earlier there were only thirty schools in this progressive category. Then there were twenty-nine colleges with tuberculosis programs available, mostly on a voluntary basis, to faculty members and administrative employees. Now there are forty-nine schools so listed.

Annually we note a gratifying shrinkage in the number of colleges where positive reactors have roentgenograms taken once only during their course. There is a coincident increase in the number where films are made annually, or oftener if indicated. There are no less than thirty-six schools using the fluoroscope as a supplement to chest films, while only five still employ the screen as their sole roentgenographic diagnostic aid. The inherent dangers in relying exclusively on the fluoroscope for diagnosis, particularly of the early lesions, have been pointed out, although we believe fluoroscopy of infinite value in rectifying the obvious shortcomings of the static, single-flat-film routine investigation. Those men who report the most outstanding results through use of the fluoroscope, almost unanimously stress their coincident reliance upon good serial films.¹⁴ It is only the use of an inadequate screen or the use of a good machine by an improperly prepared examiner that we hope to see avoided. The newer technic of minicamera snap-shots of fluoroscopic images is too recent for us to do more than mention as another medium to be carefully evaluated. If it fails to discover a reasonably complete number of the *minimal* cases now found by older methods, its cheapness and rapidity can hardly justify its substitution for those technics. Primarily, it is to be hoped that we who wield any weapon, whether it be tuberculin test, chest film, fluoroscope, blood count, sputum examination, sedimentation rate, serological reaction, or anything else in the clinician's armamentarium, will be equally as quick to appreciate and acknowledge its limitations as to claim and publish its advantages.

Student positivity to tuberculin has been indicated as now lying at about the level of 30 per cent when we restrict our consideration to those

who received adequate dosage. This is probably a fair average for the country at large within the age-group tested and within a social stratum comparable to the rather selected, favored, student mass. Unfortunately, our earlier figures are not as conclusive as those compiled latterly, but they were reasonably correct. Thus, when we note that in 1932-33 the national college returns showed 35 per cent positive reactors, we believe it is fair to presume a gradual decline in the incidence of tuberculous infection is in progress among students as it is elsewhere in the general population. Further annual surveys by the Committee are necessary, however, before any definite rate of improvement can be computed.

As found by investigators outside the college field, we likewise determine that, at a given age, a slightly higher percentage of men than women will react to tuberculin, though there is definitely a slightly higher ratio of active tuberculosis found among the women students.^{4,5,11,14} Again, with few schools yet possessed of record systems capable of supplying exact information, it appears that well less than 1 per cent of all tested will be found to have demonstrably active pulmonary tuberculosis. In the mid-West it is probably not over half of one per cent, or well below 2 per cent of those submitted to x-ray. Stiehm, at the University of Wisconsin, has shown that evidence of infection subsequent to entrance to school is relatively more to be expected than that found at entrance examinations, but that with modern methods it is possible to limit the probability of discovering moderately or far advanced cases of tuberculosis among old students almost to the vanishing point. Prior to 1933, at that university, using methods based on investigation of students with symptoms or signs, namely, sick patients, an average of ten cases of tuberculosis per year came to be diagnosed.¹² Most were well past the minimal stage. During the first five years of a case finding program beginning that year, only three of the seventy-one active cases discovered had reported because of symptoms.¹⁴

The well known rise in the incidence of tuberculous infection with advancing age is brought out in our national figures that reveal students of age 17 to average 20.5 per cent positive reactors, those of age 21 about 26 per cent, those of 25 around 35 per cent, and those few above

35 years approximately 66 per cent positive. The marked increase in infection rate among students of medicine and nursing is universally recognized.^{1,6,11} This has ranged as high as 96 per cent positive among the seniors of one Eastern medical college. The findings in Minnesota have been ably presented to you in the past by Boynton, Myers and others.¹ We must regard such professional courses of study as within a definitely "special hazard" class, where they must remain so long as there are known or unknown tuberculosis patients to be nursed and treated. The necessity for minimizing hazards through improving every technic designed to prevent infection or re-infection of students should be obvious.

Adding the examination of fasting stomach sediments to the other procedures for studying suspected cases has largely overcome the problem of the sputumless or uncoöperative patient. Stiehm reports detection of tubercle bacilli in gastric specimens from 72 per cent of those who had negative or no sputum, when reinforced by guinea pig inoculation.¹³ At Carleton College the only clinically suspicious case we found this year was corroborated from a bacteriologic standpoint only through use of this device. It is to be hoped that laboratory facilities here and elsewhere may soon permit such vital examinations to be freely available whenever needed.

Up to this point we have dealt with methods. Let us now scrutinize results. Figures for 1937-38 and for 1938-39 are almost identical in their proportions and absolutely without variation as to what they teach. They indicate one fact only: that tuberculosis can be found, and found early, by anyone willing to look for it with his clinical eyes open. Tuberculosis is missed, or found only upon rare occasion and purely incidentally by physicians or institutions pursuing out-dated methods. For example, last year in those 165 colleges supporting case finding, enrollment totalled 348,713 students. Determined search for tuberculosis turned up 241 clinically active cases, with 368 others diagnosed as apparently arrested, or, in all, 609 newly found cases of the disease. Of these, 151 students withdrew from college because of their lesions. There were, additionally, 320 old cases not included in the above, back in college under supervision. Bearing these figures in mind, let us consider the situation with regard to 129,851 students enrolled in 117 col-

leges answering the questionnaire, but not yet blessed with case finding facilities. Here, by one means or another, somebody, somehow managed to diagnose four cases as clinically active, fifteen others as apparently arrested, while there were ten formerly diagnosed cases back in school. Only four cases left college because of tuberculosis. In the first group of colleges the protected, investigated student population was considerably less than three times the volume of that in the second group, yet its active cases found were sixty times as numerous, and those advised to leave college for their own good and for the safety of others were thirty-eight times as many.

Should a student introduce smallpox or poliomyelitis to a college campus, events would move fast! Not only would he be isolated and properly treated, but instant search would begin for the source of his infection. His local health officer would be notified, and all the machinery of public health would be set in motion to prevent an epidemic. Something of this attitude must be transferred to tuberculosis work if we are to profit fully from the effort being expended to discover cases among students. We now know a positive reactor is nothing less than an infected human being, yet we are apt to go no further than careful examination of that one individual to determine if he is in need of care, or if he can spread his tuberculosis. Although it would entail a tremendous amount of work if a system of back-tracking as thorough and exhaustive as our present process of follow-up were to be supported, we must give earnest thought to this side of the problem if we are hoping for elimination of tuberculosis from the whole population. Since we know that most infections in early childhood are traceable to the home environment, later ones to a widening and more elusive circle of contacts, we are doing only a partial job when we fail to enlist the aid of relatives, family doctors, and local tuberculosis and social agencies in ascertaining where in his own community a student may have picked up his tubercle bacilli. Frequently the search might be unavailing, but there can be little doubt that many instances of unrecognized, open tuberculosis would be located in this way. Another challenge for the future is to buttress the present college case finding with pre-college programs such as we have in many progressive districts already, and with post-graduation technics on at least as high a plane

as those enjoyed by the student while in college. Instead of filing and making a cold statistic of the clue provided by every positive tuberculin reactor, we should seek ways and means of passing it on to those of our associates best able to utilize it in strengthening public health efforts against tuberculosis.

Before concluding, an appeal should be issued to physicians in general and to tuberculosis specialists in particular to coöperate with the student health doctors who are attempting to popularize a campaign built around the words "early" and "preventive." The fact that the great majority of tuberculous patients (70 to 80 per cent of entering cases) still approach sanatoria when well beyond the minimal stage, their hospitalization prolonged, their prognosis greatly modified, their personal and public economic loss magnified, their rehabilitation complicated, testifies to the task that confronts us all before most or all cases can be diagnosed and treated early and hopefully. It is axiomatic that every far advanced case, every fatality, was once a minimal case, probably remaining so for a considerable period of time, but it is just as obvious that minimal cases must be going unrecognized seven or eight times out of every ten. The discouraging phase of the problem to the student health physician lies in the fact that all too often family doctors and internists alike, together with a certain number of those devoted exclusively to tuberculosis practice, are apt to belittle or grant scant attention to the preclinical, symptomless case once it has been found. On the same unfavorable side of the ledger appear those patients prematurely allowed to resume activity. These are usually people who become impatient, or whose medical adviser may still be living among the concepts of tuberculosis taught in medical schools of his day and not brought up to date. Or, perhaps, beds are needed for more of those neglected, late-diagnosed cases that represent stimulating surgical challenges as opposed to the minimum measures necessary to restore to health the early-identified cases.

If some college physicians are open to the criticism of being overly enthusiastic and active in the direction of early diagnosis and prompt, unhurried treatment, they surely are erring on the safe side. It would be just as easy to observe that occasionally some very eminent specialists concentrate too much time and effort, proportionately, on the very thing they publicly deplore—the late manifestations of tuberculosis. So, too, many otherwise up-to-the-minute general practitioners doggedly prefer symptoms to search, stethoscope to x-ray film. Somewhere in between two wide extremes is the level of common-sense coöperation, aided by lay education, upon which we should all be laboring shoulder to shoulder to defeat an ancient enemy—tuberculosis.

EARLY DIAGNOSIS CAMPAIGN—THE RURAL HENNEPIN COUNTY PLAN*

ERNEST S. MARIETTE, M.D.

Superintendent and Medical Director

Glen Lake Sanatorium

Oak Terrace, Minnesota

SOME one—was it the currently popular Chinese savant—has said, "It is as dangerous to recall a prophesy as it is to loan money to a friend." Nevertheless, on the eve of the Annual Early Diagnosis Campaign there may be some profit in looking backward to 1904 when the National Tuberculosis Association, with the courage and zeal characteristic of all young crusaders, announced as its objective, "No Tuberculosis by 1915." The thirty-six years of continuous effort in tuberculosis control since then have taught us the futility of that early shibboleth. But at the time it was made there was already in the world assurance of its ultimate accomplishment.

Leprosy, the dreaded plague of the Middle Ages, a disease which had instilled in human beings a fear without parallel in medical history, had been driven from Central Europe in two hundred years by merely isolating the leper in some of its nineteen thousand monasteries. If Europe in the Middle Ages, without decent sanitation, without cleanliness or public health protection of any kind, could conquer the terrible plague of leprosy, then surely the United States through the isolation of the tuberculous in sanatoria could expect to control tuberculosis—and it ought not to take more than eleven years to accomplish it. At least so thought the founders of the National Tuberculosis Association.

In their minds the problem was comparatively simple, merely locate the cases of tuberculosis in the early stage of the disease, before they had become infectious to others and treat them in a sanatorium.

This seemed an excellent plan and one to which an eager nation gave unexpected response through the purchase of Christmas Seals and the passage of laws setting aside public funds for the construction and maintenance of sanatoria.

But in all this planning they forget that leprosy is on the skin and easily seen while tuberculosis is hidden deep in the lungs and therefore is more

difficult to detect. Perhaps that is why the plan did not work out as has been anticipated, for the patients who came to the sanatorium were in the advanced rather than the early stage of the disease.

In the United States right now, according to the most recent survey of the American Medical Association, there are 202,021 persons under treatment for tuberculosis, in public and private institutions, the maintenance of which represents an annual expenditure of over seventy million dollars. In some communities there are between three and four beds per death and today vacancies are occurring in some of our once crowded institutions.

To derive the maximum benefit from these facilities an active early diagnosis campaign is imperative. For in the words of the late Dr. David A. Stewart, "Known tuberculosis can be made partially safe but when it is unknown and therefore not being taken care of, it is always dangerous."

It was to find this unknown case that the Wisconsin Anti-Tuberculosis Association began its diagnostic campaign in 1918 or 1919 which has been so successfully carried out during the years since. To be sure, in this interval, the emphasis has shifted from an educational campaign and a chest examination of the sick person to the study of the apparently well person through the use of the tuberculin skin test and chest x-ray. Thus, while the objective of the early diagnosis campaign remains the same, its methods have been modified.

Because of your own well-organized plan of searching for the unknown case, discussing the early diagnosis campaign before this group is like "carrying coals to Newcastle." Nevertheless, I think you may be interested in the country-wide search for the unknown case as carried out in rural Hennepin County. This is a coöperative program participated in by the Hennepin County Tuberculosis Association, the Glen Lake Sanatorium and the private physician who reports his findings to us.

This coöperative survey includes two groups:

*Presented in part before the annual meeting of the Wisconsin Anti-Tuberculosis Association, Milwaukee, Wisconsin, April 4 and 5, 1940.

first, the school child and his adult contacts both in the school and in the home; and, second, the contacts of the new cases of tuberculosis reported to the Health Department.

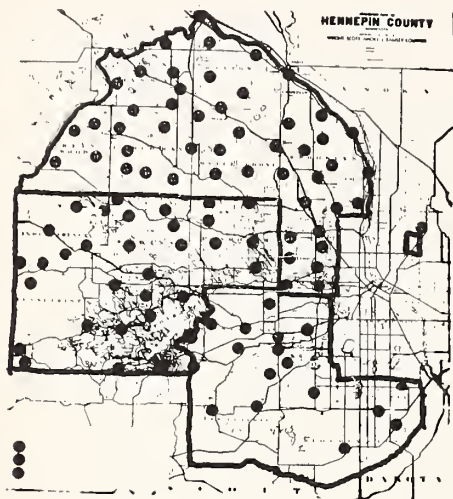

Fig. 1

To carry out the survey of the school child and his contacts, the county is divided into three parts and one part is tested each year. It takes three years, therefore, to cover the county and on the fourth year we begin all over again. The accompanying chart shows the division of the county and the location of survey centers (Fig. 1).

The work itself has two phases: (1) educational or publicity, which is directed by the Hennepin County Tuberculosis Association, and (2) medical, directed by the Sanatorium but including the private physician.

The Tuberculosis Association in its educational work contacts the schools and through talks before parent-teacher associations, letters signed by the County Superintendent of Schools, and personal work of the nurses, sells the idea of a school survey to the parents and the school employees. This publicity is very important because upon its effectiveness in securing signed cards of consent for the tuberculin skin test depends the success of the survey as far as it pertains to the number of children, school employees, and adult contacts studied.

This coöperative program was begun in rural Hennepin County in 1925. At first the positive reacting children and school employees were sent to the Sanatorium for their roentgenograms. But

by 1932 it had become apparent that this was not a satisfactory method and since then, with the approval of the Hennepin County Medical Society, we have been using a portable x-ray machine which can be set up in the schools. In approving the use of the portable x-ray machine, the Medical Society requested that the family physician be informed of any abnormality found. This we gladly agreed to do and since then we have been most careful in following out that agreement.

This is a very excellent arrangement because it enables us to take films of the household contacts at the same time with the positive reacting children and the school employees. The technicians who do this work have taken as many as 650 x-ray films in one day and can easily take about sixty an hour.

Table I shows that the publicity work has been carried out very effectively.

TABLE I. SURVEY WORK IN RURAL HENNEPIN COUNTY

	1935	1936	1937	1938	1939
Percentage of school children in district who were tested	82.7	54.3	82.8	92.2	84.9
Percentage of those tested who reacted positively....	24.4	24.4	23.3	18.1	21.6
Percentage of positive reactors who had x-ray films	94.0	64.5	95.0	97.1	94.1

With the exception of the year 1936, when a special situation occurred which will not repeat itself, we were able to secure consents for the tuberculin testing of from 82.7 to 92.2 per cent of the school children enrolled in the district surveyed. The percentage of positive reactors in the district varied from 18.1 to 24.4 per cent although in some of the one room schools there were no positive reactors.

We have often wondered why parents refused to have their children tuberculin tested. In investigating one such group we found that in every instance the State Board of Health had a record of tuberculosis in families with the same given name and surname of the parents and children as in our group. In some of the families our records included other children, born since the original record has been made. As the addresses of the families were different, the State Board of Health would not state definitely that these were the same families but it would seem quite a coincidence if they were not. It is logical to assume that when tuberculosis was diag-

nosed in these families, they moved into a new community where their neighbors would know nothing about it and because of this they refused to have their children tuberculin tested. Of course this may not be the sole reason why parents refuse to have their children tested but it may be one of the most important reasons.

The next step in the program is to take x-ray films of the positive reactors and during the years under consideration we were able to do this, again with the exception of 1936, in from 94 to 97 per cent of the positive reacting children (Table I). No x-ray films are taken of the younger children until they enter the teen age. Those in the teen age have a film taken yearly. How important this x-ray examination may be at times is illustrated by the story of I. K. who was the son of one of the bankers in rural Hennepin County. He was very active in the extra-curricular life of the school, played in the band, was on the basketball team, and seemed to enjoy life thoroughly. His tuberculin test was positive and as he was afraid that some of his pleasures might be curtailed if anything was found on the x-ray film, he refused to have this examination made. When he entered the University two years later he was roentgenographed along with the other freshmen and advanced disease was found. He was then admitted to the sanatorium and remained there almost seven years, but it was too late and he finally died. The delay in diagnosis cost him his life. This story is not unique; every sanatorium has duplications of this tragic record.

The forest ranger looks upon smoke in the forest as an indication of a fire. In the same way we look on the positive tuberculin reaction in a child as evidence that the child has been in contact with an open case of tuberculosis. Our problem, then, is to find this contact if possible. The child's contacts, who fortunately are rather limited, can be divided into two broad groups, school contacts and the household contacts.

(a) *School Contacts*.—Because of the community's interest in this program, and the excellent coöperation of the various boards of education, we have been able to tuberculin test or roentgenograph from 60.2 to 90 per cent of the school employees. I hope the time is not too far distant when public opinion will require of teachers annual evidence of freedom from tuberculosis as determined by a chest film before they

begin their work in the fall. I realize that contracts are signed in the spring and therefore my suggestion may create quite a problem, but I believe it can be solved.

(b) *Household Contacts*.—This group consists of any one, school child or other persons fifteen years of age or over living in the home. Aside from those in school and those who may be checked by their family physician our study of this group is limited to an x-ray and sputum examination if there is any sputum. The x-ray examination is made at the school at the same time that school employees and children are having films taken.

In spite of the fact that this x-ray service is furnished at the expense of the taxpayers and only requires one trip, we have been able to secure films on only from 47.5 to 69.5 per cent of this group. If it were not for the children over fifteen years of age who have films taken as part of the school survey, the percentage of household contacts examined by x-ray would be considerably less.

It is a curious commentary on human nature that people who are willing to have their cattle tested for tuberculosis apparently resent the suggestion that somebody in their household might be the cause of the infection of their child. This attitude is well illustrated by the story of a young girl who was over-weight for her age but whose tuberculin test was positive. The mother assured the nurse that she and her husband were both free from tuberculosis and could not be the source of infection. Upon further questioning the nurse found that the father had a cough. The mother thought it was due to the fact that he was an engineer and got very warm in the boiler room and then went outside to cool off. After much persuasion the father underwent x-ray examination and he was found to have moderately advanced tuberculosis. Prompt treatment in a sanatorium restored his health.

It seems to me that our next step should be to devise some means of securing better coöperation from this group of contacts. For various reasons this is most difficult at times.

The last group studied is that of the contacts of the known cases of tuberculosis who are reported to the State Board of Health (Table II). Our nurse calls on the physician, who made the original report, to offer the help of the sanatorium in having the household contacts of his

TABLE II. SURVEY WORK IN RURAL HENNEPIN COUNTY

	1935	1936	1937	1938	1939
Percentage of employees in schools surveyed who were tuberculin tested or roentgenographed	60.2	35.8	71.4	90.0	87.9
Percentage of adult household contacts tuberculin tested or roentgenographed			47.5	69.5	63.0
Percentage of household contacts of new cases reported to the Health Department tuberculin tested or roentgenographed			81.4	83.2	80.2

patient examined. He may want to examine them himself. If so, the nurse gives what assistance she can in persuading the other members of the household to go to his office for a check-up. If he wants us to examine them, we do so. Even though this study has been going on only three years, we have been able to tuberculin test or x-ray from 80.2 to 83.2 per cent of the household contacts of the known cases.

So far we have merely described our methods. Now for the results.

According to Tables III and IV, it is apparent that except for 1939, more cases of adult tuberculosis have been found by surveying the school child and his contacts, both in the home and in the school than have been found among the household contacts of the new cases of tuberculosis. In 1939, however, we found five cases of adult tuberculosis among the contacts of one known case (Table V).

These were all found in one family consisting of a father and mother and seven children who ranged in age from thirteen to twenty-three, one of whom, a twenty-three year old son, was found to have active tuberculosis. When the rest of the family was tuberculin tested, two of the children, a thirteen year old girl and a seventeen year old boy, were considered to have positive tuberculin tests. In both, the original x-ray examination was negative. It is still negative in the girl. But a lesion was demonstrated in the seventeen year old boy on a subsequent x-ray film. He is now a patient in the sanatorium.

The tuberculin test of the other four children, one boy and three girls, was considered negative and they were all told that because of the negative test they could not possibly have tuberculosis. The first x-ray film of the oldest one, a twenty-three year old girl, was negative and sub-

sequent films are still negative. In one of the remaining girls the original film was negative but subsequent ones showed evidence of tuberculosis. This girl is now a patient in the sanatorium. The original films of the remaining boy and girl were both considered positive. The boy is now a patient at the sanatorium. The girl is still at home even though her last film shows a spread.

While these four cases were discovered as a

EARLY DIAGNOSIS CAMPAIGN—MARIETTE

	Hemorrhage Dec. 29, 1938 Positive sputum	Admitted to Sanatorium July 23, 1939	Still at home	Hemorrhage Feb. 9, 1940		
	Admitted to Sanatorium Dec. 30, 1938			Admitted to Sanatorium Feb. 9, 1940		

result of a survey of the contacts of a known case of tuberculosis, it is within the realm of probability that they too could have been discovered as a result of the school survey if the parents had permitted us to tuberculin test the children when their school was surveyed. But the parents always told the nurse that there was no tuberculosis in their family and so refused to have the children tested.

The father's film is negative but the mother's shows scars of bilateral disease which is apparently inactive. She is the fifth case. Her history is interesting. She had what was thought to be pneumonia twenty-two years ago when her second child was about six months old. The nurse who cared for her at that time died of tuberculosis about a year and a half later. Also, about seventeen years ago a hired man died of tuberculosis within a year or two after leaving the farm. About thirteen years ago the mother's brother died of tuberculosis at the age of forty-two but his contact with the children was very casual and infrequent. Was the mother's pneumonia of twenty-two years ago tuberculous and has it left a long trail of infection and disease in this family? Was it responsible for the death

of the nurse, the hired man and possibly her brother?

The first x-ray films of some of the household contacts were interpreted as negative but disease was discovered in subsequent films. This illustrates the value of periodic x-ray examinations in following contacts.

Please do not misunderstand me. These statements concerning the finding of active tuberculosis when the original x-ray film was considered negative or in the presence of a tuberculin test which has been interpreted as negative are not made to disparage either x-ray examination or the tuberculin skin test. They are made for two reasons, one, to call your attention to the fact that because of variable human factors there is in my opinion no one test which is so infallible that when it is negative upon one application tuberculosis can be definitely ruled out. Also, I believe that the diagnosis of early tuberculosis should consist of far more than a bottle of tuberculin and an x-ray machine. It should include a thorough study of the individual in which all of the evidence is weighed. If there is anything to suggest tuberculosis, a thorough examination including a tuberculin skin test, an x-ray and a sputum examination, should be made.

TABLE VI.—TUBERCULOSIS MORTALITY FOR YOUNG MALES AND FEMALES

Registration States of 1900, 1900-1935 (Nicholson)

Year	15-19 years			20-24 years		
	Rate per 100,000 pop.		Excess of Female over Male Rate	Rate per 100,000 pop.		Excess of Female over Male Rate
	Male	Female		Male	Female	
1900	124.1	177.7	43%	249.7	265.8	6%
1910	111.1	133.0	20%	190.9	204.0	7%
1920	79.0	131.6	67%	137.9	179.4	30%
1930	37.4	67.3	80%	76.6	103.6	35%
1935	24.2	44.1	82%	53.8	76.2	41%

My second reason is to call your attention to the fact that in all crusades, and the battle against tuberculosis is a crusade, the pendulum always swings too far. Witness the first surge of building preventoria. One state went so far as to build preventoria for children who were considered to be predisposed to tuberculosis if they happened to be fifteen per cent underweight, while it did not have enough beds to care for all of the open cases. Now the correction has set in and some want to abolish preventoria altogether. In time we will find the proper balance. Because of the tendency to over-correct, we have not closed our preventorium. So too the pendulum has swung too far in the tuberculin studies. In time that will be correctly appraised and it will become generally recognized that active tuberculosis can exist in people who are in fairly good condition in spite of the fact that the tuberculin test is negative.

It is the accepted belief that more tuberculosis can be discovered through a study of the contacts of the known cases than through a study of the contacts of the positive reacting school child. Our studies do not support this belief. I have no explanation to offer as to why more tuberculosis was found as a result of the school survey unless it be that we are dealing with families in a mixed rural and village community. If these families have school children in contact with open cases of tuberculosis, these children should lead us to the open case of tuberculosis before he becomes sick enough to consult a physician.

One group not yet included in our study is that of the industrial worker. It is very probable

that surveying the industrial contacts of known cases of tuberculosis may be more productive of new cases than the contacts of the school child.

The early diagnosis of tuberculosis among adolescents is very important and warrants a special study.

According to Table VI it is apparent that the death rate among girls is higher than among boys. Some have attributed this difference to the dietary fad which girls adopt to attain that ideal figure and to their ideas of modern dress. But this condition has existed since 1860 in England and Wales and since 1900 in this country, and present-day ideas of dress and diet did not prevail then. Therefore, these cannot be the primary cause of this condition. It must be something else and the logical conclusion is that it is due to biological factors.

While biological factors might be the cause for the slight excess in the death rate for girls as compared with boys for 1900 and 1910, they could not account for the sharp jump in the excess death rate for girls between 1910 and 1920 and from then on. One explanation is that in this decade following the World War more women went into industry and tried to compete with men in their manner of life and work. Whether that represents cause and effect or merely coincidence, one cannot tell.

Figure 2 compares the death rate according to sex and age. From fifteen to thirty-five the death rate for females is higher than for the males with the peak occurring in the five year period between twenty and twenty-four years of age.

This coincides with the period of woman's greatest fertility and after that the death rate declines rather markedly. At fifty it begins to rise. The death rate for males reaches its peak in the seventy to seventy-four years of age period. From about eighty years on, both the males and females have approximately the same death rate.

In a report summarizing the results of treatment of the teen age individuals, Chadwick quotes Morgan who summarized the condition in 1938 of 320 children ten to eighteen years of age who had been treated at the Westfield State Sanatorium between 1920 and 1938. He reports that of this group, 62 per cent are dead, 14 per cent under treatment, and 17 per cent are well,

and only 7 per cent could not be located. The treatment used generally was prolonged bed rest supplemented by an occasional pneumothorax.

Chadwick also referred to a series of 55 boys

which, as far as tuberculosis is concerned, centers about contagious technique to prevent or reduce the massiveness of infection, and frequent x-ray examinations to detect tuberculosis before it has had a chance to develop very far.

But there is no unanimity of opinion as to what constitutes adequate contagious technic for acute disease hospitals let alone for the tuberculosis hospitals. Certainly if contagious technic alone is adequate then we should be able to agree on the type of technic which will best prevent transmission of infection from patient to nurse. But from studies made at different hospitals where different types of technic are used, it is apparent that the more elaborate technic is no more effective than the less elaborate technique. No technic that I have heard of is "foolproof." Therefore, some other means should be found to give the nurse added protection. If so, what more is there to do unless it be vaccination?

In that connection, evidence is gradually accumulating to indicate that a tuberculin positive nurse develops tuberculosis much less frequently and much less severely during training than does the nurse who was tuberculin negative when she began her training.

That raises the question—why is the tuberculin negative nurse not vaccinated with B.C.G. and thus made tuberculin positive with a non-virulent strain of tubercle bacilli? If this were done she would receive the same type of protection to enable her to care for the tuberculous that the non-immune nurse receives before she cares for other communicable diseases.

Some claim that not enough is known about the safety and the efficacy of B.C.G. to warrant its use. But evidence is also gradually accumulating to indicate that the tuberculin negative nurse who becomes tuberculin positive after vaccination with B.C.G. has almost as much immunity as the nurse who was tuberculin positive at the beginning of training. Furthermore, numerous investigators report that B.C.G. is safe. For instance, Kayne, in 1936, stated that if all the reports of disease which occurred in the 1,343,000 infants vaccinated with B.C.G. could be proved due to the vaccination, the ratio of tuberculous deaths would be less than one in 15,000.

In 1938 Asfora and Livramento of Brazil analyzed the reports of vaccination with B.C.G. and concluded that it is safe in that the morbidity and mortality rates are about one-third

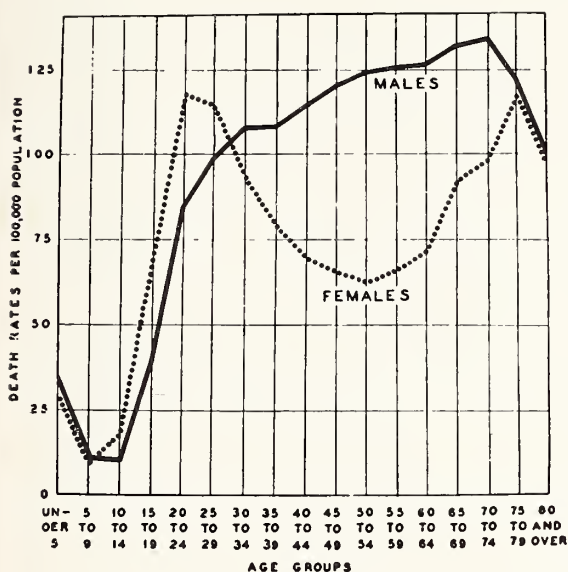

Fig. 2

and 131 girls reported by Zachs. Of the group that received routine sanatorium treatment, 30.9 per cent of the boys were dead and 34.4 per cent of the girls. However, in the group that received collapse therapy in addition to routine treatment, only 8.5 per cent of the boys were dead and 23.1 per cent of the girls.

Chadwick in a similar study at the Middlesex County Sanatorium covering a five to ten year period where 50 per cent of the group received pneumothorax, reported that 4.8 per cent of the boys were dead and 21.7 per cent of the girls.

This would also indicate that the problem is greater among the girls than it is among the boys and would suggest that the high schools might be a very fertile place for an intensive early diagnosis campaign.

Another group where the early diagnosis of tuberculosis is important is that of the sanatorium hospital personnel, particularly those who come in close contact with the patients.

Because of the greater exposure to tuberculosis and infections in general which accompany close contact with the sick person, it is imperative that whatever disease may develop in this group should be detected early.

To that end many hospitals have set up planned health services for their employees

as great in the vaccinated group as in the non-vaccinated group. Because of that he concludes that vaccination with B.C.G. is one of the strongest weapons in the battle against tuberculosis.

Thus, an impartial analysis of the literature gives rather good evidence of the protection afforded by a positive tuberculin reaction whether acquired naturally or as a result of vaccination with B.C.G. This analysis also indicates that B.C.G. is safe.

In spite of this, hospital authorities seem to consider that contagious technic will afford the tuberculin negative nurse all the protection she needs in the prevention of disease as a result of spread of infection from patient to nurse. Yet in all other communicable diseases the hospital authorities consider that contagious technic alone is inadequate and insist that the non-immune nurse be vaccinated or immunized before beginning this service. If contagious technique alone does not afford adequate protection for the non-immune nurse in the care of smallpox or scarlet fever, why should it be considered sufficient to protect the tuberculin negative nurse in the care of tuberculosis?

The converse is also true. If immunization afforded the nurse all the protection she needed against infection which was transmitted from patient to nurse, then there would be no need of her using contagious technic. Her vaccination would render her immune even to massive infection. But we know that if the dose of infection is great enough, it can break down any resistance which may have developed as a result of immunization against any communicable disease.

Thus, because neither contagious technic alone, nor vaccination or immunization alone gives the nurse adequate protection in the care of these diseases, hospital authorities insist that the nurse combine vaccination or immunization with contagious technic. What right have we to expect more protection from the use of contagious technic in the care of tuberculosis than in the care of other communicable diseases?

If vaccination with B.C.G. does nothing else, it produces a primary infection with an organism of low virulence so that the hematogenous spreads associated with massive primary infections which appear later as lesions of extrapulmonary tuberculosis would be avoided. But

from the evidence found in literature I am convinced it does far more than that.

Therefore, I look forward to the day when the hospitals in the United States will adopt the policy so prevalent throughout Norway, Sweden and Denmark where all of the tuberculin negative nurses and other hospital employees are vaccinated with B.C.G.

In this way, we can give the tuberculin negative nurse who is caring for tuberculous patients the same type of perfection that the non-immune nurse has in the care of other communicable diseases, namely, vaccination or immunization plus contagious technic.

In closing, I want to sound a note of encouragement and of warning. Encouragement in that tuberculosis is declining throughout the entire world more rapidly some places than others but still the trend is downward. Warning that we do not become too complacent and too self-satisfied over this decline. With the reduction in tuberculosis which must accompany such a reduction in the death rate, it will become more difficult to find the unknown case and find it we must for, in the words of Dr. Stewart, "The unknown case is dangerous." Thus, the importance of the early diagnosis campaign increases.

We must sharpen our tools or find new ones for the tremendous task which still remains to be done. In 1940 in the United States about 70,000 people will die from tuberculosis and about 500,000 or enough to populate a city about the size of Milwaukee will be made ill by it. So you see there is a great deal to do before we can rest secure in our belief that tuberculosis has been controlled.

We think our future efforts should center about the following: (1) an intelligent education of the public; (2) a thorough search for the open case of tuberculosis who may be infecting others; (3) securing adequate sanatorium facilities in communities which lack them; and (4) vaccination with B.C.G. of nurses, doctors, and other hospital personnel who come in intimate contact with known or unknown cases of tuberculosis and thus are unavoidably exposed to tuberculosis in their line of duty.

Education should be directed towards training the public consciousness to consider health a positive and priceless possession to be safeguarded through constant alertness. If that day ever

HISTORY OF MEDICINE IN MINNESOTA

HISTORY OF MEDICINE IN WINONA COUNTY

(Continued from June issue)

Biographies

Mrs. Lou Finch practiced as a physician at Winona City. She came in 1872 and boarded at the Riverside Hotel.

John D. Ford was born at Cornish, New Hampshire, April 18, 1816. He graduated at Dartmouth College, and subsequently from the Jefferson Medical College (1844). Soon afterward, he commenced the practice of medicine at Norwich, Connecticut. While a resident of Norwich he was interested in the educational institutions of that city, and labored earnestly in behalf of its common schools. After a successful practice of about eleven years, he was compelled to seek a climate more congenial to his health, and came to Winona in 1856. His practice was extensive. After May, 1862, he associated himself with Dr. F. Staples. Dr. Ford gave up his practice not long after that, because of poor health. In 1859 he had become the agent for the Norwich Fire Insurance Company of Norwich, Connecticut, and later he was the agent of several other eastern insurance companies. He established extensive relations between these companies and the citizens of Minnesota.

Dr. Ford held several public offices during his stay in Winona. He was elected alderman in March, 1857. In November of the same year, he is mentioned as chairman of the trustees of the school districts, and retained the office in 1858. In March, 1860, Dr. Ford was elected one of the directors of the State Normal School. Three years later, he was appointed school examiner for the second district by the Board of County Commissioners. In the same year he became government pension surgeon for Winona.

Dr. Ford died in Winona of typhoid pneumonia on November 5, 1867. He may well be considered a pioneer in the interest of the common school system of the city and state. His son, Guy Stanton Ford, is President of the University of Minnesota.

George L. Gates, M.D., was born in Harwington, Litchfield County, Connecticut, December 4, 1837. In early life he was taken to Cortland, New York, where he received his academic education and then studied medicine in a physician's office. In the spring of 1855 he came with his family to Saratoga township in Winona County. He remained on the home farm until the outbreak of the Civil War. He enlisted in the volunteer infantry in 1861. During the last months of his three-year service, he was an assistant in the ambulance corps. After returning to Saratoga for a few years, he entered the medical department of the University of Pennsylvania in 1869. He then spent two years in practice with his cousin, Dr. H. A. Balles, at Cortland, New York. In 1872 he opened an office in Caledonia, Houston County, Minnesota. In 1880 he came to Winona where he prac-

ticed for many years. He became a member of the county, state, and American Medical Associations, and belonged to several fraternal orders in Winona. Dr. Gates practiced under the exemption law.

Charles M. Gernes came to Winona in 1878, or before. He was a Hollander. Judging from available reports, Dr. Gernes did not practice medicine in Winona, but engaged in farming and the grain business. He had a farm near Saint Charles in 1878 but did not live there.

J. Gilchrist, M.D., homeopathic physician, opened an office and started practice in Winona in 1860. His card published in 1866 read:

J. GILCHRIST, M.D.

Homeopathic Physician (Late surgeon to Phila.
College Dispensary). Office hrs. 7 to 9 A.M.—
1 to 2—5 to 7 P. M. Office in the brick bldg. on
3rd st. below Huffs Hotel.

(See Steele County)

O. F. Gile, physician, practiced at Pickwick in 1878-1879. Later, between 1883-1890 he practiced at Dakota. Dr. Gile had an exemption certificate.

Arnold P. Gilmore came to Winona soon after his graduation from the Jefferson Medical College in 1874. During his stay in Winona, he was an instructor at the Winona Preparatory Medical School. In 1876 he became a member of the Winona County Medical Society, and in 1878, a member of the State Medical Society. He was considered a highly educated and skilled physician, and made a specialty of diseases of the eye, ear, and throat. In 1879 he moved to Chicago.

A. Gray was a doctor at Utica. He died in 1863.

H. C. Grover graduated at the University of Iowa in 1855. In 1881 he was practicing at Rushford. Later, he became a member of the Winona County Medical Society.

H. H. Guthrie graduated from Rush Medical College, Chicago, in 1863. He came to Saint Charles about 1868. He was a charter member of the Winona County Medical Society organized the next year. Later, in 1878, he became president of that society. In 1870, Dr. Guthrie was elected to membership in the State Medical Society. He was the first president of the library association organized at Saint Charles in December, 1871, and again held that office in 1879. Dr. Guthrie engaged in the drug business with Tamblin in 1869, and again with a man named Smith as a partner in 1873, and probably continued in that business until his departure in 1881. At that time he moved to California. It is interesting to note that Guthrie read a paper on "Indigenous Remedies" before the Winona County Medical Society in 1874.

B. Hahn came to Winona in November, 1869, and published the following card:

DR. B. HAHN
(Late Surgeon, U.S.A.)
German Physician

Medical and Surgical Office, Third Street opposite
N. H. Wood's Store.
Residence—Sixth Street, between Lafayette and
Walnut.

T. E. Hall was a doctor in Dresbach in 1883.

E. W. Hammes graduated from Rush Medical College in 1882. He lived at New Trier until he moved to Winona in 1884 or 1885. Dr. Hammes became a member of the Minnesota State Medical Society in 1883. He remained in Winona for several years and then moved to Hampton.

E. A. Hebard, M.D., came to Winona in April, 1862, and associated himself with Dr. A. S. Ferris. He later succeeded to Dr. Ferris's practice. In 1879 he moved to Grand Rapids, Michigan.

N. F. Hilbert was a doctor at Rollingstone in 1882.

A. T. E. Hilton resided in Winona for a year or two about 1865-1866. He died at East Orange, N. J., in January, 1884, at the age of seventy.

Jens Hohn was a Winona doctor in 1863.

Holeman S. Humphrey came to Winona in 1866. His first advertisement read:

"A cure guaranteed in every case of piles treated and no money required until the cure is effected." In May, 1876, he opened a surgical institute in a building on which he had a five-year lease. He had several assistants and treated all manner of surgical cases and constitutional diseases. In 1878, he started the New Turkish Bath and Surgical Institute, with a ten-year lease on his new building. His business met with unusual success in Winona. He sold his establishment in August, 1880, and moved to Janesville, Wisconsin.

Dr. Ireland practiced medicine at Beaver in 1857. He may also have lived at Elba.

I. P. Jones practiced at Dresbach at some time between 1883 and 1890. He had an exemption certificate.

W. C. Jones was one of the early settlers of Winona and proprietor of the Minnesota House (at Winona) in 1854. He did not practice medicine there. In 1881 he was living near Rock Island, Illinois.

C. R. J. Kellam came to Saint Charles with his family and started practice in the spring of 1876. He came from Lynn, Massachusetts, and was a graduate of Harvard Medical School. He published a half column in the *Saint Charles Union* the following spring, a treatise against the practice of advertising by medical men. During most of his stay in Saint Charles, Dr. Kellam kept an accurate thermometrical record of the weather. He died in that village in March, 1879.

Linn A. Kelly, M.D., was born in Schenectady, New York, May 18, 1845, and was brought to Elgin, Illinois, when a small boy. He attended the grade schools there, then studied at Galesburg, Illinois, and at Beloit College, Beloit, Wisconsin. He entered the Eclectic Medical Institution at Cincinnati and finished his medical education at the Bennett Medical College of Chicago, graduating from that institution in 1869. He at once started prac-

tice at Peoria, Illinois. After a short time, he went to Elgin and practiced there until he came to Winona in 1872. His physician's card read as follows:

DR. L. A. KELLY
Physician and Surgeon
County or City calls attended day
or night promptly

Dr. Kelly was city physician of Winona for two years in 1881-1882. He was president of the Winona Board of Education for one year, and a member for several years. He was also a member of the Eclectic Association of Minnesota, and was on the State Board of Pension Examiners. He died in Winona in 1910.

Edward D. Keyes was born and raised in Winona. He received his early education there, and at the age of twenty-two became the student and office boy of Dr. Franklin Staples. In the fall of 1883 he entered Rush Medical College. He graduated from that institution in February, 1885, and on March 1 of that year, started practice in Winona with Dr. Staples. Later, he became one of the prominent physicians of that locality. In the year he started practicing, Dr. Keyes was elected to membership in the Winona County Medical Society and in the State Medical Society. His son, John Dwight Keyes, was later associated with him.

Dennis Kimberly, M.D., practiced in Winona in 1863.

R. C. Kirk was a Winona doctor. He left that town in July, 1858.

D. A. Knapp arrived in Saint Charles from Maine in 1883 and succeeded to the practice of Dr. W. A. Chamberlain. Soon after that, he moved to New Richmond, Wisconsin. Dr. Knapp may have practiced in Winona County at an earlier date, about 1864.

N. S. Lane came to Winona about 1877 and was still practicing his profession there in 1931.

Oswald Leicht graduated from the Medical School of Northwestern University in 1898 and came to Winona to practice the same year.

Ferdinand Lessing graduated from the University of Pennsylvania in 1868. In 1871, while practicing in Wabasha, he became a member of the State Medical Society. He came to Winona City about 1875, and in that year he was elected to membership in the Winona County Medical Society. He was one of the instructors in the Winona Preparatory Medical School about the same time. Dr. Lessing was an active Democrat, and was elected County Coroner in 1876, holding the office for several years thereafter.

Hans Moritz Lichenstein was born in Germany in 1866. He graduated from the University of Tübingen in 1890 and came to Winona the following year.

Dr. Lozier was a Winona doctor about 1867.

H. Mager, M.D., opened an office in Winona in July, 1881. He was "formerly from Milwaukee, but latterly from Europe." Two months after his arrival, he moved to Le Sueur, Minnesota.

J. B. Maitland may have practiced in Winona County in 1857.

Jacob Marti was a Winona physician in 1866. He still practiced there in 1885.

R. C. Mason came to reside in Winona permanently in December, 1885.

M. M. Mead came to Winona about 1858 and practiced there until he received the appointment of Assistant Surgeon to the First Minnesota Heavy Artillery in January, 1865. He returned from service in poor health nine months later, and again took up his practice. In August, 1871, he left Winona to engage in practice elsewhere.

Dr. McCartney practiced in Winona County in 1879.

Thomas McDavitt, M.D., graduated from the Chicago Medical College in 1879. He came to Winona to practice about 1881, having practiced medicine at Minneiska for eighteen months. Originally he was from Quincy, Illinois. In May, 1881, he and Dr. J. B. McGaughey experimented on a device to rid the county of wolves by means of chloroform. Apparently the device was not a success. During the year 1882 he was elected to membership in the State Medical Society and in the Winona County Medical Society. He became president of the latter society in 1883. In 1883, he and Dr. McGaughey had offices together as partners. At a later date he moved to Saint Paul. At the time of his death, he was a trustee of the American Medical Association.

Hugh F. McGaughey was the son of Dr. J. B. McGaughey and was born in Winona in 1873. He was educated at the University of Michigan and received his medical degree from The College of Physicians and Surgeons of New York in 1896. He began his medical career in Winona in that year. He was a man of unusual ability and successfully carried on the traditions of his father. He died suddenly in Tacoma, Washington, on July 20, 1919.

James Brown McGaughey, M.D., was born near Gettysburg, Pennsylvania, December 1, 1842. In 1849, his father who was a railroad contractor and builder brought the family by wagon train to McDonough County, Illinois, and settled on a farm. It was there that James McGaughey received his early education in private and public schools and in the McDonough Presbyterian College. In January, 1862, he enlisted as a private in the Tenth Missouri Infantry, U.S.V. The following year he became hospital steward of the First Alabama Cavalry, U.S.V. Later he received an appointment in the secret service and was very successful in enlisting Union men within the rebel lines. Soon after receiving the commission of second lieutenant of Company H, First Alabama Cavalry, he was captured and taken to Libby Prison. While in the hospital service and at other times during his busy army life, he found time to follow his bent for medical studies, his reading being guided by his brother-in-law, Dr. A. B. Stuart. After the war, he attended Berkshire Medical College, at Pittsfield, Massachusetts, and subsequently completed his course in the medical department of the University of Michigan. He received the degree of M.D. in March, 1867. The following month, he came to Winona and entered on forty-one years of continuous practice. Dr. McGaughey became a successful physician and surgeon, and was reputed an authoritative diagnostician. His work was characteristic-

ally progressive as he made frequent trips to the best hospital clinics and was a tireless reader of professional literature. He came to Winona to practice with Dr. A. B. Stuart. Later he had as his partners Dr. A. B. Young, Dr. Thomas McDavitt, Dr. D. B. Pritchard, and his son, Dr. Hugh F. McGaughey. He was for seven years a member of the firm of the Associated Physicians and Surgeons.

Dr. McGaughey had an amazing number of organization affiliations. He was one of the organizers of the Winona County Medical Society, and its secretary from 1873 to 1908. He was also one of the founders of the Southern Minnesota Medical Association, and was its president in 1894. In 1869, he was elected to membership in the State Medical Association, and held the office of president in 1884-1885. He held a membership for many years in the Minnesota Academy of Medicine. He joined the American Medical Association in 1872, and was several times a delegate to the national conventions.

Dr. McGaughey took an active part in educational matters. For ten years he was a member of the Board of Education, its president twice—in 1878 and again later. For several years he was an instructor in the Winona Preparatory Medical School.

Among his public offices, Dr. McGaughey held that of County Coroner in 1872 and 1873. In 1876-1878 he was county physician in Winona.

Numerous other organizations claimed his attention. He was one of the founders and served as president of the Winona Building and Loan Association. He had a membership in the Masonic Order, in the Board of Trade, in the Arlington Club, of which he was once president, and in John Ball Post, G.A.R., of which he once served as commander and for many years as post surgeon.

In later life Dr. McGaughey served on the State Board of Medical Examiners and on the State Board of Health. He was a delegate selected by the governor to the International Congress of Tuberculosis which met in Washington, D. C. He was one of the original members of the Board of United States Examining Surgeons for Pensions in Winona and was secretary continuously from its organization until his death.

Among his reports and papers are: "The Purity and Proper Preparation of Medicine" given before the Winona County Medical Society in 1871, and a paper on "Cholera Infantum" given before the same society in 1874. In 1878 he made a report to the State Medical Society on venereal diseases, and the following year he gave the report of the Committee on the Nervous System. In 1882 before the same society, he gave the report of the Committee on Surgery. In 1885 several essays by him entitled "Fracture of the Internal Condyle of the Humerus," "Femoral Hernia—Sloughing—Death," and "Compound Fracture of the Fore-arm" were published with the Report of the Committee on Surgery. Dr. McGaughey died in Winona in 1908.

(To be continued in August issue)

President's Letter

It is repeatedly emphasized by authorities that many more cancers could be cured than are now cured if patients could be treated early.

This truth is accepted by most of us as self-evident and we have all been irked by the seeming slowness of our educational efforts directed toward bringing the cancer patient in for examination in the curable stage.

For that reason most physicians welcome the aid in this work of education offered by the Women's Field Army Against Cancer.

Every effort has been made by this organization of women to keep its educational matter and its methods under qualified medical direction. Physicians serve on its executive committee and as speakers, advisors and aids.

Competent women head the Minnesota organization, women who have the entrée to all major women's organizations and movements, and who have given satisfactory evidence, over several years of campaigning in Minnesota, of their genuine wish to work closely with physicians and to disseminate only authoritative information under ethical auspices.

That the majority of the members of the Minnesota State Medical Association are wholeheartedly in accord with the work of the organization is amply evident in the results of a questionnaire sent to all members with the last NEWS LETTER from the state office. More than 95 per cent of the approximately 300 replies already received from all parts of the state approve the Field Army and its objective. Many greet it with enthusiasm. Others regret that the effects of its work have not yet reached out to a large number of rural districts of the state. They approve the principle, however, and declare their belief in public education as a powerful weapon in the fight against cancer.

The handful who disagree, object to any campaign of cancer education on the ground that it is likely to create cancer phobia and that this danger outweighs the good that may be done.

In view of the testimony of the overwhelming majority, however, it may be taken for granted that Minnesota physicians in general are heart and soul behind this effort of the women to bridge by education the gap between the early symptoms and their discovery and treatment. The Council has repeatedly endorsed the work of the Field Army and it should be a part of the professional duty of every member to coöperate in this work.

B. S. ADAMS, M.D., President,
Minnesota State Medical Association.

Volume 23 JULY, 1940 Number 7

THE 1940 A. M. A. SESSION

THE meeting of the American Medical Association in New York City last month was a success from every angle. It was the largest in history, 12,864 physicians having registered. Those who attended were impressed by the quality and number of the scientific exhibits which have come to rank with graduate training.

The House of Delegates with its representatives from state associations, army and navy, the public health service, outlying possessions and scientific sections, is the governing body of one of the few democratic organizations left in the world. That the importance of being a delegate is realized is attested by 171 of the 175 membership having attended.

The keynote of the meeting of the House of Delegates was the importance of preparedness of the medical profession in case of war. Its action in appointing a committee of ten of its members and five association officials to take steps to canvass state and county organizations to obtain the names of those willing to serve, is characteristic of American physicians in placing national issues first.

The Delegates chose Dr. Chevalier Jackson of Philadelphia the recipient of the annual distinguished service award. Of interest to Minnesota physicians was the high tribute paid the late Dr. Charles B. Wright of Minneapolis by the chairman of the Board of Trustees. Also of special interest was the election of Dr. William Braasch of Rochester as a member of the Board of Trustees to take Dr. Wright's place.

The question again arose as to the best way for the profession to take care of its needy members and it was the general sentiment that each state should care for its own needy members.

The rather fantastic resolution that the entire population be submitted to blood typing and Wassermann testing was voted down. The bill reported to have been introduced in the United States Senate to have a National Doctors' Day was not endorsed. Really, has the senate nothing more important to do?

Medical economics came in for its share of discussion. It was recommended to leave the question of fees to local county societies; that group hospitalization plans be kept separate from medical pre-payment plans; also that any of the latter plans be submitted to the American Medical Association Bureau of Medical Economics for approval.

Anesthesia has come into its own. This struggling specialty was dignified by the Delegates by the creation of a scientific section of its own.

As the officers of the American Medical Association serve from annual meeting to annual meeting, Dr. Rock Sleyster retires. Dr. Nathan B. Van Etten became president and Dr. Frank

H. Lahey is the president-elect. Next year the convention will be held in Cleveland; in 1942 in Atlantic City; and in 1943 in San Francisco.

MEDICAL PREPAREDNESS

THE inaction following the destruction of Poland made it appear that World War II was resolving into an economic struggle. The fast and furious events of the recent two months, however, have made the world realize that a megalomaniac dictator has obtained domination over Europe, aided and abetted by an equally unprincipled dictator who has brought upon himself contempt of the world.

Of a sudden we Americans have come to realize that we are not sufficiently armed to maintain the Monroe Doctrine, and perhaps not even to defend our own shores—without the help of the English navy.

This sudden realization of our unpreparedness has swept like a wave over the country. Preparedness for modern warfare is more involved than it used to be and requires more time not only for the training of personnel, but in the production of machine equipment.

In case of war there will be the same need for the services of the medical profession. That the profession does not propose to be caught napping is evidenced by the steps taken last month at the American Medical Association meeting in New York City. A resolution was submitted to the House of Delegates by the Board of Trustees through its chairman for the establishment of a Committee on Medical Preparedness to carry out certain preliminary steps in the naming and classification of physicians available for military duties, and to cooperate with the War Department. Such a committee, consisting of ten members of the House of Delegates and five officers of the American Medical Association has already been appointed by the Speaker of the House and will work through state and county medical organization. A section in the *Journal of the American Medical Association* has already been established for publicizing the activities of the committee.

In case of war civilian population as well as the army will need medical services and the designation as to where a physician will be most useful can be better made with deliberate plan-

ning than in a hurry following the declaration of war.

In our last war the services of some 60,000 physicians were made available for military and related activities. Many entered the service who should have stayed at home, and vice versa. Such mistakes can be prevented by preliminary planning. That there will be fully as great a patriotic response in case of need in the near future as there was twenty-three years ago goes without saying. Patriotism can, however, be displayed by coöperation in this preparedness campaign as well as in actual war.

A DIABETIC MANUAL

IN SPITE of advances in our knowledge of the dietary treatment of diabetes and in spite of the discovery of insulin the incidence and mortality of the disease have been on the increase the past two decades. On the other hand properly treated diabetics live much longer than they used to. The conclusion seems deductible that diabetics are not receiving proper care. This may be the fault of the diabetic patients themselves, the medical profession, or both.

Constant dieting is a chore and it is not surprising perhaps that many diabetic patients weary of dieting and reporting regularly to their physicians.

The profession, too, is doubtless to blame to some extent in not having impressed on his diabetic patients the importance of control of symptoms. Dietary instructions have been at times so complicated that patients have thrown up their hands in disgust. Or diets have been so far removed from normal in carbohydrate and fat content that they have proven disagreeable to the patient.

Further, there is no disease the treatment of which has undergone more changes during the past two decades than has that of diabetes. This has made it difficult for the internist to say nothing of the general practitioner to keep abreast of developments without special effort.

Realizing the growing importance of diabetes as a cause of morbidity and mortality a Committee on Diabetes of the Minnesota State Medical Association was appointed several years ago. To help the physician take better care of his diabetic patients this Committee has issued

(Continued on Page 494)

In Memoriam

Arthur West Allen

Dr. Arthur W. Allen, Austin, Minnesota, died on May 6, 1940.

Dr. Allen was born in Austin in August, 1862, the son of Dr. Orlenger Allen, who was the first doctor in Austin, having located there in 1856.

Dr. Allen obtained his medical degree from Rush Medical College in 1885 and returned to Austin to practice. On September 14, 1905, he was married to Miss Nellie Sutherland of Austin, who survives him.

Although Dr. Allen never sought nor held political office, he was always interested in civic enterprises and was active in politics in former years as a Republican. Before the Panama Canal was built he accompanied a congressional committee on a visit there as a guest.

Dr. Allen was a member of the Mower County Medical Society, the Minnesota State and American Medical Associations and for years a surgeon for the Chicago, Milwaukee and Saint Paul Railway. He was a member of the American Railway Surgeons, a Mason and an Elk. In fact he was one of the few surviving charter members of the Austin Lodge of Elks. For a number of years he was a surgeon in the National Guard.

Olav Nelson Birkland

Dr. Olav Nelson Birkland was born in Bergen, Norway, August 17, 1887. As a boy he continued his education in Edinburgh, Scotland, and afterward came to America. He attended the Red Wing Seminary. After attending the Universities of Minnesota and Wisconsin he obtained his Bachelor of Arts degree May 29, 1913. He graduated from the Medical School of Northwestern University in June, 1917, and spent one year studying at the Chicago Lying-in Hospital in Chicago.

Dr. Birkland was a member of the Phi Beta Pi fraternity, the St. Louis County Medical Society, and was a member of the Rood Hospital staff of Hibbing, Minnesota for twenty-one years. He died on February 2, 1940, of coronary disease.

Arthur Stephen Hamilton

Dr. Arthur Stephen Hamilton was born on November 28, 1872, in Wyoming, Iowa, and died on June 2, 1940, at his home in Minneapolis. On January 13, 1935, he was stricken with a cerebral hemorrhage and was confined to his home up to the time of death.

He obtained his B.S. degree from the University of Iowa in 1893, and his M.D. degree from the University of Pennsylvania in 1897. He interned at the Post-Graduate Hospital in Philadelphia and then became Assistant Physician at the Independence State Hospital, Independence, Iowa, which position he held until 1904 when he came to Minneapolis.

He founded the Department of Neuropathology at the University of Minnesota, and subsequently was made Professor of Nervous and Mental Diseases and Chief of the Division, at the Medical School, and served in that capacity until the onset of his illness in 1935.

Dr. Hamilton was one of the founders of the Minnesota Society of Neurology and Psychiatry; a member and past president of the Minnesota Academy of Medicine; a member of the Minnesota State Medical Association; and a member and past president of the Hennepin County Medical Society.

He was a member of the American Medical Association and an ex-chairman of the Section of Nervous and Mental Diseases. He was one of the founders and a past president of the Central Neuropsychiatric Association. He held membership in the American Neurological Society, the American Psychiatric Association, and the Chicago Neurological Society.

During the World War Dr. Hamilton was a major in the medical corps from May of 1918 until August of 1919. He was a member of Phi Delta Theta academic fraternity and of Nu Sigma Nu medical fraternity.

Dr. Hamilton was an outstanding leader and teacher in the field of nervous and mental diseases and was widely known by the profession because of his activities in this field. He was a man with a very affable disposition, and always showed a tenderness in his heart toward everyone. He exhibited an untiring patience in everything that he attempted. At the time he was stricken, he was working very diligently, preparing a History of Medicine in Minnesota.

Dr. Hamilton is survived by his wife, Susanna P. Hamilton, and one son, David A. Hamilton.

John Snell Holbrook

John Snell Holbrook has gone to his final reward. He leaves a memory of honesty, dignity, faithfulness, in their truest meaning—as a man, physician, and friend—to all who knew him.

Born at Arkansaw, Wisconsin, December 17, 1873, he learned in childhood to watch his father, who was a lumberman, at work—and later that became his hobby. He would try out methods of bone union at his lathe, when he wasn't shaping toys and tables and "what-nots" for his children and friends.

Dr. Holbrook attended high school in Northfield, Minnesota, and studied at Carleton College. At Northfield he also met and married his wife, Mary Amaline Whiting, beginning the family life, to which he constantly devoted himself with loving, tender sacrifice. Graduating from the University of Minnesota Medical School in 1896, he served his internship at St. Mary's Hospital in Minneapolis. In 1897 he be-

came associated for several years with Dr. J. W. Andrews, at Mankato, and practiced in Mankato until his death on June 8, 1940.

He was married in 1900. His widow and two of their three daughters survive him. Mrs. Charles Rickert, who was Louise Holbrook, died a few years ago. Surviving are Mrs. Loren Hurd of Philadelphia (Eleanor) and Mrs. Reid Mohn of Red Wing (Mary), and several grandchildren.

Dr. Holbrook was justly proud of the records made in the regular U. S. Army by two of his brothers. One, Major General Willard A. Holbrook, was Chief of Staff of Cavalry, U. S. A. Major General LeRoy Holbrook is now retired, resident in Idaho. Another brother, B. F. Holbrook, lives in Minneapolis.

The First Baptist Church of Mankato claimed Dr. Holbrook's loyal membership for many years. He was also a Kiwanian and a York Rite Mason and Knight Templar.

In January, 1916, he, with Dr. A. E. Sohmer and Dr. Lida Osborn, formed the first Clinic in Mankato, which is now in its twenty-fifth year. He dearly loved the work of the Clinic, because of the opportunities that it offered for mutual consultations and discussions with his colleagues, and for the friendships of a real medical family.

A student in his profession, he kept in contact with other Clinics and attended medical meetings faithfully. In the past twenty-five years his work was limited to surgery, and especially, orthopedics. He became a Fellow of the American College of Surgeons, and was a former president of the Southern Minnesota Medical Association. In organized medicine he began as a member of The Blue Earth County Society, of which was a president, and then held Minnesota State Medical Society and A. M. A. membership. He finally became a Councillor of the Fourth District for several terms, fulfilling this exacting task with full application to the interests of his fellow doctors in medicine. At home, besides his work at the Clinic, he was surgeon on the staffs of St. Joseph's and Immanuel Hospitals, and surgeon to Omaha, Northwestern, and Great Western Railway Companies. At one time he was a member of the Mankato School Board. At the present time he was on the City Park Planning Board; a respected and useful citizen of his home community.

A full and useful life ended suddenly on June 8, 1940, at the age of 66 years; a life just short enough of perfection to make him human.

As a family man, church member, civic organizer, fellow practitioner, and friend, he will be missed, though his memory will remain as a challenge to us who remain; an example of a good man, a good doctor, and a good friend. His work was well done—it will linger on—it is a blessing to us to have known and worked with him.

The deep sympathy of his medical colleagues throughout the State, with the grateful memory that his sojourn in this life has made the world a better place because of his presence in it, is tendered herewith to his family and friends.

Clarence Prentice Rice

Dr. Clarence P. Rice of Breckenridge, Minnesota, died at Saint Francis Hospital, April 12, 1940, after having been in poor health for some time.

Dr. Rice was born in Armada, Michigan, in 1875. During his childhood his parents moved to Toledo, Western New York, Northern Illinois and to the vicinity of May City, Michigan. At the age of fourteen he came to Minnesota and made his home with an uncle on a farm in Big Stone county. He attended school at Ortonville and graduated from high school in 1895. He began his academic course at the University of Minnesota. At the outbreak of the Spanish-American war in 1898 he joined Company "E" of the 13th Minnesota. At the taking of Manila he was wounded and spent some time in the hospital. In January 1899, he was honorably discharged from service.

After teaching school in Big Stone county, Dr. Rice returned to the University of Minnesota in 1901 to study medicine. In June, 1903 he went to Mexico where he practiced his profession and acted as paymaster on a sugar plantation near Vera Cruz for a year. He then returned to the University and received his medical degree in 1906. The next two years he spent in hospital and general practice in Minneapolis, and in August 1908 opened an office in Breckenridge. After practicing many years in Breckenridge he moved his office to Wahpeton, North Dakota. He was a member of the North Dakota Medical Association.

Dr. Rice married on August 9, 1910, Agnes Hughes, who with a daughter, Margaret, of Warren, Minnesota survive. A son, Prentice Hugh Rice, died in 1936 at the age of twenty-five.

Kee Wakefield

Dr. Kee Wakefield, who until a month before his death lived with his son, Harry, in Minneapolis, died at Ellendale, North Dakota, May 8, 1940.

Dr. Wakefield was born in Green township, Trumbull County, Ohio, December 28, 1842. At the age of fourteen he came with his parents to a farm near Excelsior, Minnesota. In August, 1862, he enlisted with Company B, Ninth Minnesota Volunteer Infantry and served three years in the Civil War.

After the war he studied six months under Dr. A. E. Ames in Minneapolis and in 1867 went to Ashtabula, Ohio, where he studied in what is now the medical department of Western Reserve University. Here he received his M.D. degree in 1869.

Returning to Minnesota, Dr. Wakefield took up his profession in Hutchinson where he practiced for forty-five years.

Dr. Wakefield was married March 7, 1871, to Lucy Day at Excelsior. His wife died in 1899. One daughter, Amy, died in 1919. A son, Harry, of Ellendale, North Dakota, survives.

Dr. Wakefield and his brother, Thomas, a Hutchinson resident, were the only two remaining members of the G.A.R. in McLeod county. Dr. Wakefield practiced in Hutchinson from 1870 until his retirement in 1915. He took an active part in community affairs.

MEDICAL ECONOMICS

Edited by the Committee on Medical Economics
of the

Minnesota State Medical Association

W. F. Braasch, M.D., Chairman

PHYSICIANS AND NATIONAL DEFENSE

Two months ago it might have been predicted with certainty that the House of Delegates of the American Medical Association in session in New York would concern itself principally with new government health programs and the protection of the essentially American form of medical practice.

But two months ago Germany had not begun its victorious march in Europe and few people in America had awakened to the great issue of our own national defense.

It was typical that the fight to preserve their professional freedom—so precious to physicians—should take second place in the attention of the delegates and that the part the medical profession will play in national defense should come first.

Dr. Nathan B. Van Etten, taking office as president of the American Medical Association, warned that "the United States has arrived at a time when it must fight for the sanctity of its national life" and offered all of the resources of the organization of American physicians to the government for national defense.

Army Plan

Action on the matter was immediate. Lieutenant-Colonel G. C. Dunham of the Army Medical Corps presented the Army's plan for securing professional personnel.

This plan called for the American Medical Association, through its state and county societies:—

1. To make a complete canvass of the profession and list every doctor who is willing and qualified for military service:—
2. To keep a roster of these men according to locality and qualifications:—
3. To provide the Army Medical Department

and the War Department with names from this list as they may be required.

"This plan," Col. Dunham declared, "would distribute the professional load and, if properly administered should prevent the stripping of rural and isolated communities of their necessary medical personnel."

"Punch-Card Basis"

Dr. Morris Fishbein of the American Medical Association pointed out in press quotations that the plan would put United States physicians on a punch-card basis and that no direct enlistment of physicians on their own would be required.

A resolution was passed by the delegates calling for appointment of a medical defense committee which should work with the government to put the plan into immediate action.

The resolution granted freely that military need called for relinquishment of individual freedom in the interest of national unity but declared also that freedom must be returned after the national emergency has passed.

Committee Appointed

The committee asked for by the delegates was immediately appointed with Dr. Irvin Abel of Louisville, Kentucky, former president of the association, as chairman. Other members were Dr. Stanley H. Osborn of Hartford, Conn.; Walter G. Phippen, Boston; Harvey B. Stone, Baltimore; James E. Paulin, Atlanta; Fred W. Ranken, Lexington, Ky.; Roy W. Fouts, Omaha; Sam E. Thompson, Kerrville, Texas; Charles A. Dukes, Oakland, California, and John H. O'Shea, Seattle. Ex-officio members are Dr. Van Etten; Dr. Olin West, secretary; Dr. Arthur W. Booth, Elmira, N. Y., chairman of the Board of Trustees; Dr. Austin A. Hayden, Chicago, secretary of the trustees, and Dr. Fishbein of the American Medical Association.

Indications are that the committee, which met before the delegates adjourned, would set plan for preparedness among physicians in immediate motion.

Permanent Step Ahead

Threats of government interference in civilian practice abounded in the first Wagner Health Bill and they are not absent from the hospital bill which has already passed the Senate. They were also discussed by the delegates and vigorously opposed. Such domestic issues, important as they are to physicians and to the ultimate welfare of America, were only temporarily subordinated to the overwhelming issue of national defense.

It is interesting to note that President Van Etten seized the occasion to point out again the advantage to the national defense of a national health department headed by secretary of health in the president's cabinet which should coordinate all government health activities.

Such a move would be logical and desirable from every standpoint in the present altered state affairs. It would also mean a permanent step ahead in the government health service to the American people.

For Coördination of Insurance Plans

The problems already encountered in many quarters where medically sponsored experiments in sickness insurance are underway likewise came in for discussion by the delegates. One of the chief of these lies in the great variations between different locally sponsored plans. The variations lie in the services covered, in the premiums paid and in methods of collection and administration. Similar variations appear between hospital insurance plans in different states. A resolution calling for coördination of all these plans passed the house together with recommendations for similar coördination of hospital insurance plans. It was the opinion of the delegates, however, that medical and hospital service plans should be kept separate in every case.

Heroin Resolution Rejected

That other interests of the physicians were not entirely submerged in talk of national defense was shown in the resoluteness with which the delegates rejected a plea to endorse the repeal

of restrictions placed by the narcotics law on heroin. Louisiana delegates declared that heroin was needed for medical purposes and that the ban against its importation should be lifted but the resolution embodying the Louisiana delegates' declaration was voted down. The American Medical Association has long held that heroin is not indispensable as a medicine.

It was pointed out in this connection by Dr. Fishbein, that enough narcotics are now on hand in the United States to meet medical needs for three years.

HOSPITAL UNITS REVIVED

Plans are already going forward for reorganizations of the base hospital units which served in the last war. "Base Hospital 26" of the University of Minnesota, is being reorganized by Dean Harold S. Diehl but it will be known as "United States General Hospital 26" this time.

It is understood that there is no lack of volunteers for this service.

In New York, in fact, three times as many physicians were said to have volunteered for duty in Army hospitals as there are commissions to be filled. A call for thirty-two medical officers in a New York hospital unit was promptly answered by one hundred volunteers.

The complete hospital plan covering hospitals of the entire nation is said to provide for thirteen surgical hospitals and seventeen evacuation hospitals and thirty-two general hospitals.

FORD ENLISTS

It has been generally agreed that the initial success of Michigan Medical Service—sickness insurance plan set in motion by the Michigan State Medical Society—would depend upon response of Michigan's big industries.

Announcement at the New York meeting of the American Medical Association that the Henry Ford factories had accepted the service for its employees is important, therefore, and promises well for the financial success of the experiment.

A complete outline of the plan is now on file at the State Office. Copies can undoubtedly be secured from the Michigan State Medical Society of which L. Fernald Foster, 311 Center Avenue, Bay City, Michigan, is executive secretary.

"SURGICAL COMPLICATIONS"

(Monthly Editorial Prepared by the Medical
Advisory Committee)

The complications of medical practice in this day and age are so varied that one cannot be blamed if at times he finds himself perplexed. By the very nature of the human mind, it is impossible for him to know all and at all times foresee all complications which may arise following heroic treatment in his endeavor to save a life.

But one can by tact and courtesy forestall many serious misunderstandings with patients which lead to a court procedure.

Heavy doses of deep x-ray and radium have their effect on the human economy but are justified in the treatment of malignant disease. Patients should be told of complications which may result.

That there are complications which follow radical mastoidectomies—nerve injury for instance—is well known and not an unforeseeable catastrophe. The patient can be told in advance of the possibility.

That spurs do form on amputated long bones after surgery is not unusual. The surgeon does not always know why but at least he can provide against legal complications by word of mouth.

Keloid formation in scars is not unusual in certain types of individuals though unsightly many times; but the surgeon who opened the abdomen or sutured the accident wound cannot be blamed for the idiosyncracies of nature in the individual so disfigured.

The lack of callus formation in fractures and delayed union is not unusual. Surgical procedures used in the reduction of the fracture cannot be blamed for nature's lack of endeavor and the patient should be armed against adverse advice by giving him a full understanding of the problem at hand.

Your Medical Advisory Committee believes that when complications do arise, insistence on consultation and a full and frank discussion of these complications and their treatment will be evidence of a conscientious endeavor to meet the emergency and an honesty of purpose for which no one can be censured.

—B. J. B.

MINNESOTA STATE BOARD OF MEDICAL EXAMINERS

J. F. Dubois, M.D., Secretary

Saint Paul Woman Sentenced to 8-year Term For Criminal Abortion

Re: State of Minnesota vs. Della Mostert.

On May 23, 1940, Mrs. Della Mostert, sixty years of age, was sentenced by the Honorable Kenneth G. Brill, Judge of the District Court, to a term of 2 to 8 years at hard labor in the Women's Reformatory at Shakopee, Minnesota, following her plea of guilty to an information charging her with the crime of abortion. The statutory penalty for criminal abortion is not to exceed 4 years, but the sentence in Mrs. Mostert's case was doubled because of a previous conviction, in 1936, for a similar offense.

In the present case Mrs. Mostert, who resided at 1785 E. Maryland St., Saint Paul, was arrested on May 14, 1940, by the St. Paul Police following the admission of a 14 year old Negro girl to Ancker Hospital suffering from the after effects of a criminal abortion. The investigation disclosed that Mrs. Mostert performed this abortion at the girl's home on May 8, 1940, for which Mrs. Mostert admitted she received \$20.00. Mrs. Mostert had used a catheter in performing this abortion. A complaint was filed against Mrs. Mostert on May 16, 1940, and she was arraigned in the Municipal Court of Saint Paul on May 17, 1940, at which time she waived a preliminary hearing and was held to the District Court. On being arraigned in the District Court on May 20, 1940, the defendant entered a plea of not guilty and her case was set for trial on May 23rd. However, on that date, Mrs. Mostert withdrew her plea of not guilty and entered a plea of guilty.

Mrs. Mostert's previous conviction was in the District Court of Ramsey County on January 7, 1936, at which time she was sentenced to a term of not to exceed 4 years at the Women's Reformatory at Shakopee, following her plea of guilty to an indictment charging her with the crime of abortion. Mrs. Mostert was released from that institution on June 9, 1938, at which time she was placed on parole. Her parole expired in December, 1939. Mrs. Mostert has no license to practice any form of healing in the State of Minnesota. She also admitted that, with the exception of some work as a practical nurse, she has never received any medical education or training as a nurse.

Saint Paul Osteopath Receives Double Sentence In Abortion Case

Re: State of Minnesota vs. Samuel M. Stern

On June 3, 1940, Samuel M. Stern, a licensed osteopath, was sentenced in the District Court of Ramsey County, to a term of not less than two and not more than eight years at hard labor in the State Prison at Stillwater. Stern was sentenced by Judge Kenneth G. Brill, who, on May 13, 1940, had previously sentenced Stern to a term of not to exceed 4 years at hard labor in the State Prison following Stern's entering a plea of guilty to an information charging him with the crime of abortion.

Stern's sentence was doubled when the Court's attention was called to the fact that on January 3, 1922, Stern was convicted by a jury in Orange County, California, of the crime of embezzlement. He was received at the San Quentin, California prison on January 21, 1922, and served until January 27, 1923, at which time he was released on parole. The facts in that case indi-

cate that Stern and his brother, J. H. Stern, were convicted of converting to their own use a Premier automobile of the value of \$5,000.00, the car being in their possession as bailees. When Stern was arraigned before Judge Brill by virtue of his previous conviction, he stated to the Court that he had received a pardon from former Governor Merriam of California, the pardon being issued in September, 1938. It was contended by the defendant that this nullified his previous conviction, but Judge Brill ruled otherwise. The defendant indicated that he intends to appeal to the Supreme Court of Minnesota from the doubling of his sentence. In the meantime he will be confined in the State Prison on the original sentence imposed by Judge Brill.

Benton County Quack Jailed

Re: State of Minnesota vs. John Taylor, alias Hobo Jack, the Unlicensed Specialist

On June 12, 1940, John Taylor, fifty-four years of age, entered a plea of guilty in the District Court of Benton County, to an information charging him with practicing healing without a basic science certificate. Taylor was sentenced by the Honorable J. B. Himsl of the

District Court, to pay a fine of \$100.00 plus Court costs of \$23.15, or to serve 90 days in the County Jail of Stearns County, Benton County having no County Jail. Taylor was unable to pay the fine and the Court remanded him to the custody of the Sheriff to serve his sentence.

Taylor was arrested June 7, 1940, in Mayhew Lake Township by Sheriff Jos. A. Winkelman and Deputy Sheriff Earl Inman of Benton County, following a joint investigation made by the Minnesota State Board of Medical Examiners and Benton County authorities. A complaint was filed against Taylor by Mr. Brist on behalf of the Minnesota State Board of Medical Examiners, and Taylor was immediately arraigned before Otto C. H. Heinzel, Justice of the Peace, at Sauk Rapids. Taylor waived a preliminary hearing and was held to the September term of the Benton County District Court under \$500.00 bond, which was not furnished, Taylor being held in the Stearns County Jail. Taylor, who has no license to practice any form of healing in the State of Minnesota, or elsewhere, arrived in Benton County about May 15, 1940. Although Taylor claims to be a steel worker by trade, he was soon engaged in diagnosing the ailments of farm people and prescribing various medicines for which he would charge as high as \$20.00 for a 16 ounce bottle of medicine, and for which he always obtained the cash in advance. Taylor represented himself as Hobo Jack, the unlicensed specialist, and claimed to be able to cure arthritis, prostate trouble, hemorrhoids, stomach ulcers and many other ailments. He would purchase such items as fluff tannic acid, spirits of niter, powdered nutgalls and verocolate tablets at drug stores in Foley, Sauk Rapids and St. Cloud. By buying medicinal preparations that cost him not to exceed \$1.00, he would then manufacture a concoction that would be sold for approximately \$20.00 per bottle. Naturally it was just a question of time when such an imposition upon the public would be reported to the authorities. In Taylor's case it was immediately reported with his arrest following the investigation.

Taylor was closely questioned by Judge Himsl at

the time sentence was pronounced and Taylor, who claims to have been born at Carrollton, Missouri, admitted to the Court that he was neither licensed to practice any form of healing anywhere in the United States, nor had he ever studied medicine in any schools. He stated to the Court that he had practiced medicine unlawfully in California, Oregon and Washington, but claimed that he had never been arrested previously. The present case is the first prosecution in Benton County under the Basic Science Law, which was passed in 1927. This county has been free of quacks until the arrival of Taylor. The Minnesota State Board of Medical Examiners wishes to express its appreciation for the very fine co-operation given by Mr. J. Arthur Bensen, County Attorney of Benton County, Sheriff Winkelman and Deputy Sheriff Inman.

From the point of view of the clinical management of the individual case of tuberculosis and from the broader aspect of public health control of the disease, no one test occupies a position of greater importance and significance than that of the sputum examination. The persistence of a positive sputum is regarded as clear evidence that pathological activity of the disease has continued. An improved technic of sputum examination for acid-fast bacilli using tergitol has been reported. The use of this is said to approximate the results obtained by the use of guinea-pig inoculation, which is impractical except in selected cases because of cost.—S. A. PETROFF and P. SCHAIN, Quar. Bull. of Sea View Hosp., (Jan.) 1940.

A DIABETIC MANUAL

(Continued from Page 487)

a booklet, a revised edition* of which has just appeared. This booklet is written for the diabetic patient and is for the use of the physician. It makes easy the selection of the best diet for the individual case and bridges over the difficulty of instructing the patient regarding his diet.

When one considers the many diabetic manuals which have been published for the use of these patients, most of them entirely too complete and of the typewritten diet lists given patients on leaving hospitals, one can feel sure that this booklet will fill a widespread want. It is a gem.

*This booklet entitled "Diabetes—How to Make It Harmless" can be purchased for ten cents a single copy, \$1.00 a dozen from State Association office, 493 Lowry Medical Arts Building, St. Paul.

OF GENERAL INTEREST

A new building which will house his offices is being constructed in Ruthton by Dr. A. F. Sether.

* * *

Dr. Charles E. Rea has opened offices at 917 Lowry Medical Arts Building, Saint Paul, for the practice of surgery.

* * *

Dr. J. J. Ederer of Mahanomen has been appointed Soo Line physician and surgeon for the Mahanomen district.

* * *

A total of 344 degrees were granted by the university medical school in June. Earlier in the school year, 181 degrees were granted, making a total of 525.

* * *

Dr. Henry John Kurtin, who has been practicing at Lonsdale for the past two years, is now located in Blooming Prairie where he opened an office in June.

* * *

Dr. F. A. Figi of Rochester was elected secretary-treasurer of the American Association of Oral and Plastic Surgeons at a recent meeting held in Kansas City and St. Louis.

* * *

Dr. C. W. Woodruff and Dr. David T. Schuele of Chatfield will open a hospital there in August. They have purchased a home on a half acre of ground, and are remodeling it.

* * *

Dr. Robert Lyman Nelson of Duluth and Miss Phyllis Shaw were married June 1. The bride is the daughter of Mr. and Mrs. Percival Morse Shaw Jr. of Duluth.

* * *

Dr. Bill Henry Williams, who has been associated with the University of Minnesota Hospitals, left Minneapolis, July 1 to enter practice with Dr. Samuel Grantham of Joplin, Missouri.

* * *

The marriage of Dr. George S. Bergh, instructor in surgery at the university medical school, to Miss Patricia Stephenson (the golf-playing Patty Stephenson) took place in Minneapolis, June 15.

* * *

Dr. Charles Sheard attended the convention of the American Optometric Association in Cincinnati, Ohio, in June, and a meeting of the council on education of the association. He is chairman of the council.

* * *

Dr. C. M. Jackson, who for 27 years has headed the department of anatomy at the University of Minnesota Medical School, has been granted a partial leave of absence next year because of his health. He has held the post of department head since 1913. Dr. E. A. Boyden has been appointed acting head of the department for next year.

Dr. G. Frank Corbett of Minneapolis, who has been clinical professor of surgery at the University of Minnesota Medical School for many years, is retiring from his university duties. He has been made clinical professor emeritus of surgery.

* * *

Dr. Richard Varco and Louise Miller were married June 4 in Pasadena, California. They will make their home in Minneapolis, where Dr. Varco is a research assistant in surgery at the University of Minnesota Medical School.

* * *

Dr. Henry E. Michelson of Minneapolis has been appointed a member of the American Board of Dermatology and Syphilology, bringing Minnesota's representation on the board to two. Dr. Paul O'Leary of Rochester is also a member.

* * *

Dr. Eugene T. Leddy of Rochester attended the recent meeting of the American Radium society, of which he is an officer, in New York City. While in the East, he also attended the twenty-fifth reunion of his class at Harvard, and the American Medical Association meeting.

* * *

Dr. Joseph D. Selmo of Minneapolis has taken over the medical practice of Dr. Milo H. Larson in Norwood and Cologne. Dr. Larson has returned to Nicollet where he will operate the Nicollet Hospital. Dr. Selmo has been associated with Fairview and St. Joseph hospitals.

* * *

An honorary degree of doctor of science was awarded Dr. Louis Blanchard Wilson of Rochester, director emeritus of the Mayo Foundation, at the 68th annual commencement exercises of the University of Minnesota, June 15. He was one of three alumni to receive honorary degrees of their alma mater.

* * *

A sabbatical furlough for the spring quarter of the 1940-41 school term was granted last month by the university board of regents to Dr. Arthur T. Henrici, professor of bacteriology, who will conduct research in marine bacteriology and be Walker Ames professor at the University of Washington.

* * *

Dr. A. H. Logan of Rochester and his associates were awarded second prize for their exhibit at the American Medical Association meeting in New York City. The award was in a group made on the basis of excellence of presentation of previously known facts.

The five-unit exhibit on the diagnosis and treatment of polyps of the colon and rectum was compiled by Drs. Logan, C. F. Dixon, J. de J. Pemberton, L. A. Buie, P. W. Brown, H. H. Bowing, J. A. Bagen, H. M. Weber, C. W. Mayo and A. H. Bagenstoss.

Dr. Ralph V. Ellis, associate professor of preventive medicine, at the University of Minnesota Medical School, was in Saskatchewan, Canada, last month to address two divisional meetings of the College of Physicians and Surgeons of Saskatchewan. He spoke at Regina on June 13 and at Saskatoon on June 14.

* * *

Representing the University of Minnesota Medical School at the University of Pennsylvania celebration of its bicentennial anniversary, September 16-20, will be Dr. Owen Harding Wangensteen and Dr. Alfred W. Adson, surgeons. A program in fine arts, humanities, medical sciences, natural sciences, religion and social sciences will be presented.

* * *

From LaFayette College in Easton, Pa., which similarly honored his father several years ago, Dr. P. S. Hench of Rochester received an honorary degree of doctor of science at commencement exercises, June 7.

While in the East, Dr. Hench attended the convention of the American Rheumatism Association, of which he is president.

* * *

A distinguished service award was presented Dr. A. H. Sanford of Rochester by Northwestern university in June. Dr. Sanford, an alumnus of the university, was attending a committee meeting of the United States Public Health Service in Washington, D. C. at the time, and Mrs. Sanford accepted the award for him.

* * *

Dr. Charles F. Stroebel, who has been practicing medicine in Northfield for the past three years, has gone to Rochester to begin a fellowship in the Mayo Foundation. Dr. A. M. Nielsen of Minneapolis has taken over Dr. Stroebel's practice. A graduate of the University of Minnesota Medical School, Dr. Nielsen served his internship at St. Joseph's hospital in St. Paul.

* * *

Dr. W. F. Braasch of Rochester has been named trustee of the American Medical Association to fill the vacancy created by the death of Dr. C. B. Wright of Minneapolis. Dr. Braasch, a former president of the Minnesota State Medical Association, is chairman of the state association committee on medical economics.

* * *

Dr. F. L. Smith of Rochester, colonel in the medical reserve of the United States Army, has returned from third army maneuvers at Fort Benning, Ga. Forty-five thousand men composing the Blue army, mobilized at Fort Benning, opposed the Red Army of approximately 30,000 men, mobilized at Fort Sam Houston in Texas, in the most extensive maneuvers ever participated in by the regular army in peace time, from May 2 to May 29.

Colonel Smith was attached to the 6th medical regiment from Camp Devan, Mass.

* * *

Dr. and Mrs. Harold S. Diehl and children are vacationing in Honolulu. The University of Minnesota

dean of medical sciences and his family left Minneapolis, June 24, driving to the West Coast via Estes Park and the Grand Canyon. They sail from San Francisco July 19 to spend two weeks on the island. Their return to Minneapolis is scheduled for the latter part of August.

* * *

Appointment of Dr. Lester Breslow to the University of Minnesota Health Service staff, effective July 1, is announced. Dr. Breslow has completed his second year internship at the United States Public Health Service Marine Hospital at Stapleton, New York. A graduate of the University of Minnesota (B. A. cum laude, 1935; M. D., 1939), Dr. Breslow will do graduate work in the department of preventive medicine and public health also.

* * *

Dr. E. W. Minty, who for the past seven years has practiced medicine in Rapid City, South Dakota, as an associate surgeon of the Midwest Clinic, has opened a general practice in Faribault, Minnesota. Dr. Minty, was graduated from the Northwestern university school of medicine in Chicago in 1933.

* * *

There are many physicians in the state who, as officers, have given much time to their county medical societies. They are in a large part responsible for the success of their associations.

Oldest of all secretaries of county medical societies in Minnesota, in point of service, is Dr. William F. Wilson of Lake City. With the exception of one year when he was president, Dr. Wilson has been secretary of the Wabasha County Medical Society since 1896.

* * *

Dr. George O. Burr, physiological chemist who has been attached to the department of botany at the University of Minnesota, has been appointed director of the division of physiological chemistry in the Medical School, succeeding Dr. J. F. McClendon who left the university a year ago to accept a research post in Philadelphia. Dr. Burr is widely known for his pioneer work on the fertility vitamin "E" and for his discovery of the indispensability of unsaturated fatty acids in the diet of growing animals.

* * *

Dr. A. J. Herbolzheimer, Minneapolis eye, ear, nose and throat specialist, has accepted an appointment as a medical administrator for the civil aeronautics authority in connection with training of civilian aviators in the national defense program. He has gone to Washington, D. C., to assume his duties.

A World War veteran and a major in the army reserve medical corps, Dr. Herbolzheimer has been a medical examiner for army aviators 15 years. He is a former member of the city welfare board.

* * *

The announcement has been made that on recommendation of the Committee of Revision of the United States Pharmacopeia and with the approval of the Board of Trustees, the enforcement of the standards

for surgical catgut, which were amended in the Second Supplement of the U. S. P. XI, which were to have become effective July 1, 1940, have been postponed to January 1, 1941. This action was taken because certain stock now on hand conforming, except as to labeling, with new requirement would be unsalable and would result in needless financial loss.

* * *

Two Minnesota men were members of the committee which revised the manual for physicians conducting periodic health examinations, recently published by the American Medical Association. They are Dr. G. B. New of Rochester and Dr. William A. O'Brien of Minneapolis.

Acknowledgment is expressed to Dr. Walter C. Alvarez, Rochester, and Dr. Harold S. Diehl, Minneapolis, and others, for their assistance in preparing sections of the manual, entitled, "Periodic Health Examination."

* * *

Dr. Mancel T. Mitchell, former medical fellow in obstetrics and gynecology at the University of Minnesota who went to Eau Claire, Wisconsin, to practice, is now in Salt Lake City, Utah, having accepted an appointment as obstetrics consultant with the Utah State Board of Health in the Division of Maternal and Child Health.

Before leaving for Salt Lake City, Dr. Mitchell and Miss Harriet Waller, a graduate of the Eitel Hospital School of Nursing, were married.

* * *

Dr. Charles F. Code, assistant professor of physiology at the University of Minnesota, is returning to Rochester to take charge of some aspects of physiological research in the Mayo Foundation. Awarded the Theobald Smith award of the American Association for the Advancement of Science in 1938 for his work on the physiology of histamine, Dr. Code has spent the past two years at the university.

Replacing him in the physiology department will be Dr. Stanton Fetcher who will hold the post of instructor. Dr. Fetcher has been an instructor in physiology at the University of Chicago.

* * *

Dr. David G. MacMillan of St. Paul has taken over the medical practice of Dr. J. H. Raymond in Triumph.

Dr. Raymond, who has practiced there for the past five years, has gone to Canby to enter private practice. He recently returned from Chicago where he did post-graduate work in intestinal surgery at the Cook county hospital.

Dr. MacMillan, a graduate of the University of Minnesota Medical School, served his internship in hospitals in St. Paul and Duluth. He practiced in Duluth prior to going to Triumph.

* * *

Honorary degrees of doctor of science were awarded to Dr. Louis Blanchard Wilson of Rochester and

to Dr. Thomas S. Roberts of Minneapolis, at the 68th annual commencement exercises of the University of Minnesota, June 15.

Dr. Wilson is director emeritus of the Mayo Foundation, and Dr. Roberts is director of the university's Museum of Natural History and well-known author of "Birds of Minnesota."

Another honorary degree of doctor of science was awarded Charles Peter Berkey, secretary of the Geological Society of America. Fred B. Snyder, president of the University board of regents, was awarded an honorary doctor of law degree.

* * *

Examinations for Navy Medical Corps

The next examination for physicians desiring to enter the Medical Corps of the U. S. Navy, will be held at various naval hospitals August 19, 1940. Great Lakes Illinois, is the nearest location for Minnesota physicians.

Applicants must be graduates of Class A medical schools, must have had internship in a civilian hospital, must be physically qualified, under thirty-two years of age, citizens of the United States, and must pass professional examinations to be commissioned as Assistant Surgeons. Pay is \$2,699 if without dependents, and \$3,158 with dependents.

Additional information may be obtained from the Bureau of Medicine and Surgery, Navy Department, Washington, D. C. Applications must be completed and received in the Bureau prior to August 1, 1940.

Advanced Course in Sight Conservation

An advanced course in sight conservation is being offered for the first time by the University of Minnesota at its first summer school session.

Primarily for teachers, the course is being offered through the co-operation of the National Society for the Prevention of Blindness, the Minnesota Society for the Prevention of Blindness, the Minnesota Academy of Ophthalmology, and the Department of Ophthalmology and Otolaryngology and the College of Education of the University of Minnesota.

It is being given under the direction of Dr. Frank E. Burch, head of the department of ophthalmology, and Mrs. Winifred Hathaway, of New York City, associate director of the National Society for the Prevention of Blindness.

Lecturers will include Dr. T. R. Fritzsche of New Ulm; Drs. A. G. Athens, A. O. Olson and A. C. Hilding of Duluth; Drs. W. T. Wenner and J. B. Gaida of St. Cloud; Drs. H. P. Wagener, A. de H. Prangen and C. W. Rucker of Rochester.

St. Paul men, who will lecture are: Drs. T. J. Edwards, J. J. Prendergast, C. L. Larsen, R. O. Leavenworth, and E. P. Burch. Minneapolis men are: Drs. M. C. Pfunder, W. E. Camp, J. S. Macnie, E. W. Hansen, C. W. Spratt, C. E. Stanford, W. H. Fink, E. J. Borgerson, and Charles Hymes.

MEDICAL BROADCAST FOR JULY

The Minnesota State Medical Association Morning Health Service.

The Minnesota State Medical Association broadcasts weekly at 11:00 o'clock every Saturday morning over Station WCCO, Minneapolis, Station WLB, University of Minnesota, and KDAL, Duluth.

Speaker: William A. O'Brien, M.D., Associate Professor of Pathology and Preventive Medicine, Medical School, University of Minnesota. The program for the month will be as follows:

July 6—Summer Skin Problems.

July 13—The Value of a Vacation.

July 20—Gastro-intestinal Diseases in Summer.

July 27—Toothache.

COURSE IN CLINICAL ALLERGY

A course in Clinical Allergy will be given for physicians at the Center for Continuation Study, July 29 to August 3. Dr. Ralph V. Ellis of the University of Minnesota Medical School and his associates will give the entire program. For further information, physicians may write to the Center for Continuation Study, University of Minnesota.

MINNESOTA RADIOLOGICAL SOCIETY

The Minnesota Radiological Society held its twelfth annual meeting in Rochester on April 23, 1940. Doctor Bernard Nichols of Cleveland delivered the Annual Carman Lecture the same day before the Minnesota State Medical Society. The title of the lecture was "Indications for the Use of Excretory Urography In Diagnosis."

At the dinner and business meeting in the evening, Dr. Nichols addressed the society on, "The Future of Radiology." The following officers were elected for the following year: Harry Weber, Rochester, president; G. T. Nordin, Minneapolis, vice president; J. P. Medelman, Saint Paul, secretary-treasurer.

THE CAROTENE AND VITAMIN A CONTENT OF MARKET MILKS

The Council on Foods in formulating policies regarding processed foods has been cognizant of the lack of sufficient data on the vitamin A content of natural foods. Milk and dairy products are known to be important sources of this factor. Data on the carotene and vitamin A content of market milks have been obtained by Professor Peterson and his collaborators at the University of Wisconsin and are made available in a report authorized for publication by the Council on Foods. The following is a summary of the data compiled by Professor Peterson and his collaborators:

The carotene and vitamin A content of milks marketed by eight large distributors in the Madison and Milwaukee areas of Wisconsin have been determined monthly during a period of eighteen months. These milks fall into four groups: (1) market (mainly Hol-

stein), (2) Guernsey, (3) vitamin D (mainly Holstein) and (4) certified. All milks showed marked seasonal changes in both carotene and vitamin A contents. The seasonal changes in carotene were greater than those for vitamin A. The milks were fairly similar in vitamin potency per gram of butter fat. Certified milks were somewhat higher than the other milks during the late winter months. Guernsey milk, because of its higher fat content, had a higher potency on the fluid basis than the others. (J.A.M.A., May 4, 1940, p. 1748.)

WOMEN'S AUXILIARY

MRS. A. C. BAKER, Fergus Falls, *President*

MRS. E. V. GOLTZ, 2259 Summit Avenue,
Saint Paul, *Publicity Chairman*

The joint annual dinner meeting of the Rice County Medical Society and the Women's Auxiliary was held at the Carleton Tea Room, Wednesday evening, May 8. Following a brief business meeting of each organization the group adjourned to the new Northfield Community Hospital which was open for their inspection. Professor E. A. Fath of Carleton College showed specimens of color photography for the group.

* * *

Mrs. J. A. Cosgriff of Olivia has been elected as director of the St. Paul Archdiocesan Council of Catholic Women at the recent annual meeting of the council held in the Hotel Radisson, Minneapolis.

* * *

At a recent meeting of the Washington County Medical Auxiliary, Mrs. Olson of Elk River was the guest speaker. The meeting held at the home of Mrs. C. H. Sherman at Bayport was attended by nine members and two visitors. Mrs. Olson's subject was "Control of Cancer."

* * *

Mrs. J. A. Cosgriff, retiring president of the Renville County Medical Auxiliary, presided at the recent meeting held at the school house in Olivia. Reports were given and new officers were elected. Mrs. R. Billings of Franklin was elected president; Mrs. C. Hartmann of Fairfax, president-elect; Mrs. R. Erickson of Hector, vice president; and Mrs. C. H. Mesker of Olivia, secretary-treasurer. Mrs. Cosgriff gave a report of the recent state convention which was held in Rochester. Miss Eleanor Dougherty as guest speaker, spoke on "International Affairs." Other members who attended were Mrs. J. Dordal of Sacred Heart and Mrs. W. J. Bushard of Bird Island.

* * *

At the annual meeting of the Washington County Medical Auxiliary Mrs. F. M. McCarten was elected president for the coming year. The meeting was held at the home of Mrs. Landeen. Mrs. Gertrude Stevens of Lake Elmo was elected vice president and Mrs. C. H. Sherman of Bayport, secretary and treasurer. Eleven members were present.

PROCEEDINGS of the MINNESOTA ACADEMY OF MEDICINE

Meeting April 10, 1940

The regular monthly meeting of the Minnesota Academy of Medicine was held at the Town and Country Club on Wednesday evening, April 10, 1940. Dinner was served at 7 o'clock and the meeting was called to order at 8:10 p.m. by the President, Dr. James Johnson.

There were 52 members and 3 guests present.

Minutes of the March meeting were read and approved.

Amendments to the constitution, as published in the April program, were voted upon and accepted by the members present.

The scientific program followed.

SOME USES OF SULFAMIDOPYRIDIN PREPARATIONS IN THE TREATMENT OF INFECTIOUS DISEASES

MOSES BARRON, M.D.

Minneapolis

Discussion

Dr. Barron gave a very favorable report on the effect of sulfamidopyridin preparations in various infections.

Dr. F. C. RODDA, Minneapolis: I would like to comment about some of our statistical conclusions. They may have to be modified as the years go by. There is a definite cyclical change in disease prevalence and virulence. About 1830, Bretonneau, in writing a text on medicine, disposed of scarlet fever in a paragraph. It was mild, unimportant, and he referred to it as scarlatina. About ten years later he revised his text and his most prominent chapter was devoted to scarlet fever. In the interval there had occurred a violent, killing epidemic of scarlet fever. In about 1918 we had an epidemic in which the patients died within 36 to 48 hours after the onset of the disease. At present scarlet fever is very mild, even hard to diagnose. It may be that sulfanilamide may not be able to cope with the severe disease as successfully as is now indicated. In furtherance of this idea, in the past years, epidemics of diphtheria in Germany have been described which have been resistant to present-day antitoxin and immunization obtained by toxin-antitoxin and toxoids. I think we have to take into consideration, in appraisal of therapeutic agents, the cyclical changes in diseases.

Dr. S. E. SWEITZER, Minneapolis: I would like to congratulate the internists on the spread of their field of internal medicine from broken bones to scarlet fever and gonorrhea. We have treated quite a lot of erysipelas with sulfanilamide and sometimes get very good results. I think perhaps in pneumonia and some of the acute infections, this is a marked advance in therapy.

Dr. A. A. ZIEROLD, Minneapolis: I hardly feel that the discussion thus far has been entirely fair to the internist. While I realize that he has increased his field tremendously, nevertheless, the results are not

invariably as questionable as has been intimated. As Dr. Rodda has stated, the systemic infections are cyclic in character and require observation over a long period of time to determine their susceptibility to control by any one form of treatment. Compound fractures, on the contrary, are local injuries which are reasonably consistent in their behavior. We feel that our treatment of compound fractures at the General Hospital has been eminently successful and we feel satisfied that the use of sulfanilamide is a distinctly valuable agent in our routine. Before the advent of this drug, the incidence of sepsis following compound fractures was 30 per cent at the Minneapolis General Hospital and I believe that this represents a common experience. As the result of the investigation and initiative of the surgical residents, sulfanilamide was implanted in all compound fractures with the result that subsequent infections dropped to less than 1 per cent. This has been confirmed by the experience of men in other clinics and I believe is definite objective evidence of the worth of this drug in this particular field.

Dr. S. E. SWEITZER: We heard about these results which were claimed in fracture cases and we thought it might be used in leg ulcers. We packed some of them in sulfanilamide and did not get anywhere with it. I wonder, if you get such good results in fracture cases, why we do not get anywhere with the leg ulcers which are treated with it—which are a definite infection. In fracture cases there isn't usually an infection present at first, but there is in leg ulcers.

Dr. ZIEROLD: I believe that I am able to answer Dr. Sweitzer's question. The basis of treatment of compound fractures is the implantation of the drug within a closed cavity, which permits slow diffusion in the immediate vicinity of the wound for a considerable period of time. Only in this way can a satisfactory concentration of sulfanilamide be maintained. Dr. Sweitzer's treatment failed because of the presence of pus and its contained peptones which inactivate sulfanilamide, and because of his inability to implant or completely enclose the drug.

Dr. F. H. K. SCHAAF, Minneapolis: I would like to ask Dr. Zierold whether or not there is a possibility that a change in surgical technic alone has something to do with the favorable results. During the recent Spanish War, one army surgeon treated all compound fractures with radical excision of the injured tissues, and immobilization of the extremities in plaster-of-Paris, with tremendously favorable results. Sulfanilamide applied locally may be of considerable value, if it will remain in a sufficiently high concentration for some time. While I agree with Dr. Barron in many respects, many of the extremely favorable results following the use of sulfanilamide smack a bit of a Wednesday night Christian Science Testimonial Meeting. I especially object to the indiscriminate use in ordinary throat infections, unless definitely proven of streptococcus-hemolyticus origin. Sulfanilamide is not effective unless used in proper dosage, and many of us have seen dangerous cases of agranulocytosis and hepatitis follow the use of ordinary therapeutic doses. Consequently, it is my feeling that we should use sulfanilamide and the related drugs only when there is a definite indication for their use. I do not agree with Dr. Barron that either sulfanilamide or sulfapyridin have given uniformly good results in staphylococcal infections. At the New Orleans meeting of the American Congress of Physicians, directly contradictory results were reported by two groups of investigators. I

think, perhaps, it will be best for us to be somewhat critical at the present moment, to prevent the unnecessary use of these extremely valuable but dangerous drugs.

DR. O. H. WANGENSTEEN, Minneapolis: I wish to speak briefly concerning the value of local implantation of sulfanilamide about the operative site in experimental gastro-intestinal surgery upon the dog. There has been a lively local interest relating to the implantation of sulfanilamide in wounds since Dr. N. K. Jensen of the Minneapolis General Hospital and his associates first pointed out the efficacy of employing sulfanilamide in this manner as a bactericidal and bacteriostatic agent.

During the current year, Dr. Richard L. Varco, one of my young associates, has made a very interesting application of the use of local implantation of sulfanilamide. Upon completion of gastro-intestinal anastomoses of varying kinds, Dr. Varco has been placing 4 to 5 grams of sulfanilamide about the suture. He has now an operative series of between forty and fifty operations, many of which involve triple anastomoses, such as the interpolation of a short segment of the terminal ileum and ascending colon between the pyloric outlet and the jejunum to imitate the function of the Dragstedt valve, with transfer of the biliary and pancreatic secretions to a lower level in the bowel (duodenal drainage according to the Mann-Williamson method), transection and end-to-end anastomosis of the esophagus, the establishment of Pavlov gastric pouches, gastric resections and similar procedures with only three deaths in the group (none with peritonitis).

This is really an unusual accomplishment for any surgeon. Markowitz, a pupil of Frank Mann, has said quite appropriately, "If an operator has mastered the technic of resection in dogs, he need not doubt his ability to make a safe anastomosis of the human intestine. When a surgeon can perform on dogs the operation of functional exclusion of the duodenum, known as 'duodenal drainage' with a mortality of only 20 per cent, we should say that he has mastered the technic of intestinal anastomosis" (Experimental Surgery. William Wood and Company, 1937, p. 73).

The difficulties in the dog are well known to all who have had extensive experience in this type of surgery. Dr. Varco and I had been able to confirm Markowitz observation, and from my own experience in the hospital, I have the impression that similar anastomoses on man may be carried out with definitely lesser risk.

Even with employment of closed or so-called "aseptic" anastomoses in the dog, leaks may occur where the gut is punctured with the needle even though fine needles and silk are used. It is very discouraging to spend three to four hours making a complicated anastomosis in the dog to find in forty-eight hours, that the anastomosis appears to leak in many places, particularly when everything seemed in order on completion of the procedure.

It is Dr. Varco's impression that the local implantation of sulfanilamide about the anastomosis exerts a bacteriostatic effect upon the bacteria which escaped through needle punctures of the gut wall. The presence of pathogenic bacteria on the peritoneal surfaces of the anastomosed segments, Dr. Varco feels, interferes with fibrin formation and stops the healing process. Local implantation of sulfanilamide holds the bacteria in check, preventing the lysis and destruction of fibrin, thus permitting the healing process to continue normally. Dr. Varco failed to observe a similar protective influence when the sulfanilamide was administered subcutaneously.

It is well known that the dog tolerates relatively larger doses of sulfanilamide than does man. Further, the dog does not acetylate a portion of sulfanilamide administered, as does man. Consequently, in the dog,

all of it is available for bactericidal and bacteriostatic purposes. We have used sulfanilamide in this manner in colon resections, implanting usually 4 grams about the anastomosis and 2 grams in the abdominal wall above the peritoneum. The blood levels of sulfanilamide in man, following such implantation come up to maximal levels in two to three hours time. If the sulfanilamide could be implanted locally in oil, permitting even slower absorption, the protection afforded might be enhanced. It does appear that local implantation of sulfanilamide in the peritoneal cavity of the dog about complicated gastro-intestinal anastomosis is a worthwhile procedure.

MODIFICATION OF VIRUSES FOR USE AS VACCINES

ROBERT G. GREEN, M.D.
University of Minnesota
Minneapolis

Abstract

Previous to the time of Jenner it was well recognized that smallpox epidemics were severe or mild. During the eighteenth century the practice of inoculating human beings from lesions of cases of the disease in mild outbreaks became common in Europe and America. This practice was brought from the Orient to Europe early in that century through its introduction into Turkey. The introduction of inoculation with cowpox by Jenner in 1798 we recognize as one of the greatest practical achievements in medicine, but the real significance of the smallpox-cowpox relationship is just now being understood. The concept of filterable viruses did not have its beginning until a hundred years after Jenner's time, since the first filtration experiment on the mosaic virus of plants was done by Beijerinck in 1894, and the first experiment with an animal virus was performed with the virus of foot-and-mouth disease by Loeffler and Frosch in 1898.

During the past decade two virus-modifications have been accomplished by animal-passage of the virus which seem to establish the significance of this process. Beginning in 1934, Theiler and Smith passed the virus of yellow fever serially through chick embryos from which the central nervous system had been removed, and reduced thereby the pathogenic properties of this virus for man. After preliminary tests and field trials, 57,000 people, mostly in Brazil, were inoculated with the modified virus in 1938. During 1939 more than a million people were vaccinated against yellow fever.

In our Minnesota investigations on viruses during the same period, the virus of distemper was passed serially through ferrets, and the decrease in the virulence of this virus for canines was carefully determined. After fifty-four passages the virus produced uniformly mild infections in foxes and dogs. The live modified virus has been used to inoculate more than 100,000 foxes and 1,000 dogs.

It now appears that passage of certain filterable viruses successively through one species of animal decreases their virulence for unrelated species. Indications are that the property of modification is more or

less a general one, and that the use of live modified viruses as vaccines may in the future be the outstanding method of attack in controlling virus diseases.

Discussion

DR. JAMES JOHNSON, Minneapolis: What have been the conclusions in regard to this extensive vaccination against yellow fever?

DR. GREEN: The process of immunization against yellow fever as a field study is still too new to permit drawing conclusions. In preliminary experimental work, it was shown that this virus would produce antibodies in the blood which were considered, from mouse-protection tests, to be sufficient for protection against yellow fever. Similar tests are being made on individuals vaccinated in the field inoculations to determine the degree of immunity produced.

DR. RODDA, Minneapolis: Is the modified distemper virus now being used for the immunization of dogs?

DR. GREEN: Field studies are now being carried on in the vaccination of dogs by veterinarians, and it seems that a single inoculation with a modified distemper virus produces a satisfactory immunity in dogs. Such a vaccine cannot be made available for general use until extensive field trials have been completed.

The meeting adjourned.

A. G. SCHULZE, M.D., *Secretary*.

The prognosis of pleurisy with effusion with negative, doubtful or extremely slight pulmonary findings by x-ray is excellent if patients receive at least four months of sanatorium care; in fact, it is almost as good as the normal population in the same age group.—FRANCIS B. TRUDEAU, M.D., *Amer. Rev. of Tuberc.*, (Jan.) 1939.

BOOK REVIEWS

Books listed here become the property of the Ramsey, Hennepin and St. Louis County Medical libraries when reviewed. Members, however, are urged to write reviews of any or every recent book which may be of interest to physicians.

OPERATIVE SURGERY. Fifth Edition. J. Shelton Horsley, M.D., LL.D., F.A.C.S. Attending Surgeon, St. Elizabeth's Hospital, Richmond, Va.; and Isaac A. Bigger, M.D. Professor of Surgery, Medical College of Virginia Hospitals, Richmond, Va. 2 Vols. 1,567 pages. Illus. Price, \$18.00, cloth. St. Louis: C. V. Mosby Co., 1940.

PSYCHIATRY FOR NURSES. Louis J. Karnosh, B.S., Sc.D., M.D. Associate Clinical Professor of Nervous Diseases, School of Medicine, Western Reserve University, Director of Neuropsychiatry, City Hospital, Cleveland, Consulting Neuropsychiatrist, Cleveland Clinic; and Edith B. Gage, R.N., Supervisor, Neuropsychiatric Division, City Hospital, Cleveland. 327 pages. Illus. Price, \$2.75, cloth. St. Louis: C. V. Mosby Co., 1940.

THE POISON TRAIL. William F. Boos, M.D. 380 pages. Price, \$3.00, cloth. Boston and New York: Hale, Cushman & Flint, 1940.

THE MARCH OF MEDICINE. Edited by the Committee on Lectures to the Laity of the New York Academy of Medicine. 168 pages. Price, \$2.00, cloth. New York: The Columbia University Press, 1940.

DOCTORS IN SHIRT SLEEVES. Musings on Hobbies, Meals, Patients, Sport and Philosophy. Edited by Sir Henry Bashford. 294 pages. Price, \$2.50, cloth. New York: Veritas Press, 1940.

ENDOCRINE THERAPY IN GENERAL PRACTICE. Third Edition. Elmer L. Sevringhaus, M.D., F.A.C.P.

SILVER PICRATE

Wyeth

HAS SHOWN A CONVINCING RECORD* OF EFFECTIVENESS IN ACUTE ANTERIOR URETHRITIS

due to *Neisseria gonorrhoeae* • *Trichomonas vaginalis*
Monilia albicans

Silver Picrate is a crystalline compound of silver in definite chemical combination with picric acid. Dosage form for use in anterior urethritis: Wyeth's Silver Picrate Crystals in an aqueous solution of 0.5 percent.

Supplied at all pharmacies in vials of 2 grams

Complete literature on Silver Picrate as used in genitourinary and gynecological practice will be mailed on request.

*"Treatment of Acute Anterior Urethritis with Silver Picrate," Knight and Shelanski, *AMERICAN JOURNAL OF SYPHILIS, GONORRHEA AND VENEREAL DISEASES*, Vol. 23, No. 2, pages 201-206, March, 1939.

JOHN WYETH & BROTHER, INCORPORATED, PHILADELPHIA, PA.

Professor of Medicine, University of Wisconsin; Editor, Department of Endocrinology, Year Book of Neurology, Psychiatry and Endocrinology. 239 pages. Illus. Price, \$2.75, cloth. Chicago: Year Book Publishers, 1940.

DERMATOLOGIC THERAPY IN GENERAL PRACTICE. Marion B. Sulzberger, M.D. Assistant Clinical Professor of Dermatology and Syphilology, Skin and Cancer Unit of the New York Postgraduate Medical School and Hospital of Columbia University; Associate Attending Dermatologist, Montefiore Hospital, New York City; and Jack Wolf, M.D.; Attending Dermatologist and Syphilologist, Skin and Cancer Unit of New York Postgraduate Medical School and Hospital of Columbia University; Director of Dermatology, New York City Cancer Institute. 680 pages. Illus. Price, \$4.50, cloth. Chicago: Year Book Publishers, 1940.

PRINCIPLES OF SURGICAL CARE—Shock and Other Problems. Alfred Blalock, M.D. Professor of Surgery, Vanderbilt University School of Medicine, Nashville, Tenn. 325 pages. Illus. Price, \$4.50, cloth. St. Louis: C. V. Mosby Co., 1940.

AN INTRODUCTION OF BIOCHEMISTRY. Second Edition. William Robert Fearon, M.A., Sc.D., M.B., F.I.C. Fellow of Trinity College, Dublin. Member of the Royal Irish Academy. 475 pages. Illus. Price, \$3.75, flexible binding. St. Louis: C. V. Mosby Co., 1940.

CHEMISTRY AND MEDICINE. Papers presented at the Fiftieth Anniversary of the Founding of the Medical School of the University of Minnesota. Edited by Maurice B. Visscher, Professor of Physiology at the University of Minnesota. Cloth. Price \$4.50. pp. 296, illus. Minneapolis: The University of Minnesota Press, 1940.

Chemistry, despite the disclaimer in the foreword of this book, is by all odds the most important single factor in the development of modern medicine and it was therefore most appropriately chosen as the single theme of the program for the commemoration of the completion of the first semi-centennial of the University's Medical School. Seven of the fourteen papers are by members of the University's own faculty, the others by teachers from other centers. All are by workers of acknowledged standing in the various subjects they have chosen, in which they have all done important original research.

It follows logically, then, that the volume is one of great value. It is divided into four parts, covering the physical, the metabolic, the immunologic and chemotherapeutic, and the neurologic aspects of chemistry in medicine, adequately illustrated by excellent charts and graphs drawn in the Medical Art Shop of the University, with a few half-tones from other sources.

Obviously the main object of the book is to preserve in permanent form these valuable contributions, both for the benefit of those who attended the sessions and those who were unable to be present, as stated in the foreword. To this extent it is a complete success, and one can readily understand that from its non-encyclopedic nature it was not meant to be regarded in any sense as a text book or even have the appearance of an attempt to make it look like one. Yet with the wealth of authoritative material which it contains it could have been made much more useful if it had been

provided with a uniform system of alphabetical reference lists, properly numbered, and given an index. It is like a rich feast served in the dark, or at least without a bill of fare.

GILBERT COTTAM, M.D.

DIAGNOSTIC STANDARDS AND CLASSIFICATION OF TUBERCULOSIS. Published by the National Tuberculosis Association, 50 West 50th Street, New York City, 1940.

Currently accepted standards in diagnosis, treatment and prevention of tuberculosis are given in the new edition of "Diagnostic Standards and Classification of Tuberculosis." It incorporates many ideas of physicians who gave the Standards in the tentative edition, published in 1938, a practical trial during the last two years.

Some of the changes in the new edition are in terminology. The terms "primary" and "reinfection phases," are used to replace the terms "childhood type" and "adult type," respectively. This change is due to the fact that primary infections occur in adult life more frequently than formerly simply because fewer children become infected. The term, "frankly active," is now employed to include the cases formerly classified as "improved and unimproved," though these terms are retained as subdivisions.

The section presenting the pathogenetic development of pulmonary tuberculosis discusses fully the primary reinfection phases of tuberculosis, initial lesions, prevalent types of retrogression and progression, and the histologic characteristics of the two phases of the disease.

The necessary correlation of the clinical symptoms of tuberculosis with the pathological course of the disease is emphasized and many such correlations are given as illustrations.

The diagnosis of tuberculosis is discussed from the standpoints of pulmonary tuberculosis with and without symptoms, the primary phase of the disease, non-pulmonary tuberculosis and differential diagnosis.

Tuberculosis case-finding and control are dependent upon the mutual understanding and coöperation among physicians, clinics and health organizations, according to the publication. The rôle of the private physician is pointed out as a major one.

The form sheet, "Classification and Descriptive Summary of Tuberculosis," is more comprehensive than any previous one. This form, when used, will give on brief inspection a full picture of the patient regarding medical history, evaluation of symptoms, physical, roentgenographic and sputum examinations, treatment, clinical status and complications.

The technical procedures in the diagnosis of tuberculosis are fully presented. The methods and the interpretations of the intracutaneous tuberculin test are discussed, as well as the demonstration of the tubercle bacilli in the sputum, stomach washing and other body fluids.

The x-ray is pointed out as the foundation of early diagnosis, and the many factors involved in the taking of the x-ray and the interpretation of the film are evaluated.

MINNESOTA STATE MEDICAL ASSOCIATION

Eighty-seventh Annual Session

April 22, 23 and 24, 1940

Rochester, Minnesota

HOUSE OF DELEGATES

Sunday, April 21, 8:00 P. M.

The first meeting was called to order at 8:00 p.m., Sunday, April 21, by Dr. W. W. Will of Bertha, Speaker of the House.

Following a report from Dr. E. S. Boleyn, Chairman of the Committee on Credentials, that a quorum was present, it was moved, seconded, and carried that reading of the minutes of the last meeting be dispensed with and, at the request of the Speaker, Dr. W. F. Braasch of Rochester introduced Dr. Nathan B. Van Etten of New York City, President-elect of the American Medical Association. (Dr. Van Etten's Address will be printed in full in a future issue of MINNESOTA MEDICINE—Editor.)

The Speaker then requested Dr. Adams to introduce Dr. R. G. Arveson, President of the Wisconsin State Medical Society.

DR. ARVESON: I am very glad to know that Dr. Adams comes from Wisconsin, and I would like to invite you all to Wisconsin next year to help us celebrate the 100th Anniversary of our organization as a continuous state medical society.

Wisconsin, especially western Wisconsin, owes a great deal to Minnesota. In western Wisconsin, we have made your medical centers ours and your men have been very willing to come across the state line and teach. Furthermore, before I go farther, I want to say that your executive secretary knows no state lines medically and has done much for western Wisconsin. In fact, I have talked so much about Minnesota to my Council and House of Delegates that they are on the verge of deporting me.

Wisconsin has been pushed around a good deal of late. The federal government threatened to make us pay an income tax and a large number of trips back and forth to Washington have been necessary, also the aid of an influential Minnesotan, before that threat could be removed. It would seem that the statement made recently by Hogan of the American Bar Association is right: This nation is fast becoming a government of men, not of law.

Some of you probably know that there has been a good deal of criticism of the Wisconsin State Medical Society in the Wisconsin legislature. We sent Mr. Crownhart to Europe to refute the arguments of some of our legislators and social service workers about the general excellence of the European system and we sent a committee around the state to investigate the adequacy of our own system in Wisconsin. We had planned to spend two or three Saturdays at it. Actually we spent the week-ends of nearly nine months. We talked to industrialists, mayors of cities, sheriffs, scrub-women and WPA workers and, gentlemen, we found not one instance where a physician had refused medical care or failed to see that it was provided; not one instance where a physician had failed to play ball with his patient.

We attempted in Wisconsin to establish a state-wide hospital insurance but the hospitals have taken it out of our hands and though it is now being pushed in Milwaukee, the outlook is not very hopeful. The CIO is fighting it in Milwaukee and x-ray and pathological services are being included in defiance of the law. We should probably have left it to the hospitals to handle

from the start. In any case, a great war is on and will probably be carried to the Supreme Court eventually to decide whether or not the hospitals can practice medicine.

The Wisconsin State Medical Society presents its best wishes through me for a successful meeting in Minnesota.

Dr. Will then introduced Dr. B. S. Adams of Hibbing, President of the Minnesota State Medical Association. (The Presidential Address of Dr. Adams is printed in full elsewhere in this issue—Editor.)

Dr. Felix Hennessy of Iowa, President of the Iowa State Medical Society was introduced.

DR. HENNESSY: May I extend to you the greetings of the 2,430 members of organized medicine in Iowa.

As I observe this House of Delegates meeting and as I have looked at ours over a period of many years, I have wondered if the message of what is going on here and in the practice of medicine everywhere is really being carried back home to the members and to the public.

We representatives are likely to debate the issues of medicine with complacency in our meetings but the general practitioner at home is outside of the combat, and, so far as he is concerned, our words fall on barren ground. It is through him that we must carry our message to the public. If we reach the public properly it is certain that we shall find appreciation and assistance.

DR. WILL: Thank you very much, Dr. Hennessy. I hope our delegates here assembled will take to heart what you have said about carrying the message home to our members.

You are all familiar with the re-organization plan in the state government of Minnesota. You are aware of the fact that Mr. Walter Finke heads the new Division of Social Welfare, and I am told by people who are in a position to know, that a better selection couldn't have been made. It is evidence of Mr. Finke's appreciation of the importance of medical problems of his department that he has appointed a medical advisory committee to aid him in the solution of these problems. Dr. A. W. Adson is Chairman of this committee and he will explain the functions of this committee.

DR. ADSON: I must confess that I was somewhat suspicious at the outset of the object back of the appointment of the Medical Advisory Committee. It occurred to me that perhaps we were appointed only to whitewash certain activities that would be presented to us as a formality for our approval. It was not until we saw the first orders issued to the Welfare Boards that I, for one, was fully convinced that Mr. Finke was seriously seeking our help in the solution of the medical problems involved in administration of relief and social security aids.

At our first committee meeting we suggested that we utilize the County Contact Committees as advisory committees to local county welfare boards. I'm taking the privilege of reading excerpts from the first regulations issued January eighth to the local county welfare boards and based upon the suggestion of the committee.

"In handling medical care cases, every county welfare board and its staff members often face the need of decision which is primarily medical and outside of the province of anyone but a

physician to make. From the standpoint of the welfare board, three factors are present. They are produced by a mutual need of assistance, the need for medical care, and the comparative limitation of funds. Of these, the first and the last are the responsibility of the welfare board. They are usually known, tangible facts. The need for medical care, its duration and type, are within power of the physician only to determine."

Now, gentlemen, that's very important. You are all familiar with the conflicts that have arisen in all our counties with reference to the type of medical care necessary in a given instance and to what extent it should be administered. When funds are limited, relative needs for medical care assume a special importance.

To quote this bulletin further:

"To assist them in this problem many counties have used committees of physicians formally designated by the county medical society for this duty. This committee activity sponsored by the medical society and carried out with the close cooperation of the physicians has been of immense value to the county welfare boards and a very real contribution to the handling of local welfare problems. We are happy to report that on November 24, 1939, the State Medical Advisory Committee to the Division of Social Welfare, after study of medical care as it relates to the welfare program, formally went on record urging extensive use of local medical advisory committees."

"The State Medical Advisory Committee recommends that the present County Contact Committees act in the capacity of the County Medical Advisory Committees as herein specified until the next annual meeting of the State Medical Association when formal action can be taken to change the name of such committees."

It seemed wise to the committee, it should be pointed out, that the word "contact" be omitted in the name of these committees and that they be known as "medical advisory committees." Such a change will have to be submitted to you, perhaps, in the form of a resolution.

The functions of the county committees were outlined as follows:

"(1)—On request of the County Welfare Board, aid in solving any problem involving compensation for medical care and provision for receiving public assistance." Obviously the men who make up these committees should be alert and willing to cooperate—and if they are, Mr. Finke will certainly see that their opinions are respected.

"(2)—On request of the Board, to aid in solution of problems that arise in connection with emergency cases. On the request of members, to bring to the attention of the Welfare Board, problems that arise in connection with emergency cases."

"(3)—On request of the Welfare Board, to be available to assist in the solution of problems arising by reason of a difference of opinion on recommendations as between doctors."

"(4)—On request of the County Welfare Board, to aid in solving problems of patients waiting for admission to the University Hospitals and other types of tax supported hospitals and to advise relative to the economy that might be effected in the transportation costs through treating certain cases with local facilities."

As the state committee has met from month to month, many different problems have been submitted. We have given our best thought to solution of conflicts and adjustment of differences. But the arrangement means more than that. It means that the medical profession of Minnesota has an opportunity to participate in the discussion and to outline the plans in conjunction with the Division of Social Welfare in the handling of intricate problems. I believe that many of these problems will be amicably and wisely settled and that there will no longer be a struggle in Minnesota between two strong forces. I am convinced that Mr. Finke is sincere and that he is willing to work with us as a profession. If we will do our part, we may be able to set up a plan that will benefit everybody in Minnesota. We have the pleasure of having with us tonight both Mr. Finke and Dr. Hilleboe and I want to present Mr. Finke to you now, not only as a Director of the Division of Social Welfare, but as a humanitarian who is genuinely interested in the solution of public problems that confront us in Minnesota. Mr. Finke.

MR. WALTER FINKE, Director of the Division of Social Welfare: I should like to state for you briefly

the four or five principles that govern our working relationship as we advance in these welfare programs in Minnesota.

First, I think it is important that the state should put its own house in order administratively before it asks any profession to work with it in the solution of any of its problems. Nothing is more difficult than an effort to deal with government when administrative responsibility is divided between numerous agencies and individuals and when there is overlapping and disagreement. We believe that we have taken the first step toward removing such obstacles in Minnesota. We have thrown together into one hat all of the diverse agencies that were previously concerned with the welfare program and we have definitely clarified administrative responsibility so that you can now point out who is responsible for what and definitely put your finger on the person, the bureau, and the unit which is charged with carrying out the program in which you are interested.

We are trying to create one state agency and one county agency in each county which will, between them, handle all the problems of social welfare. I think you will be interested to know that, as a by-product of integration and consolidation, we have been able to reduce staff and overhead expenditures substantially. Whereas, previously there were some 425 to 450 people in the various state offices concerned with this general program we now operate on a stabilized staff of 275 people and we are getting broader service and we are making better use of the qualifications and abilities of those who are on our staff. Of course the reduction in administrative expenditure is in proportion. It is our aim to put your welfare programs on a business basis because I believe that the administrative performance of a welfare program should be judged by the same standards as the accountant applies to a private business.

In our approach to the medical problems in the field of welfare, all of us know the importance of sound administration; but we are also proceeding upon what seems to me to be a basic premise—that the way to solve the medical problems of a welfare program is through, by, and with the medical profession itself. Since we started operation of the newly created Division of Social Welfare, no policy and no principle affecting medical care in any of these programs has been made or released until it has been approved by our Medical Advisory Committee. And that, gentlemen, will be a fixed policy of that Division as we proceed to administer these programs through the coming years. (Applause).

Likewise important for your consideration, I think, is the fact that we base our administrative procedure upon the theory of decentralization. We believe in the soundness of participation by local persons, in a local community, in a local unit of government, in the responsibility for administration of the problems connected with a welfare program. And so we operate in this state very soundly, I believe, through eighty-seven county welfare boards. Wherever it is possible, decision and responsibility are turned back to the local unit of government to be exercised by local people with knowledge of local conditions. This fact is important in working out our medical relationships. Medical problems must be solved wherever possible, on the local level, also, and by local people. The interest of the state is to see that certain broad general principles hold throughout all counties so that there is no discrimination as between geographic divisions in the state; also to act as umpire if necessary to assist local people in solving disputes.

Thus we have created a structure made up of local medical advisory committees subject to general policies which are worked out through our statewide Medical Advisory Committee which meets regularly each month with us in St. Paul.

Notice I say "we have created a structure." I do

not say that we have found a panacea because I do not believe we are going to hit upon any one idea that will suddenly solve all of our welfare problems for us. We must expect to find the answers the hard way—and the hard way is to work out our problems, detail by detail, until, eventually, concentrated effort finds the solution.

We now move into the second part of our process—that of making the structure, which we have created, work. And it won't work unless we have the full co-operation and interest of the medical profession itself. The form, standing alone, is worthless. It only becomes valuable by your own participation and willingness to work. We think our structure so far is sound. We have made tremendous progress, so far, in local participation and in raising standards of performance. I have every reason to believe that much will be accomplished, likewise, in raising the levels of coöperation between county welfare boards and county medical committees.

You will perhaps be interested to know that we believe the work of our Division must be characterized by openness of mind. We are willing to face our problems squarely without pre-conceived opinions and biases. We want the opportunity to sit down with those who are interested in any given problem and arrive jointly at solution. We recognize, for instance, that the general practitioner is probably the person most concerned in the medical problems of the county welfare board and that reference of welfare clients to a specialist should come best through him, so far as beneficiaries are concerned. In all cases, we hold fast to the idea that medical problems ought to be answered by medical men and not by others in some other field of activity. Upon that basis, I'm here to ask your continued help and coöperation in working out our problems in Minnesota.

Frankly, I have been amazed at the response which has been obtained from medical men in the various counties and that kind of response, I know, will continue.

I often see statements to the effect that this set of circumstances and that set of circumstances represent democracy at work. To me that's a static concept. I would rather turn it around and put it this way. If we are to get anywhere, we must work at democracy and in the process of working at democracy we find that thing we seek. If you are willing to work with us, we may together improve the health and welfare of all of the people of the state of Minnesota.

Dr. Adson then introduced Dr. H. E. Hilleboe, Medical Coördinator of the Department of Social Security and Chief of the Medical Unit of the Division of Social Welfare.

DR. HILLEBOE: When our State Medical Advisory Committee was first organized, I was a little bit doubtful about asking the men to come down to consult with us too frequently. Mr. Finke shared my feeling and suggested that perhaps the Committee could meet every three months at the time of the Council meetings. It is certainly to the credit of committee members that one of them got up and said, "We feel this work is too important to sandwich it in with other medical work. For a while, at least, and for as long a period as necessary we should meet at least once a month." In the intervening months since November it has been possible to set up medical policies relating to the use of County Medical Advisory committees, to Old Age Assistance and to Aid to Dependent Children.

Now we have started on the tremendous job of looking into the program of medical care for relief clients, and, frankly, we wish to take about six to nine months to study this program from a medical as well as the welfare point of view.

Our field representatives have already begun to accumulate information from the welfare board side of the picture. They have been instructed to find out

from the county secretaries if the relationship in their counties with the medical group is satisfactory. If it is satisfactory, no additional information is sought. If it is not satisfactory, then we ask for additional specific information. We hope that by July first we shall have the information from each of the eighty-seven counties and, at that time, we are going to ask our Medical Advisory Committee to recommend to the Council that Mr. Rosell or some other representative go with me to the medical societies in each of the counties where there have been difficulties to try to get at the problem. By the end of the year, then, we hope to take the picture as seen by the welfare boards and the picture as it is seen by the medical societies and bring the two together. By that method, perhaps, we can find the misfits and do something about them.

It has not yet been mentioned that Dr. Chesley is an ex-officio member of our Medical Advisory Committee. His membership is very important because it means that in the development of our program we are not overlooking the important part played by the State Board of Health and its various divisions. It means, too, that there will be no duplication in the development and execution of the program.

It may interest you also to know that we have in our office the obligation of consulting with the Director of the Division of State Institutions and that, for the first time in the history of Minnesota, all of the medical work that is not under the State Board of Health is in one unit. To give you an example of just what that means: One of the first things we are going to study in the state institutions is the use of drugs. In 1938, for example, \$90,000.00 was spent for drugs in nineteen institutions. A preliminary survey showed, also, that over 900 different schedules were on the drug list. The question of whether all of the 900 are in the United States Pharmacopeia or in the New and Non-Official Remedies certainly needs investigating and this investigation will be part of a consultation service for the institutional program.

So far we have had excellent coöperation from all of the non-medical people in the Division of Institutions and the Division of Social Welfare.

There are three things to be considered in all these activities: First, the needs of the patients; second, the practitioners who will be available to render needed service and third—and equally important, the limitation of funds available. Thank you.

Dr. W. W. Will next introduced Dr. Chesley.

DR. A. J. CHESLEY: There was one title that was not read for Dr. Hilleboe, that is Assistant Surgeon of the United States Public Health Service. This is a very important title because it gives him an important relation with the United States Public Health Service, a relation which is essential to the kind of work he is doing.

Mr. Finke also has very important relations with the Federal government since a very large amount of money used in welfare work comes to the state under provisions of the Social Security Act. Mr. Finke is the one man who represents Minnesota at Washington on all these questions of relationship, and he takes his advice on all matters relating to medicine and also public health from Dr. Hilleboe. While Dr. Hilleboe was with the old State Board of Control he worked closely with the State Board of Health and we gained confidence in his judgment and admiration for the way he does things. We're very fortunate in having him, as an officer of the United States Public Health Service, here in the state in this position. Thanks, of course, to the Governor's recognition of his ability and of the unique opportunity presented of keeping him here in this dual capacity.

My part on the State Medical Advisory Committee is simply to listen in. I have no vote but I'm very glad to have the privilege of knowing what they are doing.

We have a very good Committee. I don't know if they are much better than the State Board of Health but, of course, they are all doctors and on the Board we have a variety.

The finances under which we operate in the Department of Health continue to come partly under Title V of the Social Security Act from the United States Public Health Service and partly under Title VI from the Children's Bureau. Congress makes the appropriations under the law at each session. In the case of the Children's Bureau, it is implied but not exactly stated that the Chief will consult state and territorial health officers before setting down regulations to govern their use. In the case of funds under Title VI, the Surgeon General is required by law to consult the state and territorial officers with regard to regulations governing allotments which he recommends to his superior, now Mr. McNutt, for adoption. In Minnesota, we use funds from both sources to pay some of the salaries of public health nurses, for instance, and our program is of necessity worked out between the Children's Bureau and the United States Public Health Service.

As you perhaps know, Congress amended the Social Security Act to require a merit system. Our State Civil Service Act fulfills the requirement so far as state employees are concerned but does not cover some of these local employees whose salaries are provided by Social Security funds. For these employees, then, we shall have to work out something to meet the requirements of the Federal Act or there will be danger of losing the aid allotted to Minnesota. Inasmuch as the same thing applies to employees of many county welfare boards, also, I have been waiting for Mr. Finke to take the initiative because the state receives, relatively, \$1,000.00 for relief and welfare purposes to ten cents for health purposes. Furthermore, the qualifications set up so far can well be met by anybody that we employ. Health officers have always been in favor of increasing the standards and requirements for public health workers. They have not been in favor of the use by federal authorities of the terms "you must, you shall, you will, or else," because, after all, at least a part of their money comes from the citizens of Minnesota.

The whole matter will come up for discussion at the Surgeon General's Conference in May and this is a very important session because a good many issues that really deal with state medicine in implication, though not in so many words, are likely to come up. Many of these issues seem of small immediate concern but they must be examined with consideration for the principle involved. I believe that some of the people who talk so much about broadening the social structure and the expanding needs of the public health forget that public health is merely a branch of medicine and that there would be practically no organized public health work in the United States if there were no medical organizations. As you know, it was the Minnesota State Medical Association which put through the bill providing for the State Board of Health in Minnesota. That was in 1872 and Minnesota was the third state to establish such a board. Members of the Board furthermore have been selected with very little idea of political advantage by our governors. We have distinguished medical men with no axes to grind on the Board. They receive no salaries; there are times when they get better than a sixty-five cent luncheon—that's when I can't get them into a place where I can give them a a sixty-five cent luncheon.

People like these who take the time to study our problems solely from the obligations of citizenship and their feeling of obligation to the profession are not going to go very far wrong in what they decide to do.

Tomorrow morning the members of our Board will meet with your Council and any questions which are brought up there and may need your attention will be brought to you. I take pride on being invited here

to talk to you and in having your confidence. I feel sure you can trust the Board to consider carefully all of the problems that the new programs present to them and to consult your Council before any new policies are established. As you know, we asked and received the sanction of the House of Delegates a few years ago to use the Council as an Advisory Committee to the Board on all matters of policy and especially on those related to aid secured under provisions of the Social Security Act.

In addition, a representative of your Association, Dr. Theodore Sweetser, faithfully attends every meeting of the executive committee of the Board. You will be interested in the fact, also, that we have Dr. O. O. Larsen of Detroit Lakes as president, this year, of the Minnesota Sanitary Conference. The Conference hasn't much money but President Larsen attends the meetings anyway at his own expense. I think we have a good man, there, too—reasonable, progressive and courageous. If he sees a point that involves a principle he fights for the principle regardless of who may disagree with him.

It seems to me that our public health program is in good hands in Minnesota.

Dr. J. F. Dubois made a report which was not recorded from the State Board of Medical Examiners.

Mr. John Pratt, Executive Secretary of the National Committee of Physicians for Extension of Medical Service, was introduced by Dr. W. F. Braasch. He spoke briefly but his remarks were not recorded. Dr. Braasch announced a luncheon meeting of the Committee to be held Tuesday, April 23.

Dr. W. W. Will called for a report from Dr. H. Z. Giffin, Chairman of the Council.

DR. GIFFIN: Dr. E. M. Hammes, Chairman of the Editing and Publishing Committee, reported to the Council today on the excellent financial status of MINNESOTA MEDICINE. There was a surplus this year of approximately \$1,600.00 and, after the supplement which you received with your January number was paid for, more than \$1,000.00 was transferred to the permanent fund.

The financial condition of the Association, as a whole, was also reported as excellent. The Fiscal Agency Account is now \$37,000.00 with a market value of something over \$35,000.00. The annual meeting last year showed a profit and the net surplus for the year 1939 was \$5,000.00 in spite of the fact that it was a legislative year and we had increased our office space and expanded our educational program. It was decided by the Council that the Finance Committee should use its own discretion as to disposition of this surplus. If it seems wise, the Committee will add it to the Fiscal Agency Account.

The action taken recently by the House of Delegates of the Oregon State Medical Society criticizing the exhibit sent by the Mayo Foundation and Clinic to the San Francisco Exposition and objecting, also, to the pictures and text which recently appeared in *Life* was discussed. The councilor for the First District presented the facts in connection with both matters and a committee of five consisting of three councilors, the president, the immediate past-president as ex-officio members was appointed to review them in detail and report to the Council and subsequently to the House of Delegates tomorrow.

Representatives of the three insurance companies, the Aetna, the Medical Protective and the Lumbermen's Mutual, which sell malpractice insurance in Minnesota, appeared before the Council and discussed their respective policies. The gist of these discussions will be summarized and presented to you later.

Dr. J. C. Hultkrans, Chairman of the Committee to Study Motor Vehicle Accidents, presented a preliminary report for his Committee which was accepted by the Council and which he asked me to present to you here. The committee reports the opinion that the specificity and reliability of chemical tests for the presence of alcohol in the blood has not been completely and satisfactorily established. They suggest, therefore, that no specific methods for testing volume of alcohol in blood and no specific percentages to determine intoxication be recommended for legislation at this time. They wish to go on record encouraging further studies looking to future legislation in this matter.

Dr. L. R. Critchfield, Chairman of the Committee on Vaccination and Immunization, presented a supplementary report for his Committee which was approved by the Council and will be presented to you later here. Dr. W. A. Coventry of Duluth and Dr. W. F. Braasch of Rochester were nominated by the Council for re-election as Delegates to the American Medical Association with Mr. J. C. Hultkrans of Minneapolis and Dr. W. L. Burnap of Fergus Falls as Alternates.

The statement of membership presented to the Council showed an increase of approximately 100 members since last year, and Dr. C. A. Hobbs and Dr. A. E. Booth of Minneapolis, Dr. Fred Sheppard of Hutchinson and Dr. D. P. Dempsey of Kellogg were granted Affiliate memberships.

It was voted to permit the Division of Social Welfare to use any records or surveys made by the State Association which are not of a strictly confidential nature, provided these records are presented through the medium of the State Medical Advisory Committee.

Dr. W. W. Will here called for the report by the Chairman of the Reference Committee on Medical Education reports, Dr. F. W. Lynch of St. Paul. The following committee reports were reviewed:

REPORT OF THE COMMITTEE ON DEAFNESS PREVENTION AND AMELIORATION

Your committee reports a noticeable increase in interest among the medical profession and laity in the problem of conserving the hearing.

A number of communities have recently for the first time included in their school health programs the periodic testing of their pupils by modern methods.

There has been an increased demand for lectures by public health, parent-teacher, nursing and public service groups for hearing surveys and information regarding the subject. This demand has been met by members of this committee. Numerous inquiries from school authorities for specific information concerning audiometers and hearing aids have been received and answered. The opportunities for more effective work in this field have never been as great as today. The recent release of reliable audiometers at a low cost, and of greatly improved hearing aids, which meet the requirements of the Committee on Audiometers and Hearing Aids of the Council on Physical Therapy of the American Medical Association for such instruments greatly increases the possibilities of attainment in this field of preventive medicine. Your Committee advises that in the prescribing of hearing aids or the purchase of audiometers for clinical use, members of this association will wisely choose instruments which have been approved as "acceptable" by the Council.

A careful study of the situation reveals increased recognition of the need of a practical program to be administered through the cooperative efforts of the State Board of Education, the State Board of Health, the State Public Health Association and the State Medical Association as the logical agencies whereby the hearing, especially of school children, can be safeguarded by means of periodic, standardized hearing tests and the application of needed corrective medical and educational care. This need is especially acute in rural areas.

Contrary to our former teaching, recent research has shown that hearing deficiencies for the higher frequencies occur often among young children and are frequently the first indication of ear disease resulting from tubal obstruction. If undiscovered and uncorrected, this leads to hearing deficiencies of a handicapping degree. This fact emphasizes the importance of translating recently acquired knowledge of ear diseases into legislative and administrative action as has been successfully accomplished in several other states and in many local communities.

Your committee at the present time in cooperation with interested agencies, is working on a tentative, practical program whose application will meet the existing need in Minnesota. The active interest of every medical man will be

needed to help put such a plan into action as a public health measure.

We respectfully recommend that in keeping with its larger field of activity, the name of the committee be changed to read "The Committee on the Conservation of Hearing."

We further recommend that the committee be enlarged, subject to the approval of the President and the Council, by the appointment of interested physicians as additional members from different parts of the state, to more effectively carry on its objectives in their respective communities.

HORACE NEWHART, M.D.

COMMITTEE ON SYPHILIS AND SOCIAL DISEASES

No significant change has occurred in the last year in Minnesota's fine venereal disease program. New funds allotted the State Department of Health have been used to finance special postgraduate courses for physicians; but the services of the State Department of Health have continued along their well-established lines and no new programs have been brought to the attention of the committee.

The effectiveness of Minnesota's program has been reflected in the steadily decreasing incidence of venereal disease in the state. The committee stands ready to advise on any matter that is brought to its attention but sees no need for the present for any special campaign for the control of either syphilis or gonorrhea in Minnesota.

WALTER E. HATCH, M.D.

REPORT OF THE COMMITTEE ON VACCINATION AND IMMUNIZATION

It has been pointed out in studies of comparisons of death rates made by the Bureau of Medical Economics of the American Medical Association that diphtheria mortality provides a fairly accurate measure of the efficiency of the medical profession in any county or community. Government public health agencies may well be expected to use just such a measure in evaluating medical service in a given community.

By that measure the medical profession of Minnesota has made a fine record for itself. The death rate last year was 0.3 per 100,000 population, while the rates in many German cities rose to 11 per cent and more.

There is another way to look at the situation, however, and that is that even one diphtheria death is unnecessary and could be prevented if every medical society in the state were launched upon a regular annual program of immunizing and vaccinating the children of its community.

The smallpox situation is undoubtedly more serious than the diphtheria situation, since there has been a gradually rising smallpox case and death rate over the last few years in Minnesota. At the same time, the absence of any major smallpox scare since 1924 has lulled many people into neglect of vaccination. An epidemic of malignant smallpox at this time—and such an epidemic is more than a possibility—would find many people unprotected.

The responsibility for preventing such a catastrophe and for reducing our diphtheria death rate to zero in Minnesota CAN BE AND SHOULD BE assumed by the medical profession. This has been the established policy for many years of the Minnesota State Medical Association and the policy was reaffirmed this year with the creation of this committee by the Council.

It is well known, of course, that a large number of our societies have been regularly engaged in immunization programs for some time. In many cases, the programs are well established and working satisfactorily. In some other communities the physicians have done the work sporadically and unsatisfactorily both to themselves and the community because of the lack of well-coordinated working plans or because no funds were available to pay for service to indigent children of the community or for some other reason which proper organization might have removed.

The results of community protections of this sort are so obvious and so dramatic that every American community will eventually demand them, and it is certain that, if the physicians of the community do not set the program in motion, government agencies will come in and undertake the work.

Therefore, it is the object of this committee to promote county and district medical society programs for immunization and vaccination in every community wherever such programs are not already in existence and working effectively.

A survey of all societies to see what is already being done and what the immediate needs may be is already under way. The committee is also studying model community plans including preparation and management, actual procedures, fees to be charged, etc., to give to any society that requests it as an aid to establishment of new programs. It is hoped that a report on the survey may be ready soon and that, as a result of this new effort, no child in Minnesota will reach school age without having been offered the opportunity for protection against these two scourges.

In the meantime, members and society representatives are invited to write to this committee for any information the committee may have in its files on this subject and also for speakers at their own meeting or for public groups in their communities.

L. R. CRITCHFIELD, M.D.

REPORT OF COMMITTEE ON MATERNAL WELFARE

A request was received through Dr. Adams for obstetrical information for the State Department of Highways and a letter was sent to Mr. Eldon Rowe, Chief Highway Patrol Officer,

outlining the directions and instructions for highway patrolmen when a baby is born on the highway. This information has been sent by Mr. Rowe to all patrol officers with instructions that it be kept in a convenient place for reference if such emergency arises.

Mention is made of the coöperation between the State Maternal Welfare Committee and the State Department of Health relative to the changes in the birth and death certificates; as yet this work is not completed but we feel that much valuable improvement will be made when the Division of Birth and Death records and Vital Statistics of the Department of Health have completed this work.

RUSSELL J. MOE, M.D.

REPORT OF THE COMMITTEE ON OPHTHALMOLOGY

Optometrists have been very insistent of late upon development of a system for testing the eyes of automobile drivers on the highways.

They have appeared before the Safety Council with their program and also before the Safety Division of the State Highway Patrol.

No action in favor of their program has been taken by either agency as a result of efforts of this committee and the State Office. We have been assured, in fact, that nothing of the sort would be approved or incorporated in their program.

Changes in the Drivers' License Law are being considered, however, and a sub-committee of the Committee on Traffic Legislation of the Minnesota Safety Council is now being formed which will consider all of the medical factors involved in safe driving. In connection with the formation of this sub-committee, Mr. W. F. Rosenwald, chairman of the Traffic Safety Section of the Safety Council has asked us to appoint an oculist to act as medical representative and as sole consultant on vision and eyes for that committee.

J. S. REYNOLDS, M.D.

REPORT OF THE COMMITTEE ON HOSPITALS AND MEDICAL EDUCATION

The work of this committee has been concerned entirely with the Coördinated Medical and Public Health Program which is now in its second year.

Subjects for the new year were chosen at a general meeting of committee chairmen and officers of the association and were designed to confine the fields of discussion within narrower limits than the subjects of the first year.

The same general plan has been followed as before in assembling materials for the monthly packets. Wherever possible, statistical studies have been supplied by the State Department of Health and these studies, based upon the latest figures available, have been among the most illuminating and valuable of all the contributions to our packets.

New and well-written popular pamphlets such as those prepared by the Metropolitan Life Insurance Company have been secured whenever they were available and appropriate reprints have been purchased from time to time from *Hygeia*.

Considerable material prepared for recent courses at the Center for Continuation Study has been made available through the courtesy of the Department of Postgraduate Education at the University of Minnesota. This material is new, comprehensive, and authoritative, and it has greatly enhanced the value of our packets. In addition to these sources of material we have drawn several times upon our members for material, some of which was prepared especially to cover some important phase of the month's subject.

It was possible to secure, also, the valuable compilation of the Vitamin series, published last year in the *Journal of the American Medical Association* for those who requested the December packet. The volume was contributed to the packet by Mead Johnson and Company, and the Committee wishes to express its thanks not only to this company but to all the above who contributed so much to the interest and value of the packets.

That the packet is popular is amply proved by the growing number of requests for it. The monthly average is well above 250, and February requests totalled 300, and March requests exceeded 400.

Requests for speakers on the subject of the month have been handled through the Speakers' Bureau. The offer which has appeared in the newspapers each month in connection with announcements of the program to provide speakers for any interested organization has met with a surprising response and every effort has been made to provide well qualified speakers.

A considerable amount of newspaper publicity has accompanied each change in program, in addition to the regular weekly news stories all dealing with phases of the subject and released from the State Office.

Inquiries about the program have been received from many quarters outside the state, and United States Public Health service representatives in Washington are watching its progress with interest. They have particularly commented on the fact that it represents a practical coöperative effort between the state health department and the physicians in which both unite in an effective program under medical sponsorship.

Judging by more than a year's experience with the program, as well as by the interested comments of these on-lookers, the Minnesota State Medical Association appears to be well on the way in this program to the development of a most significant and far-reaching program.

A. H. WELLS, M.D.

REPORT OF THE COMMITTEE ON DIABETES

I wish to submit the report of the Diabetic Committee for the year 1940.

The new pamphlet *HOW TO MAKE DIABETES HARMLESS* has been revised, and has been released from the press. There are many changes in this new pamphlet. The diets are more liberal in carbohydrates, and there is more specific information in regard to insulin reactions. We have definitely described the reactions caused by protamine zinc insulin in contrast to those of regular insulin.

ARCHIE H. BEARD, M.D.

REPORT OF THE COMMITTEE ON CANCER

The work of the Committee on Cancer has been largely advisory during the last year. The chairman has served on the Executive Committee of the Women's Field Army of the American Society for the Control of Cancer, has provided speakers for meetings held under the auspices of the Field Army, and has supervised and approved educational material distributed through the women's organization.

This general supervision of public education material on cancer serves to standardize and coördinate our teaching about cancer and to avoid unfortunate conflicts in statements which have been made by public speakers in the past.

The committee has also advised with the Committee in Charge of the Coördinated Medical and Public Health Program in preparation of material for the packet on Cancer of the Digestive Tract, the subject for the month of April.

Inasmuch as April is also the month of the annual membership drive of the Women's Field Army, this choice of subject is particularly opportune and should serve to emphasize in the public mind the close coöperation now existing between the physicians and the Women's Field Army.

The fact that more and more cancer cases are coming in the early stages for treatment is proof enough of the soundness of a program of public education in elementary facts about cancer. This program should be fostered in every possible way as one of the best means open to us for controlling the cancer scourge.

M. W. ALBERTS, M.D.

DR. LYNCH: In conformity with the request of the Committee on Deafness Prevention and Amelioration, of which Dr. Horace Newhart of Minneapolis is Chairman, the Reference Committee suggests that the name of the Committee be changed to Committee on Conservation of Hearing and also that the Committee be enlarged. This Committee is asking for continued coöperation with the Committee on Public Health Education. He also requests, and the Reference Committee agreed, that all or a part of a monthly packet should be devoted to the subject of conservation of hearing. If only part of a packet is used for this purpose, the other part might well be used for the subject of conservation of sight. Speakers for county medical society meetings will be provided by Dr. Newhart's Committee. The Reference Committee recommends that this report be accepted.

A little addition was made to the report of the Committee on Syphilis and Social Diseases by the Reference Committee, calling attention to the fact that the State Department of Health has offered to diagnostic laboratories throughout the state the opportunity to coöperate in a program for evaluation of sero-diagnostic tests for syphilis. The results of the tests are to be confidential but members of this House should be informed of the plan. The Committee recommends that the report be accepted.

The report of the Committee on Vaccination and Immunization submitted is also recommended for acceptance. If the physicians themselves do not set a program of vaccination and immunization in motion, government agencies will come in and undertake the work. A tentative outline of procedure is supplied in the report. The Reference Committee recommends that Dr. Critchfield, the Chairman, be given an opportunity to present the program to the Delegates and pointed out the rising incidence of smallpox and the neglect of vaccination which has preceded and accompanied this increase.

Dr. W. W. Will then called for a supplementary report from Dr. Newhart.

DR. NEWHART: We bespeak the coöperation of all of you in bringing to the men in the individual county societies essential knowledge about the prevention of

unnecessary hearing loss. It is only by this means that we can bring our membership up to date on certain fundamental principles, some of them learned only during the last few years. Most of us, even including some of our Otologists, are today living in the horse and buggy stage and we must help our members bring themselves up to date before we can educate the public on these matters.

Dr. W. W. Will then asked for supplementary reports from Dr. D. W. Wheeler, Chairman of the Heart Committee; Dr. R. J. Moe, Chairman of the Committee on Maternal Welfare; Dr. J. S. Reynolds, Chairman of the Committee on Ophthalmology, and Dr. L. R. Critchfield, Chairman of the Committee on Vaccination and Immunization.

DR. L. R. CRITCHFIELD: The Committee on Vaccination and Immunization has made its first report to the House of Delegates. An outline for the County Medical Societies, who wish to carry on immunization campaigns against diphtheria and smallpox, has also been prepared for your approval. Before I read this outline to you, I should like to call your attention again to the fact that prevention of disease should be considered a community undertaking and responsibility. Doctors who do vaccination for fifty cents apiece in group immunization programs are performing a community service, and that fact should be clearly understood by the people of the community. If the work is done at these reduced fees in groups at schools and other convenient centers, there will be very little danger that people will confuse this community service with private practice in the doctor's office, and very little opportunity for the complaint, "You gave my child a vaccination for fifty cents, why should you charge me two or three dollars for some other hypodermic treatment?" In any case, vaccination and immunization of the children is a community undertaking in which many community organizations should cooperate, and which should be regarded by all as an essential part of the health protection of the community.

I. The local medical society should decide to institute and carry on a program of Immunization and Vaccination against diphtheria and smallpox. (*At a meeting of which advance notice is given to the members.*)

It is recommended that county organization be carried out in furthering the program. If several counties form one district a county club may be formed.

Some local newspaper publicity may be given to this action of the medical society.

II. The local medical society should appoint a Committee (*not temporary*) whose duties should include the following:

- A. Appraisal of number of children in the community.
 1. Those not immunized (*requiring immunization*).
 2. Those already immunized.
- B. Appraisal of resources for carrying on a program of immunization.
 1. Physicians—all members of the county society who so desire should be called upon.
By making this an undertaking of organized medicine, a means of controlling cut-rates and chiseling is at hand.
 2. Lay assistance—Various agencies should be called on to assist in the Program—such as the Parent-Teacher Association, the Red Cross, the Legion Auxiliary, Civic Clubs, the County Public Health Association, etc. The decisions as to the number of organizations should be reached early, but all who are interested should be invited.
 3. Public Health agencies should include, State Board of Public Health, District Health workers, and Public Health nurse of the county.
 4. Centers for work if group immunization is carried out. (This must be decided by the society or by the committee.)
 5. Publicity—
 - a. For the immediate undertaking.
 - b. For general health education.
 - c. For the medical profession.
 6. Financial resources—It may be well to consider this phase of the problem when selecting lay aid.

III. The local medical society or its authorized Committee shall decide—

- A. Whether immunization shall be applied in groups or individually in physicians' offices.

B. Immunizing material to be used—

1. smallpox—standard virus
2. diphtheria—
 - Plain (formalin toxoid) 3 doses at 1 month intervals
 - Alum toxoid 2 doses at 1 month intervals
 - Alum toxoid 1 dose
 - Alum toxoid 2 doses is, at present, considered to be the most effective material. (Comm. Evaluation of Administration Procedures—Am. J.P.H. March 1940.)

C. Age of children to be immunized—

1. Smallpox vaccination may be performed at any age.
2. The common practice at this time is to commence diphtheria immunization at 6 months of age.
3. It is recommended that a Program to immunize all children from 6 months to 10 years be undertaken at as early a date as possible. When this is accomplished, the effort required each year to maintain an immunized group will be much less.
4. Under 10 years of age 2 doses of Alum Toxoid one month apart are recommended.
5. Over 10 years of age 3 doses of (Plain) Formalin Toxoid one month apart are recommended.
6. The use of the Schick test may be dispensed with in group immunization work. It may be used for private patients if desired.
7. If a child has been immunized in infancy it is recommended that a single dose $\frac{1}{2}$ the size of the original immunizing dose be given when he enters school.

IV. The local medical group may request from this Committee a packet of materials used in various parts of the state including samples of letters, cards, etc., and suggestions for carrying on the program. The Minnesota State Board of Health will lend assistance freely in organizing a program.

V. Preliminary Contact work with lay groups includes—

1. Selection of lay assistance.
2. Assignments of locations and dates.
3. Publicity—
 - a. newspapers
 - b. schools
 - c. letters
 - d. blanks: 1. request for immunization (sent to parents).
 2. permanent records.

VI. Fee to be charged should be decided by local society. Refer to this Committee for suggestion as to fees.

VII. Set up for continuance of Immunization Program from year to year.

It appears to be true, at the present time, that group immunization has been more successful in reaching a high percentage of children in a community, than individual immunization. Nevertheless, some county societies are successfully carrying on Individual Immunization programs. It is evident that lay cooperation is most essential for the success of either method.

This Committee is prepared to render assistance to any local medical group who desire to carry on a thorough program of immunization, whether it be on a local basis or group basis.

DR. W. W. WILL: What do you wish to do with the supplementary report by Dr. Critchfield on Vaccination and Immunization?

DR. T. H. SWEETSER: Mr. Speaker. It seems to me that Dr. Critchfield's remarks represent a distinct change from the attitude of the Committee on Public Health Education on immunization and vaccination. If I remember rightly, the Committee on Public Health Education believes that preventive medicine should take a larger and larger part of the physician's time, but that all the work should be done, if possible, in the doctor's office. I recognize the difficulties involved in getting people to go to the private office of the physician for immunization in these programs. But it seems to me that a distinction should be made between the work that is done in these clinics and groups and the preventive work that is done in the private office of a physician, particularly the pediatrician.

DR. W. W. WILL: I wonder if there are any men here from the country who would like to talk about their experiences. I know that some of you have been asked to do this work for ten cents for vaccination and some for twenty-five cents. . . . If not, I will call on Dr. Barr to discuss the matter.

DR. R. N. BARR: I think that most of you have heard Dr. Sogge tell how they have handled immunization in his county. Of course, anything that I may

say on this matter represents only my personal reaction. We have checked through many reports, however, on immunization campaigns carried on in groups and otherwise, and we find that a much higher percentage of children is immunized under the group plan. I think we all recognize the importance of the question of contact between the individual physician and his private patients. The only solution I personally see for this matter is for the medical society to take up the immunization program as a part of its own program and as a part of its own contribution to the community health.

Beltrami County has done it for a number of years. They have charged a minimum, I believe, of fifty cents for each vaccination and seventy-five cents if a dose of toxoid is included. The funds thus earned went to the County Medical Society and the work was not done as a part of private medical practice. If the individual desires private service, he goes to the doctor's office and pays the regular fees. The result has been a very high percentage of pre-school and school children immunized against diphtheria and vaccinated against smallpox.

In many other communities, where there has been no comparable set-up, the doctors have got together and made plans but, unfortunately, two or three years have passed before they came to an agreement on the type of a program that they wanted to put on. And often it was not until the third year that the work was done. This is not a criticism of physicians but the fact is that the public is criticizing them because the large majority of our children is not immunized in Minnesota. The children are going to be immunized and it seems to me that the best solution is for the County Medical Society to do it. If the County Medical Society carries on a group program in the schools, then the work will be divorced from the individual practice of the physician in his office. Also there will be no question of cutting fees.

There are many other advantages in this type of program. In the first place, it does strengthen the relationship between the medical society and the people in the community. In addition, it puts a fair amount of money in the medical society's coffers to be used as the physicians see fit. Also it gives the County Medical Society leadership in this work and the State Board of Health and other groups, who are working for preventive medicine, can aid in the development of the program. It will put us in the position of helping the medical society to do the work. We should be able to provide sample cards, sample letters, and many other types of material to be used at the direction of the doctors in their own community. I think that it should be clearly understood that the State Department of Health does not wish to carry on these programs and will not do so in Minnesota. The physicians themselves must do this work.

DR. J. P. McDOWELL: We carried on the work in the schools in St. Cloud. Different doctors came out at different hours so that all had about the same amount of work to do. The money was turned over to the doctors who did the work, but the program did not reach the children in the country. I don't believe that we could get the country children in to be vaccinated and immunized unless we have a nurse or somebody to go out and round them up.

DR. E. S. PLATOU: I would like to say one word about this matter. Mr. Finke and his Division of Social Welfare are trying to decentralize the program of relief. It seems to me that this program of immunization should be decentralized in much the same way. The particular method to be employed in each community should depend largely on the conditions in that community.

The most important thing seems to me to be that we should coordinate all existing facilities to do this

work, and try to do it periodically, at the same time each year. These should be community campaigns, not state-wide campaigns. They should have the advice of the State Health Department and the County Medical Advisory Committees; of the County Welfare Boards as well. But every effort should be made to publicize the need of the thing to the people.

DR. L. L. SÖGGE: I think the important thing, as Dr. Barr and Dr. Platou said, is to get the work done. Our Southwestern Minnesota Medical Society is composed of four counties, a medical club in each of these counties. Each of these medical clubs get together and agrees on the plan for our immunization program.

In our county, there are 3,500 students. The county was divided for the purposes of the program into twelve stations, and this year we put on our third vaccination and immunization program. We have reached about 78 or 80 per cent of the school population, and about 50 per cent of the pre-school population through these programs. We divide the work up among the doctors who are nearest the stations selected. For instance, the doctors in Westbrook take all the school-houses near Westbrook; the same plan being carried out with all the towns in the county.

A certain time is set and the doctor goes to the schoolhouse selected. Mothers of pre-school children are informed that they must bring their children to the school at that time.

We get the assistance of the Farm Bureau people, the Parent-Teacher Association, and the superintendents of schools. We meet with the teachers in the fall and tell them what we are going to do and ask their cooperation.

People who can pay the fifty cents apiece for each child; if they have both immunization and vaccination, they pay one dollar. Those who don't want to pay or cannot pay are cared for through the Red Cross. There are no "ifs or ands" about it. The teacher keeps the record. The doctors in the county have, on the average, made better than \$25.00 an hour for the time they have spent at this work. We feel that that is all the pay we farmer doctors are entitled to.

I want to call attention also to the program of Mantoux testing for tuberculosis that was carried on last week and the week before by Dr. Slater, who is our Superintendent at the Southwestern Minnesota Sanatorium. For this campaign, we had places selected in the county and all the children were brought to those places. We had a splendid response.

DR. D. S. BRANHAM: It seems to me that the children of indigent families and of recipients of Social Security Aid should be given immunization and vaccination if they wish to take advantage of it. These children form a large group in the rural areas, and I do not see why the county relief board should not be able to authorize a fee for immunization just as they authorize a fee for other medical attention. I think it would be easier to handle the people who can afford to pay if the relief group could also be immunized.

DR. B. C. FORD: It might be encouraging to some of the men here to know that we have been quite successful in our county in having this work done in the doctor's office. The record would show that we take care of nearly 80 per cent of the children and we get one dollar for each immunization and each vaccination. I think we reach a large percentage of the children out in the country as well as in the city. We have carried on this program for about five years. Our Parent-Teacher Association works with us very cooperatively and is very strong, and this may have attributed largely to our success.

DR. W. W. WILL: Mr. Rosell, our Executive Secretary, says that he will take up the matter of financing

immunization and vaccination for the relief clients with the Welfare Board.

It was moved, seconded and carried that the supplemental reports of the Committee on Vaccination and Immunization be accepted.

It was moved, seconded and carried that the report of the Reference Committee on Medical Education reports be accepted.

Dr. W. W. Will then called for the report of the Reference Committee on Miscellaneous Scientific Reports, of which Dr. A. E. Cardle of Minneapolis was Acting Chairman. The following committee reports were reviewed:

REPORT OF THE COMMITTEE ON INTER-PROFESSIONAL RELATIONS

The Committee on Interprofessional Relations had its first meeting this year in Minneapolis, January 26, 1940.

At this meeting were representatives from the Hospital Association; Pharmaceutical Association; Dental Association; Nurses and Medical Auxiliary. All representatives were enthusiastic over the idea of having close contact with the medical profession.

They all approved of having an opportunity of sitting in with representatives of the medical profession for discussion of matters common to all. Some of the problems of the various professions were discussed. Government control was one of the main topics of discussion. All seemed to agree that to prevent this was our greatest problem.

It was the hope of those present that this relationship of the various professions be made state-wide. At the Secretaries' meeting in St. Paul, February 24, 1940, this group met at breakfast and again discussed the same problems. We also listened to representatives from various parts of the state where such meetings had been held in the past.

A plea was made at this time for each county secretary to make an effort to get representatives of the various professions together in his locality for the discussion of these same problems.

It was decided at our meeting in St. Paul to send out a questionnaire and a group of suggestions to each county secretary for his guidance in establishing local interprofessional groups.

J. M. HAYES, M.D.

REPORT OF THE HISTORICAL COMMITTEE

Your Committee held one meeting last year at which the work of the Committee was discussed. No new work has been undertaken this past year except preparing the material on hand for printing in MINNESOTA MEDICINE. A committee at Rochester, however, is preparing a history of medicine in Olmsted and the adjoining counties which no doubt will be available sometime this year. Your Committee has on hand sufficient material to furnish copy to MINNESOTA MEDICINE for the next two years. A number of the members of the Association and others have sent in additions and corrections to the material already published which will, at a later date, be added to the history. For this we are grateful. Your Committee hopes that others may send in corrections or additions if other corrections or additions should be added. Questionnaires have been sent by the Secretary of the Association to each member requesting biographical information. About 800 of these have been returned. As this material will be of great use to future medical historians it is hoped that those who have neglected to return the material will do so.

The Committee wishes to call your attention not only to the historical material published in MINNESOTA MEDICINE, but also to that which has appeared in *Minnesota History* and the *Journal-Lancet* in the past and present year.

J. M. ARMSTRONG, M.D.

REPORT OF THE COMMITTEE ON MILITARY AFFAIRS

1. *Commissioned Personnel.* Physicians holding Army and Navy Commissions in the State as of recent date are as follows: Army—608; National Guard—21; Navy—51. This is slightly below the number of last year.

2. *Legislation.*

During the past year, training for 50 flight surgeons, five from each Corps Area, and five from the Surgeon General's Office has been made possible. This provision is a decided step in the right direction as in the Annual Report of 1938, there were very few Medical Reserve Officers being trained who had completed the required correspondence courses necessary for appointment to a flight surgeon training school. Several schools have been established for such training since the last report.

The War Department has recently announced the appointment of 30 medical reserve officers for commission in the Medical Corps of the regular army as a result of examination held in December, 1939. There is a definite shortage of medical reserves for active duty service and for that reason there should be efforts to enlist the interest of recent graduates of the medical schools to take out commissions.

CCC Medical Reserve Officers serving with CCC units since December 1, 1939, have had a change of status from Reserve Officers to that of a civilian. However, the physician must be recruited from the Medical Reserve Corps so far as pos-

sible. The number of CCC Companies have been reduced, yet Army authorities have had difficulty in supplying the existing units with medical personnel.

There are two bills to be presented at this Congress regarding first, uniform allowances, and second, pay allowance for inactive status training. These bills, especially the latter one, should have the support of all medical societies as under the existing law no provision is made whatever for compensating Medical Reserves who wish to attend Inactive Status Training Units at which military medicine is emphasized. The officers not only sacrifice their practice but incur additional expense and in justice to their patriotic duty the Government could well afford to show its appreciation by contributing an allowance to offset their outlay of expenditures.

3. *War Department Ruling regarding Appointments.* By a recent enactment of the War Department, all appointments have been discontinued except in the Medical Service and Air Corps.

4. *Activities.* The Eleventh Annual Medical Military Inactive Status Training Unit was held in Rochester under the auspices of the Mayo Foundation, from October 8 to 22, 1939. The School was well attended, 269 officers registering from 45 States. The principal instructor of the school was Colonel Kent Nelson, The Surgeon Seventh Corps Area, Omaha, Nebraska. The instructor for the navy was Captain Ernest W. Brown, Medical Officer of the Navy Yard, Brooklyn, New York.

F. L. SMITH, M.D.

REPORT OF THE COMMITTEE ON FRACTURES

A Committee on Fractures of the Minnesota State Medical Association has now been appointed each year for several years and is considered as a necessary committee in our organization. The fracture problem is important for several reasons. Fractures are on the increase and will probably continue so as the speed of our existence increases. With the increase in the number of fractures and the increase in the general knowledge of fractures there is an increase in the public's expectation and demands from our profession in the treatment of fractures. When we recall the teaching in fractures which we received in medical school we have to admit that our knowledge of fractures has for the most part been gained since graduation. In addition there is a continuous improvement in our knowledge of fractures, and inasmuch as fractures occur everywhere and at all times it is important that the State Medical Associations endeavor to meet the demands of the fracture problem through a permanent set-up as the Committee on Fractures.

The Committee on Fractures for 1940 has been greatly enlarged. There has been at least one member appointed from each of the component medical societies of the State Medical Association. It has been the intention to have a local committee on fractures appointed in each of the component medical societies. The members of these local committees are chosen from those who are interested in fractures and who are also willing to work as members of the local fracture committee. Where the component medical society comprises more than one county it is hoped that there will be at least one member representing each county and similarly that there will be a member representing each of the larger communities in the different counties. The chairman of each of the local fracture committees should logically be a member of the state fracture committee.

The work of the State Committee may be divided into two parts. The first part has to do with the annual meeting of the State Medical Association. It may arrange for papers on fractures to be presented by members of the State Medical Association at a symposium on fractures which may be presided over by the chairman of the State Committee. The Committee may arrange for an address on fractures to be presented by a speaker from outside the state. The Committee may also arrange for an exhibit on fractures to be presented at the annual meeting of the State Medical Association, this exhibit to be preferably arranged by the local committee of the county entertaining the state meeting. At this exhibit first aid and transportation methods of handling fractures of the long bones and of the neck and spine should be presented for some years to come. Methods of studying fractures with the x-ray may be presented. Equipment for the treatment of fractures in hospitals particularly and also in offices and homes may be presented. Anatomical problems connected with fractures may be shown. Pathological studies may be presented. Physiotherapy exhibits may well be placed near the fracture exhibit. Methods and results of treatment of special fractures may be exhibited. Individual fracture exhibits may be encouraged and placed next to the committee's exhibit. Also the Committee may arrange a moving picture exhibit on fractures. There is one movie recently purchased by the State Association on "First Aid and Transportation of Fractures of the Long Bones." Another available movie on "First Aid and Transportation of Fractures of the Neck and of the Dorsal and Lumbar Spine" could be advantageously shown. Other movies of fracture subjects are obtainable.

The State Committee on Fractures could hold two committee meetings each year. One meeting should be held early in the year shortly after the Committee is appointed, and the second meeting could be held as a breakfast meeting during the annual meeting of the State Association. At the first meeting the duties of the Committee could be discussed and planned, and at the second meeting, reports of progress and experiences could be presented.

The second part of the work of the State Committee consists of the work of the individual members on the Fracture Committee in each of the component medical societies. Too

often the bad results obtained after the treatment of fractures are the result of several different factors over which the doctor may have no control. The medical profession is often criticized for these bad results and malpractice suits occasionally result.

The local Fracture Committee could arrange an annual meeting of the component society devoted to fractures. The following subjects might be presented at such a meeting:

1. "First Aid and Transportation of Fractures of the Long Bones."
2. "First Aid and Transportation of Fractures of the Spine."
3. "The Diagnosis of Fractures With the X-ray."
4. "The Minimal Equipment for Hospitals Caring for Fractures."
5. "Anatomical Problems Occurring in Certain Fractures."
6. "Pathological Problems Occurring in Fractures at the Time of Injury and in the Process of Healing."
7. "The Treatment of Individual Fractures."
8. "The Treatment of Compound Fractures."

When a patient receives good first aid and good transportation with proper splinting and the doctor has only to treat him for the damage produced at the time of accident he can get a better result in the treatment of the fracture. The local Fracture Committee may obtain from the State Medical Association the 16 mm. movie film demonstrating the application of traction splints for first aid and transportation of fractures of the long bones. Also the State Medical Association will soon have available a movie film demonstrating the handling of fractures of the cervical spine and also of the dorsal and lumbar spine. These movies could not only be shown to the members of the component medical society at the annual fracture meeting, but they could be shown to lay groups such as the Boy Scouts, Girl Scouts, Red Cross groups, policemen and firemen, highway patrolmen, ambulance companies and undertakers who operate ambulances, to first aid groups in industrial organizations and to general groups such as church organizations, lodges and local movie houses. The splints are obtainable from one of the ambulance companies in Minneapolis, and it is advisable to place them in as many places as possible where they may be of service. It is also advisable to place them in local hospitals for exchange when splinted patients are brought in. For this reason the splints should be standardized and inexpensive.

If the doctor is given a patient who has received good first aid and transportation, and if he is also given a proper set of x-rays of the fracture giving him the diagnosis in an understandable manner he can treat the fracture better and get a better result. A set of instructions for the guidance of technicians for the proper x-raying of fractures from a surgical standpoint is available. These instructions tell only the number and direction of the required views, the size of films to be used in order to show a proper amount of the skeleton which may be involved in the different common fractures, when to use the Bucky diaphragm and when to use stereoscopic views in order to give necessary diagnostic assistance from a surgical treatment viewpoint. The local Fracture Committee could endeavor to get such standardized instructions into the hands of x-ray technicians in their respective areas.

When the doctor has a fracture which has been given good first aid and transportation and which has been adequately x-rayed and when he has the necessary equipment with which to treat his fracture in the hospital he is well on the way toward getting better results in his fracture treatment. The local Fracture Committee can study the facilities in the various hospitals in their respective areas and make recommendations as to equipment which should be available. This should include good plaster, equipment for overhead suspension of fractures, for skeletal traction, portable x-ray equipment, inexpensive splints for upper and lower extremities, and a Gatch bed for the reduction of fractures of the spine. Demonstrations in the use of this equipment could be presented at the annual meeting of the component medical society and at hospital staff meetings and other medical meetings.

At the annual fracture meeting of the medical society, different papers on the different types of fractures could be presented by the different members, and also an outside speaker might be obtained as was done at the March meeting of the Hennepin County Medical Society which was devoted to fractures. There are two related subjects which could be profitably presented. A paper on anatomical problems arising in the treatment of fractures might be very valuable. The pathological conditions arising at the time of injury and the pathology of the healing of fractures is a subject which is receiving increased interest and attention.

The fracture problem is one of the most serious that is confronting the medical profession today, and the number of cases will not only not be reduced but will probably be increased so long as the speed of our existence is increasing as it is today.

The treatment of fractures at the present time is largely a postgraduate problem. Annual meetings devoted to fractures in the county medical societies and frank discussions of the problems connected with the treatment of fractures should reduce the number of malpractice cases which are too frequently arising. The bad results which cause malpractice cases are too often the result of factors which were beyond the control of the doctor treating the patient. If the local Fracture Committees could eliminate these factors in their communities they would not only improve the welfare of the people in general, but they could also improve the general status of the medical profession. In that connection Dr. Adams has stated

that active efforts on the part of the local Fracture Committees should furnish one of the best answers to those who would advocate socialized medicine.

The first problem of the State Fracture Committee and of each local fracture committee is to see that every fracture case anywhere in Minnesota gets good first aid and transportation no matter where the accident takes place, that satisfactory diagnostic x-ray pictures are taken and that all hospitals have a minimum standard equipment for the treatment of the more common fractures.

R. C. WEBB, M.D.

REPORT OF THE COMMITTEE ON INDUSTRIAL HEALTH AND OCCUPATIONAL DISEASES

This new Committee was appointed by President B. S. Adams to study the above named fields. Several members of the Committee attended the 2nd Annual meeting of the National Committee of the same name held under the auspices of the American Medical Association at Chicago in January, 1940. Dr. Carl M. Peterson, National Secretary in charge of this work visited the State February 24 and discussed this field with other members of the Committee.

A meeting of the Committee together with Mr. F. Manley Brist, Dr. A. J. Chesley, Dr. R. N. Barr and other interested officials was held in the Saint Paul Hotel March 30. A report of that Committee meeting is appended.

It is felt that the Committee has made a good start, but no definite recommendations can be made without further study. This will be followed through and reported on by the end of the year.

J. LAWRENCE MCLEOD, M.D.

Extract of Minutes

The Committee on Industrial Health and Occupational Diseases meeting, March 30, 1940, St. Paul:

Need for this Committee to study occupational diseases is shown in the large number of lawsuits started in St. Louis County pertaining to silicosis in which doctors have been testifying on opposite sides. As a result, juries do not consider the testimony of the doctors at all. A committee to study the occupational diseases and industrial hygiene of the state would tend to clarify this situation.

It was pointed out that there are 34 different types of conditions in the law of Maryland which the Minnesota law does not cover. Also that ten per cent of lost time in industry was caused by accidents and the balance by illness.

The functions of the Committee were outlined as follows:

1. To study occupational diseases from both the legal and the legislative angles.
2. To stimulate interest of the various industries in the study of practice of industrial hygiene.
3. To try to provide for the proper training of medical men so that they may be ready when they are needed.

Attorney F. Manley Brist pointed out that the Minnesota law does not define compensable occupational diseases, but if a person has a condition that was made worse for the first time through industry, he is entitled to compensation. A state law was passed in 1939 providing for the study of occupational diseases and provided also for the report of accidents by physicians to the State Board of Health.

A study, under the title of "Casual Inspection Survey of Industry" is now being made by the State Board of Health. This study will be made available to committees and other groups for the purposes of investigation and for correction of the condition revealed. The report will not be available for any lawsuit of any kind, or for any court. It is hoped that this study by the State Board of Health will be complete by the first of September.

Most of the diseases that are compensable in the state of Minnesota are rare and uncommon, with the exception of Lead poisoning, Dermatitis, Undulant fever, Ringworm, Tuberculosis and Silicosis are also prevalent in Minnesota. In the course of a discussion on the relation of periodical physical examination to industrial hygiene, it was pointed out that several companies in the mining district, notably International Harvester Co., Pickands-Mather and Butler Brothers—are making physical examinations of their employees at the expense of the company. Each man is examined physically each year and during every third year an x-ray film is made of his chest to guard against Silicosis. It was suggested that the whole subject of compulsive physical examination for employees be approached carefully because of the labor situation and the danger that many men might not be hired, especially men over forty if the laws are drawn too strictly.

Compensation has done more, in the opinion of Dr. B. S. Adams, to prevent accidents than anything else in history.

Dr. A. J. Chesley, Secretary of the State Board of Health, offered to secure a study of the industrial laws in the various states for the use of the Committee; also copies of the Minnesota Occupational disease law. He hoped also to be able to furnish the committee with copies of the history of the compensation laws of Minnesota.

It was agreed that the biggest problem was the proper method of preventing occupational diseases.

It was suggested that the Committee work with the State Board of Health to teach both the employer and the employee how to prevent conditions which lead to accidents and disease in industry. A suggestion was made that every physician in the state should report any occupational disease treated which he felt might have arisen out of industry to the State Board of Health. Thus the State Board of Health could make an intelligent study and appropriate recommendations.

The meeting adjourned.

REPORT OF THE COMMITTEE ON PSYCHOPATHIC PERSONALITIES

The Committee for the Study of Psychopathic Personalities has not had any meetings since its formation for the reason that the Minnesota Bar Association has not yet appointed their committee. It was agreed that when the President of the Bar Association appointed his committee your chairman would be notified and a joint meeting would be held. Your chairman interviewed Assistant Attorney General Mr. Kent Vandenberg on several occasions and Mr. Vandenberg intends to communicate with the President of the Minnesota Bar Association relative to the appointment of a committee to work with your committee on the question of psychopathic personalities.

At that time some of the controversial aspects of the psychopathic personality laws which now exist will be discussed and possible remedies formulated.

GORDON R. KAMMAN, M.D.

DR. A. E. CARDLE: The Committee has reviewed the reports included under this heading and wishes to report the following:

Committee on Interprofessional Relations: This is an important function of our State Medical Association inasmuch as it serves to bring in closer harmony the Hospital Association, Pharmaceutical Association, Dental Association, Nurses and Medical Auxiliary. They have considered the problems which are directly related and it is hoped that this Committee will persist in their efforts to bring these groups in closer harmony with one another.

Historical Committee: It was the consensus of the Reference Committee that this is an extremely important part of the activities of the State Association. It is our recommendation that the interest which has already been shown be continued and, if the members of the State Association have any material on hand which would be of interest to this Committee that they send it to the Committee. The work that they have done appeared to be more or less restricted to certain interested members in certain localities and it is hoped that at some future time a definite organization may be set up which may start a history of medicine in Minnesota as a whole.

Committee on Military Affairs: The report of this Committee shows that in Minnesota there is a total of 608 commissions in the army, 21 commissions in the National Guard, and 51 commissions in the navy. Since legislation is being considered from time to time in regard to military matters, we wish to recommend to the Committee that they keep in active touch with such legislation and activity which may be of value and interest to the State Association.

Committee on Fractures: The Reference Committee wishes to give this report special commendation. It shows the result of marked activity on the part of the Chairman, Dr. R. C. Webb, and members of the Committee. We wish to recommend that this report be read by all the members of the Association, and as a medium of doing it, we would suggest that this report be published in detail in MINNESOTA MEDICINE. Also we would like to suggest that this report serve as an example of what various committees might do.

We regret that there has been no report from the Committee on Asphyxia and Asphyxial Deaths. More and more interest is being shown in this matter in various states and localities, and it is to be hoped that Minnesota will progress with the times and will realize the importance of these diseases.

Committee on Industrial Health and Occupational Diseases: Dr. Horace Newhart, who is Chairman of the Committee on Conservation of Hearing, visited the Reference Committee in person and wishes to recommend that they consider the importance of hearing in industry. Industry and the medical profession have been slow to accept any specific method of testing for hearing and much disability has resulted. Other

states are showing great activity in this matter, and Minnesota must keep pace. We hope that this Committee will consider this point and so do something along these lines.

The Report of the Committee on Psychopathic Personalities: The Committee is working closely with the Bar Association and awaiting such time as it can meet with the association and review some of the controversial aspects of the Psychopathic laws which now exist. We hope this Committee will continue this activity.

The Reference Committee wishes to thank the various chairmen and their committees for their interest and work during the past year.

It was moved, seconded and carried that the report of the Reference Committee on Miscellaneous Scientific reports be accepted.

Dr. W. W. Will then asked for the report of the Reference Committee on the reports of the Officers and Council. The following reports were reviewed:

REPORT OF THE SECRETARY AND EXECUTIVE SECRETARY

The Minnesota State Medical Association has made definite progress in many directions during 1939 and 1940.

Membership has increased substantially this year with the total of 2,449 on April 4, 1940, as compared with 2,323 on the same date last year, and dues have reached the State Office more promptly this year than last, thanks to the assistance and fine cooperation of secretaries all over the state. The early date of the 1940 meeting and the fact that the roster was published, as a consequence, a month earlier than usual made this cooperation on the part of county society officers especially welcome and greatly appreciated by the State Office staff.

Finances

The finances of the association will be reported in detail by the treasurer but it is surely worthy of note, here, also, that the end of 1939 found us with a substantial surplus in spite of the fact that it was necessary to pay the Social Security taxes covering the entire period since passage of the Social Security law, this year. The care exercised by all Committees to live within their budgets has contributed greatly to this achievement.

Annual Meeting

It may be of interest to point out, also, in this connection that last year's meeting, held in Minneapolis, paid for itself with a net profit after all expenses, not only of the scientific sessions, but of the public health exposition had been paid. It was unnecessary, therefore, to use any of the money which has always been set aside out of the general funds for that purpose. Accounts have not yet been fully settled for the Rochester meeting, but the probability is that a profit will accrue to the association from this meeting also. Attention of all the members should be called to the fine technical exhibit section which presents many new exhibitors this year and which makes possible these fine meetings at no expense to the association. Members are urged to investigate all exhibits and discuss the products displayed with firm representatives.

Social Security Status

A word of explanation about the status of the association in relation to the Social Security taxes might be of interest here. The Minnesota State Medical Association, together with most of the state medical associations of the country and the American Medical Association, has been held liable for Social Security taxes on the ground that, although it is undoubtedly an educational institution, it cannot be called a non-profit institution because membership yields a definite and demonstrable benefit to its members. Since it has been held liable for the Federal Social Security tax, it is also liable for state Social Security taxes, including the unemployment insurance tax. The taxes have been paid under protest pending final disposition of an appeal to change the ruling.

Increase in Office Space

In connection with this discussion of association finances, something should be said, also, about the increase in office space which was approved by the Council at the beginning of the year. An additional office unit has been acquired and alterations have been made to provide a new and enlarged committee room, enlarged files, work space, and store room. The enlarged storage space has permitted us to purchase office supplies in large enough quantities and at sufficient savings to cover the increase in rental.

The increased work space and filing facilities were necessitated by the expanded program which was undertaken at the direction of the Council this year. Details of this program are given in reports of the various committee chairmen. It is reviewed here, briefly, in order to give a general picture of the scope of our work in Minnesota.

Coördinated Program

The Coördinated Medical and Public Health Program got off to an auspicious start last year and is now a major part of our regular activities. Between 300 and 500 packets are now sent out on request each month, and requests for speakers on the subject of the month are more and more numerous. Many of the latter are filled from the State Office through the Speakers' Bureau. Many others are made direct to members throughout the state. In addition, the regular weekly news releases of the association have been directed exclusively to the subject of the month and the radio broadcasts by the association's radio speaker, Dr. W. A. O'Brien, have been largely directed to the same subject.

In connection with the radio broadcasts, an experiment is now underway by which copies of Dr. O'Brien's talks may be made available eventually to any one who wishes to send 10 cents to cover mimeographing and mailing. If the experiment should prove to be successful, this service will be added to the regular program of the association.

Thus education on these subjects is reaching to the far corners of the state and to a large number of people. Even more important, in the opinion of many observers, the packet provides a very practical and important aid to the postgraduate work of the association. The effort of the committee in charge to provide in each packet some new and important scientific information, much of which is not yet available in the literature, is especially noteworthy. Also the fine statistical studies provided by the Minnesota State Department of Health have brought a service which was never before available in this form to our members.

A large number of requests for packets and information about the program have come from representatives of the United States Public Health Service in Washington and from other large foundations and institutions who are interested in health and postgraduate education. Many have offered pertinent suggestions and constructive aid.

Speakers' Bureau

Expansion of the Speakers' Bureau has followed inevitably upon the development of the subject-of-the-month program. Many new speakers have been added to our list of qualified lecturers and much additional material has been added to our speakers' library. Included in this new equipment is a new 16 millimeter motion picture projector and screen and a stereopticon. New motion picture films are being added to the library also, notably a film on first aid in the handling of fractures of the long bones. This new aid to speakers will be expanded.

College Lectures

The College Lecture Course, which continues each year as a Speakers' Bureau activity, has been highly successful this year judged by the enthusiasm displayed by college authorities who reported to the State Office at our request on the lectures and their reception. Two lectures are offered each college during the year and a choice of eight subjects with four lecturers for each subject. As far as possible, each college picks its own lecturer as well as subject. All bookings and other arrangements are carried on by the State Office staff as part of the regular office routine. It is of interest to note that by far the most popular subject offered this year was "Mental Hygiene for College Students" though all of the subjects were selected by one or more colleges.

Talks on Government Medicine

Other requests made through the state office for speakers reflected the overwhelming interest of women's groups, luncheon clubs, and others in the general subject of Government Medicine and the National Health Program in particular. Securing speakers and material for speakers on this subject alone meant a substantial addition to the work carried on in the office. A special packet of material from various sources was gathered for this purpose and is being constantly added to and brought up to date.

The most recent addition to our Minnesota material on the subject was prepared in the office at the request of the State Federation of Women's Clubs in the form of a brief which should present the attitude of physicians and public health officials of Minnesota toward the proposals of the Wagner Health Bill of 1939. It was designed as an answer to another brief urging the necessity of the Wagner Health Bill and the National Health program which is being distributed through the League of Women Voters to the women of Minnesota.

News Service

The regular newspaper health service of the association which has long taken the form of a short weekly news release issued to country newspapers, through the Minnesota Editorial Association, by the Committee on Public Health Education, is about to be converted into a Question and Answer Service for the same newspapers. This change is being made in response to the request of many individual newspapers and of the committee of the editorial association appointed to keep a contact with our association. The development of the new service will entail considerable additional work in preparing copy and authoritative answers to readers' questions.

Radio

The radio program, long confined to the weekly broadcasts over WCCO will be expanded shortly to provide for a different type of program, possibly of the round table type over KSTP and its affiliated Minnesota stations. Details of the new program have not yet been fully worked out, but a promise of

time for the purpose has been secured from station officials. In the meantime, it is gratifying to note that Dr. O'Brien's broadcasts are now carried also by WLB and KDAL, Duluth.

Medical Service for Welfare Clients

An important part of the work of the State Office and the executive secretary has been, for many years, the close contact maintained with state and government agencies of all sorts, so many of which are now concerned in some manner with the delivery of medical care.

It is interesting and very encouraging to note the important rôle now being assumed by our committees in this work and in the actual functioning of many public welfare programs.

The handling of medical care for relief clients and for recipients of the social security aids is now, to an important degree, in the hands of our own committees and representatives.

The handling of all medical problems connected with public welfare has undergone re-organization with the establishment of the new Department of Social Security under which the Division of Social Welfare, directed by Mr. Walter Finke, now correlates all categories of relief and aid.

New Status for Committees

As a direct result of Mr. Finke's expressed determination to seek the aid of physicians in all matters relating to medical care, a medical advisory committee was appointed from among nominees made by the Council. This committee now meets regularly as an adjunct to the State Division and works out all regulations with Mr. Finke. Similarly, the county contact committees, established some years ago to assist in the handling of local relief problems, have been revived and given an official status as advisory committees to each County Welfare Board. The boards have been urged by the State Division to use these local advisory committees as closely as Mr. Finke and his aids now use the state committee.

Out of this new approach should develop a better plan and better working cooperation between physicians and welfare officials than ever before existed in Minnesota. It is noteworthy that as much is expected in the way of understanding and cooperation from the physicians as from the officials who carry responsibility for authorizing funds. The willingness of physicians to cooperate in these matters has long been in evidence in Minnesota.

The principle of free choice of physician for which this association has always stood has been challenged in several quarters this year. The handling of this matter has taken a great deal of the time of our attorney, Mr. F. Manley Brist, who has spent many hours with the State Office and in the courts defending the principle as it operates in Workmen's Compensation Insurance, in contract practice, and in medical care for relief patients. Pressure is being brought to bear, of course, by a number of organized groups to do away with free choice as it applies to several types of patients. The importance of this matter to everyone in the practice of medicine is obvious.

Farm Security Plan Rejected

No cooperative plans for medical care of Farm Security Administration clients have been inaugurated as yet in Minnesota. With the consent of the Committee on Low Income and Indigent Problems which has had the government proposals under consideration for some time, one county society gave the matter considerable study, however. Administration representatives urged adoption of a plan in the county in question but eventually the members voted against it. Nowhere in Minnesota was any need demonstrated that would justify experiment of this sort. The collapse of Dakota plans and the dissatisfaction with the working of similar plans elsewhere has entirely justified this attitude.

Malpractice Insurance

Under the direction of the Medical Advisory Committee, the executive secretary has continued to assist in the investigation of the malpractice situation in Minnesota. Complaints have been quite general during the last few months concerning certain additional premiums for malpractice insurance that are being asked by one company and concerning changes in coverage announced by another. The complaints have promoted the Council to order a thorough study of all malpractice policies offered physicians in Minnesota by Mr. Brist. Mr. Brist will report on this study to the delegates at this session, and the delegates, it is hoped, will adopt some definite recommendation on the basis of it.

New demands are made constantly on the resources of the State Office and on the time of the secretary and staff. These demands could not be met without the most generous cooperation and assistance from all of our committees and officers and from our county and district secretaries. They could not have been met, either, without the loyal cooperation of the members of our office staff all of whom have taken a personal interest in seeing that the work of the association is carried on.

We do not know what new developments in Washington may bring us in the way of national legislation or of altered relations between physicians and the government. We do know that in Minnesota the doctor is still a trusted public servant, a leader in his community, a professional man whose word is still heeded where the welfare of the public is concerned.

There seems to be no reason why this fortunate status should change provided we continue as individual physicians and as an association to assume our share of the responsibility for the health and welfare of the people of Minnesota.

B. B. SOUSTER, M.D., Secretary
R. R. ROSELL, Executive Secretary

PROCEEDINGS EIGHTY-SEVENTH ANNUAL SESSION

REPORT OF THE TREASURER

The attached statement of cash receipts and disbursements for the year which ended December 31, 1939, was made by Shannon and Byers, Certified Public Accountants, who finished auditing the books of the association, February 24, 1940, and found them to be correct in all respects.

It will be noted from this statement that the finances of the association continue in excellent condition.

The year 1939 was a legislative year, and in spite of the heavy extra expense always incurred during a legislative year, there was a surplus on December 31 of \$5,038.34.

Special mention should be made of the fact, also, that the Herman M. Johnson Memorial Fund is not included in the above mentioned surplus. This fund of \$2,000 plus the accrued interest is held in a separate account under the special jurisdiction of the Council.

Delegates and members are urged to study this statement carefully for a better understanding of the administration of association affairs.

W. H. CONDIT, M.D.

STATEMENT OF CASH RECEIPTS AND DISBURSEMENTS FOR THE YEAR ENDED DECEMBER 31, 1939

CURRENT FUNDS	
CASH ON HAND, DECEMBER 31, 1938:

REPORT OF CHAIRMAN OF THE COUNCIL

At the time of the annual meeting of 1939, four sessions of the Council were held. The important features of two of these were reported to the House of Delegates. However, it may be of interest to review some of the actions taken at the meetings of June 1 and 2 which were not reported. These meetings were held chiefly in connection with the State Board of Health and finally led to the approval of the suggestions of the State Board of Health in connection with the following points: (1) That free drugs for the treatment of venereal diseases be supplied only to those who are financially unable to pay for them. (2) That standardization of the laboratories of the state did not seem to be necessary at the present time although it was regarded that standardization should be an optional matter in the future with the assistance of the laboratory of the State Board of Health. (3) That no venereal disease clinics need be established in Minnesota at the present time. (4) That the policy of treating venereal disease in the private office of any duly licensed practitioner be approved.

Close cooperation between the Minnesota Public Health Association and the Public Health Education Committee of the State Association was urged with expenditure of necessary funds by the Chairman of the Public Health Education Committee on the approval of the Chairman of the Council.

During the year meetings were held September 3, 1939, November 26, 1939, and February 23, 1940. The meeting of September 3 was again held chiefly in connection with the members of the State Board of Health. It was pointed out by Dr. Chesley that under H. R. 6635 an amendment to the Social Security Act, an additional appropriation of approximately \$10,000 would be allotted to Minnesota for the fiscal year of 1940 and the wise expenditure of funds was the chief topic of consideration with special reference to pneumonia, cancer, malaria, industrial hygiene, dental hygiene and tuberculosis.

It was stated that there had been some desire on the part of the Federal Administration to place the activities in industrial hygiene under the Department of Labor rather than the Public Health Service. This has been opposed by the State Boards of Health, the American Medical Association and the American Public Health Association. There has also been pressure from the Federal Administration to provide specifically for medical care for maternity cases and children in selected areas. Dr. Chesley, as you know, opposes any extension of medical treatment by State Boards of Health. Activities and expenditures in connection with the various diseases mentioned were considered in detail and the utmost cooperation between the State Board of Health and the Council was evident.

The urgent necessity for vaccination and immunization campaigns, especially in rural districts, was discussed and referred to a committee for definite action.

The College Lecture Course for 1939 and 1940 was approved. The report of the Committee on Industrial Relations in connection with the situation in St. Paul was accepted and the Council reaffirmed its former stand in favor of free choice of physician in compensation cases. This report of the Committee on Industrial Relations gave in detail the activities of the St. Paul City Council in connection with the so-called "five doctor panel plan" for the treating of all city employees and explained the opposition of the Ramsey County Medical Society and the St. Paul Trades and Labor Assembly to this panel. The filing of a brief on the case by the State Medical Association "as a friend of the court" if it should be necessary was approved by the Council. Dr. Adson explained the case of the Eagles Fraternal Order of Austin versus the Mower County Medical Society (for comments on this see the report of the Councilor of the First District). This case, involving the question of the practice of medicine by the Eagles Lodge, is of such importance as a precedent that the Council voted financial assistance to the Mower County Medical Society if it should be necessary in the event that the case be carried to the State Supreme Court or the United States Supreme Court. So far the expense has been assumed by the Mower County Medical Society.

It was decided to approve of a Pilgrimage and Memorial Service in honor of Dr. W. J. Mayo and Dr. C. H. Mayo, to be held October 27 in conjunction with a meeting of the Alumni Association of the Mayo Foundation. This was later carried out as planned and proved to be a very effective ceremony.

The Distinguished Service Medal of the Association and Citations were awarded to Dr. W. J. Mayo and Dr. C. H. Mayo and Dr. H. M. Johnson. These were presented at the time of the Fiftieth Anniversary of the founding of the Medical School.

PROCEEDINGS EIGHTY-SEVENTH ANNUAL SESSION

At the meeting of November 26, 1939, the finances of the Association were given special consideration. Two budgets for 1940 were presented, one based on the present program and the other on an enlarged program of activities. The program calling for increased activities was adopted in view of the surplus of 1938 and the apparent surplus of 1939. It will be remembered that at the end of 1938 \$4,000 was transferred to the permanent investment fund of the Association and it seemed wise to increase the activities of the Association rather than to place so large a portion of the surplus into a permanent investment account. This enlarged program necessitated additional office space which has now been supplied and I am sure the offices of the Association are worthy of a visit by every member. They are offices of which we can be proud. Other increased activities are in connection with the speaker's library, the purchase of lantern slides, and possibly motion picture films, the President's monthly packet, and educational program, necessary office equipment and an increased budget for the Public Health Education Committee. With the increased office space for storage it will apparently be possible to save by purchasing materials in larger quantities an amount equal to the additional rent. As a result of the enlarged program of activities and the additional cost of the legislative year, it will be found that the surplus for 1939 is not as large as for 1938. The technical exhibit is now more than carrying the entire cost of the annual meeting.

Mr. Walter Finke, of the State Division of Welfare, outlined the general policy of his Division. This was approved and the Council expressed its appreciation to Dr. Hilleboe and Mr. Finke for the cooperation shown by them in meeting relief problems.

Dr. Chesley submitted a plan for obstetrical teaching, demonstration and home delivery service which will be in charge of Dr. McKelvey of the University of Minnesota as a proper expenditure of Federal Funds.

Council Committees and the President's Committees for 1940 were approved. The following members were named to the Finance Committee of the Council: E. M. Jones, C. A. Stewart and H. Z. Giffin. President Elect, Dr. Adams, was given authorization to appoint two new committees, one on Industrial Hygiene and Occupational Diseases, with J. L. McLeod as Chairman, and the other on Vaccination and Immunization, with L. R. Critchfield as Chairman. E. L. Tuohy was named as Chairman of the Public Health Education Committee. The following names were suggested as an Advisory Committee to the State Division of Social Welfare: A. W. Adson, W. A. Coventry, E. J. Simons, C. A. Stewart and L. L. Sogge.

At the meeting of February 23, 1940, the following general topics were considered: (1) The organization of a Society for Research in Convulsive Disorders, as outlined by D. E. McBroom. (2) The continued laxity of certain physicians in filling out and filing birth and death certificates. (3) The drafting of a bill by the Minnesota Hospital Service Association. (4) The licensing of Rest Homes. (5) The advertising of oleomargarine in medical journals. (6) Advertising in connection with the opening of new hospitals. (7) The variations in policies of insurance companies for malpractice insurance and the question of fees for testimony in malpractice cases. (8) The purchase of pure grain alcohol for office and scientific use.

These are some of the topics which have been considered and the most important actions taken by the Council during the year. Detailed minutes are open for inspection by any of the Delegates or other members.

May I take this opportunity to express my appreciation of the fraternity, loyalty, honesty, tolerance, fairness and good judgment of the members of the Council and the officers of the Association and to commend the efficiency and ability of the Executive Secretary and the Administrative Staff.

H. Z. GIFFIN, M. D.

REPORT OF THE COUNCILOR OF THE FIRST DISTRICT

The Societies of the First District have been more active than ever before and have handled their own problems effectively. This is as it should be.

The most important problem of the year has been the situation created by the practice of medicine by the Eagles Lodge at Austin in which instance the lodge hired a physician and an osteopath to care for illnesses among members; but even this situation is being handled by the local Society in association with the State Board of Medical Examiners. Your councilor was requested to attend a meeting of the Mower County Society to which were also invited our Secretary, Executive Secretary, representatives of the State Board of Medical Examiners and legal advisors. The decision of this meeting led to the entering of a restraining order against the Eagles Lodge by the court and in counter-action the lodge has appealed to the State Supreme Court. Because of the importance of the final decision in this case both for the medical profession and the public in Minnesota and in fact from the national standpoint, as a precedent, the local society requested the financial assistance, if it should be necessary, of the State Association and possibly even of the American Medical Association. So far the expense has been met by the local society. This matter was brought before the Council of the State Association by your Councilor and the Council favored giving the Mower County Society every assistance that might be necessary. The case is still pending.

There has been, as is well known, some lack of cooperation

in certain counties between the Public Welfare Boards and our Contact Committees. In view of the new and very reasonable regulations of the present Director of the State Division of Public Welfare concerning the handling of medical relief, it is to be hoped and expected that Contact Committees will establish and maintain from now on the utmost cooperation with County Welfare Boards.

The President's program for focusing discussions each month on one or two general topics and the monthly packets on these subjects have been most favorably received. I know of no other problems which the Societies of this District desire to have referred to the House of Delegates either for their action or for their information.

H. Z. GIFFIN, M. D.

REPORT OF THE COUNCILOR OF THE SECOND DISTRICT

The Societies in the Second District have been very active during the past year. They are making good use of all postgraduate opportunities as shown by large attendance at all courses. Their own scientific programs have also maintained a high standard.

There are medical clubs in most of the counties and these clubs handle all medical programs in their own communities. Most of them, for instance, have put on county vaccination and immunization programs though the men who are doing obstetrical work are also making a special effort to instruct their patients in the value of looking after both vaccination and immunization in the first year of life. We believe that this is the ideal way to promote preventive measures.

The men of the second district are quite sympathetic, I believe, to the policies of the Minnesota State Medical Association.

L. L. SOGGE, M.D.

REPORT OF THE COUNCILOR OF THE THIRD DISTRICT

As Councilor of the Third Councilor District of the Minnesota State Medical Association, it is my pleasure to make the following report:

There has been an increase in the membership in each one of the component County Societies during the last year. Programs as given at the various meetings have been of high class, and unusually well attended showing a continuance of the marked and increasing interest along both medical and economic lines as they affect the professions of Western Minnesota.

I bespeak a further increase in membership during this next year as we are fortunate in having a large number of younger men who are taking up the practice of medicine in my district. The care of those who come under various parts of the Social Security Program, as well as Hospitalization of these same classes of people, is still of paramount importance, and it is the hope of the Councilor of this District that a program of settled nature may be worked out in the very near future.

B. J. BRANTON, M.D.

REPORT OF THE COUNCILOR OF THE FOURTH DISTRICT

The affairs in the Fourth Councilor District, since the present Councilor has taken office on the first of January, have run smoothly. Doctor Holbrook, the retiring Councilor from our District, who was in office to the first of the year, reports also that everything has been in good condition here.

A. E. SHMER, M.D.

REPORT OF THE COUNCILOR OF THE FIFTH DISTRICT

I herewith submit my report as councilor of the Fifth District:

In my report of April 27, 1939, I mentioned the fact that Dr. F. E. Mork and Dr. B. W. Bunker of Anoka, Minnesota, had had some difficulty in obtaining a membership in the East Central Medical Society. I am very glad to report that these men have since been admitted to membership in the East Central Medical Society.

In September, 1939, I received a letter from Dr. Fredlund of Milaca, Minnesota, in which he complained about newspaper notices that were being inserted by Dr. C. J. Henry, who is a member of the Stearns-Benton County Medical Society. I took this matter up with Dr. J. N. Libert of Saint Cloud, who is secretary of this Society, and he called Dr. Henry for a conference. The matter apparently has been satisfactorily adjudicated.

I attended the meeting of the Washington County Medical Society February 13, 1940, at which time there was a discussion of several problems regarding various memberships in the society. A number of plans were discussed, and I believe satisfactory solutions were reached in each case.

At the request of the Council of Medical Education and Hospitals of the A.M.A. I investigated the Cherokee Sanitarium of St. Paul, Minnesota, and the Community Hospital at Farmington, Minnesota. These institutions had made application for recognition in the next hospital number of the American Medical Association Journal and the new American Medical Association Directory. I recommended the Community Hospital at Farmington for such recognition.

Several attempts have been made to have a meeting called in order that Mr. Rosell, Dr. Souster and myself could meet with the members of the Dakota County Medical Society. So far, we have been unsuccessful, and apparently it will be very difficult to again have this Society functioning as a unit. As many of the members in this county belong to the Ramsey County Medical Society, there is a lack of interest in rebuilding the Dakota County Medical Society. It has been felt that the other men could continue their medical affiliations by transferring to nearby societies.

This matter was proposed to the Washington County Medical Society, and they were very willing to take in men that live in Hastings who belong to the Dakota County Society. It would seem that this is the best solution to the problem.

E. M. JONES, M.D.

REPORT OF THE COUNCILOR OF THE SIXTH DISTRICT

During the past year the membership of the Hennepin County Medical Society has increased from 622 to 641. The licensed physicians living in Hennepin county who are not members of the Society include some of the full time professors at the University, resident physicians, interns and physicians in government service at Fort Snelling. Practically all physicians engaged in private practice who are eligible are members of the Society. The same is true of the physicians of Wright County.

During the year representatives of the Federal Farm Rehabilitation Bureau conferred with the Wright County Medical Society relative to providing medical care to farm relief clients on the basis of loans made by the Federal Government to these clients. After considerable study it was decided that the number of relief families in this category was too small to warrant this special venture into the field of federal subsidy for medical care.

Recently the Federated Women's Clubs and the League of Women Voters have manifested a genuine interest in the Wagner Bill and Socialized Medicine. Through meetings with officers of these organizations the defects of the Wagner Bill, the disadvantages of socialized medicine, the platform adopted by the American Medical Association, and the fact that medical care is now available to the poor, as well as to the financially independent, have been explained in detail. It is our opinion that the representatives of these organizations now understand the viewpoint of the Medical Association, appreciate its soundness and reasonableness and are in sympathy with it.

Occasionally the physicians in Rural Hennepin County find themselves disagreeing with the County Commissioners relative to compensation for services rendered to relief clients. These difficulties probably can be solved satisfactorily by providing a Medical Advisory Committee to which problems of this nature can be referred. This recommendation is transmitted to the Executive Committee of the Hennepin County Medical Society.

The tuberculin testing project sponsored by the Hennepin County Medical Society has resulted in reports of an excess of 7,000 tuberculin tests applied in the private offices of our members.

C. A. STEWART, M.D.

REPORT OF THE COUNCILOR OF THE SEVENTH DISTRICT

Membership in the two component medical societies in this district is slightly higher than at the same date a year ago. A recent review of membership in the district made by Mr. Rosell, Executive Secretary, showed that no desirable physician in the territory of the Stearns-Benton County Society was not either a member or an applicant for membership. Very few reputable physicians in its territory were not members of the Upper Mississippi Medical Society.

Extension of the activities of the Minnesota Hospital Service Association into this district has occurred this year in the St. Cloud and Wadena territory. Danger of discrimination, and encroachment on the privilege of free choice of hospitals, and consequently, physicians, was avoided by joint action of the officers of the Association, physicians and hospital administrators. Before promotional work was started, efforts were made to extend membership in the Association to all hospitals in competitive territory. Qualification for such membership is facilitated in the interim between regular meetings of the component medical society by the appointment of a Hospital Committee empowered to approve or reject hospitals, should such action be necessary to safeguard the interests of either hospitals or physicians.

As an outgrowth of a problem raised in the Todd County Medical Club, both component medical societies and later the Park Region Medical Society and the Red River Valley Medical Society of the Eighth Councilor District adopted minimum medical fee schedules and sanctioned a uniform 25 per cent reduction of these schedules for medical services for the indigent sick. This action was necessary to avoid giving 40 per cent reduction to one township or county and 25 per cent reduction to another separated only by an imaginary line. During discussions of the matter, opinions were expressed that both a uniform minimum medical fee schedule and a uniform reduction of such fees for medical services for the indigent sick should be obtained throughout Minnesota with the possible exceptions of Minneapolis, St. Paul, Duluth and Rochester.

EDWIN J. SIMONS, M.D.

REPORT OF THE COUNCILOR OF THE EIGHTH DISTRICT

There is little to report from the Eighth District aside from the usual high type of practice and medical meetings, except that some progress has been made in the handling of the depressing problem of medical and hospital care for the indigent and low income groups.

As a trial area for hospital insurance, outside the larger cities, Fergus Falls was selected as the point of entry into the Eighth District. The Minnesota Hospital Service Association canvassed the city with good success. After a few months' operation, it appeared to offer much for the groups which have been reached, establishing for them the desirable principle of "pay before you go." Those who have required hospital care are much pleased and those who have not seem satisfied with the security assured.

1. As yet, the problem of groups in the rural areas has not been solved. Much interest has been aroused among the creamery patrons. It is hoped soon that a sufficient per cent, can be interested so that the fees can be deducted from the cream checks. When this comes about, the hospital insurance in the rural areas will be on a firm financial basis.

2. Indigent. Here there continue to be great difficulties and many misunderstandings. Mr. Finke is doing all that he can to clear the way by impressing upon all Welfare Officers their legal obligation to provide medical care of the indigent and the right of indigents to free choice of physician. The great variation in doctors' fees is still the source of much trouble. We are, therefore, in the Eighth District, making an effort to standardize them.

3. The low income group continues to be the chief sufferer here as everywhere. It is likely that those just above indigency should have, at least, the same discounts as indigents.

W. L. BURNAP, M.D.

REPORT OF THE COUNCILOR OF THE NINTH DISTRICT

A review of the accomplishments of medical organization, professional and public relations of the Ninth District during the past year evidences a continued and improved interest by its membership. Proceedings of the St. Louis County Medical Society and its branch, the Range Medical Society, are regularly devoted to organization and medical economics questions and the high percentage of attendance and the work of the various committees is an expression of recognition of the ideals and purposes of our state organization.

Surveys throughout the year show that membership completely covers all available and acceptable physicians.

The society receives with accord the program presented by the Director of Welfare of the state and hopes this may improve our relations with the local responsible relief authorities. Expenditures of large funds for new hospitalization and a proposed revision of the method of handling medical relief are of immediate importance for disposition. We are assured consideration from the above source will be obtained.

The representation at the county officers meeting was in good number and subjects were reviewed by each individual at the following meeting.

The Interprofessional Relations Committee had occasion to meet with all local District Judges recently and an early meeting with a group from the Bar Association is contemplated. This program will be enlarged.

After considerable time, the extension of the weekly program of Dr. O'Brien to one of our local stations has been consummated and there is hope that there will be no interference with its continuance.

This district anticipates with interest the coming meeting in Rochester and expresses to the officers of the state association its appreciation for the cooperation and assistance during the past year. To Mr. Brist, we also extend our thanks.

F. J. ELIAS, M.D.

Dr. S. A. SLATER (acting Chairman): We have nothing but praise and few recommendations for the reports of the Officers and Councilors.

We have carefully examined the reports assigned to you and wish to submit the following recommendations:

1. *Report of the Secretary and Executive Secretary:* We wish to compliment them and express our appreciation of their work. We wish to especially recommend that the Speakers' Bureau, College Lectures, and Talks on Government Medicine be continued, and, if it is felt justified, enlarged. We approve the action of the Officers in making available Dr. O'Brien's talks, and wish to compliment them on the fact that the radio program has been enlarged. We recommend that the report of the Secretary and Executive Secretary be approved by the House of Delegates.

2. *Report of the Treasurer:* It is highly gratifying to learn that there has been a satisfactory surplus after the achievements have been attained by the Officers, Council, and Executive Secretary. We wish to recommend the approval of this report.

3. *Report of the Chairman and Members of the Council:* Your Committee notes the excellent condition throughout the various districts. We wish to call attention to the fine relationship they have been able to maintain with the State Board of Health and appreciate the cooperation that Dr. Chesley and his Department has given us.

DR. D. P. HEAD: This is a very very pleasing treasurer's report, and I wish to compliment the treasurer, but there is one thing that I think we should have as a matter of policy. We should have the previous year's figures listed beside the present year's in the report, in order to evaluate the present trend of our financial expenditures. I should like to make a motion in the House that the Treasurer be instructed to do so.

It was moved, seconded and carried that the future reports should be made in accordance with Dr. Head's suggestion to the Delegates.

It was then moved, seconded and carried that the report of the Reference Committee be accepted.

Dr. W. W. Will then called for the report of the Reference Committee on State Health Relations reports. The following committee reports were reviewed:

REPORT OF THE COMMITTEE ON STATE HEALTH RELATIONS

The usual assortment of minor problems was referred to the Committee on State Health Relations during the year. The committee kept in touch with the State Board of Health and had a representative at practically every meeting of that Board.

On instructions from the Council we have offered our assistance to the State Civil Service Board for the drawing up of examination blanks for applicants for medical positions under the State. Our assistance has not yet been requested.

The committee has arranged to meet two weeks before each meeting of the Council on notification from the Executive Secretary, to hear reports from the members and to report to the Council.

T. H. SWEETSER, M.D.

REPORT OF THE COMMITTEE ON PUBLIC POLICY

No legislative session has intervened since the last meeting of the House of Delegates. Several matters which involved the legislative policy of the association have been referred to the committee, however, and I shall be glad to make a verbal statement on the committee's activities with regard to them to the Reference Committee and, if called for, to the Delegates.

L. L. SOGGE, M.D.

REPORT OF THE COMMITTEE ON UNIVERSITY RELATIONS

At the Secretaries' Meeting held in February, Mr. Ray Amberg, Superintendent of the University Hospitals, emphasized the fact that the University Hospitals comprise a teaching institution; their present bed capacity is 500, and it is reasonably adequate for that purpose with certain exceptions of addition for special conditions. If the hospital were to try to take care of all the indigent in the state, Mr. Amberg thought that a 5,000-bed hospital would be needed, because, even now, the waiting list averages 1,000 patients. The hospital tries to present to its students a cross-section of medical problems that they will encounter in practice; that is why many tonsillectomy cases must be turned away and why many hernia cases remain long on the waiting list. Some emergency cases are taken since it is evident that a certain amount of emergency work is important from the teaching standpoint.

The problem of the indigent then reverts to the local board in charge. Medical societies in recent years have encouraged as far as possible the care of the indigent in their local areas because traveling expenses, accommodations, while waiting for admission to the hospital, attendant and nursing care, outside the hospital are costly.

The state society has felt also that aside from the question of costs, people get quicker service in their local community. The question is how to present this to the boards who have local control. In this the doctors themselves must take a good share of the educational process. The state association has felt in the past that not enough emphasis has been placed on social relationships the student is going to encounter when he enters into practice. Even for those students who are not going into private practice the view-point of organized medicine represent-

ing largely the private practitioners should be given to future teachers and public health workers, so that they will understand fully the problems of private practice.

We have been pleased with the compulsory senior lectures instituted along these lines and wish to commend them.

GEORGE EARL, M.D.

DR. E. S. PLATOU: We recommend the adoption of the report of the Committee on State Health Relations and want to compliment the work of Dr. Sweetser, especially, in his very conscientious attendance at meetings of the State Board of Health.

We recommend the adoption of the report of the Committee on Public Policy with commendation for Dr. Sogge in his untiring efforts in behalf of the medical association.

We recommend also the adoption of the report of the Committee on University Relations with emphasis to be placed on the suggestion of Dr. Earl's Committee that careful study be given to the admission of patients to the University Hospital and Out-patient Department by local County Boards.

It was moved, seconded and carried that the recommendations of the Reference Committee be accepted.

Dr. Will then called for the report of the Reference Committee on Lay Education Reports. The following committee reports were reviewed:

REPORT OF THE COMMITTEE ON PUBLIC HEALTH EDUCATION

The work of this Committee so far has been largely a continuation of that excellent program devised and organized under the previous chairmanship of Dr. L. R. Critchfield of St. Paul. The next circumstance calling for brevity stems from the comparatively short period in which your Chairman of the Public Health Education Committee and the Chairmen of the various subcommittees of Child Welfare, Radio, Speakers' Bureau, Editorial, Red Cross and Tuberculosis have had to work. Plans, however, have been well laid.

It must be obvious that such relatively large committees, made up of members residing throughout the state, make meetings difficult. Nevertheless, the distribution of membership is the chief agency whereby the objectives and intentions are furthered and the purposes (particularly of an educational committee) are devised and understood.

Speakers' Bureau

Despite the difficulties of getting together all the members of various subcommittees most of them have had one or more sessions. Dr. F. H. Magney of Duluth, head of the Speakers' Bureau, has continued the effective method carried out in previous years. He reports for his Committee as follows:

"The College Lecture Course was offered to the college on the same basis as last year and 16 colleges accepted. The lectures were officially limited to two for each college but one college especially requested and received four lectures. The subjects selected for the year are enclosed.

"The most popular subject was 'Mental Hygiene Problems of College Students.'

"Other talks arranged through the Speakers' Bureau this year were practically all in response to the offer made in the newspaper for speakers on the subject of the month. Talks were made before PTA groups, luncheon clubs, church groups, Auxiliary groups and others. So far this year twenty-seven talks have been booked through the State Office and there will be many more before 1941. In addition to this number, there have been many talks given by our members for which material was provided by the Speakers' Library, but about which we have no definite information as to date and place. Many of these requests have been for material on government medicine and an unusual number have been from doctors' wives. A total of one hundred or more such requests have been made this year to the State Office." The outline of the College Lecture Course follows:

MENTAL HYGIENE PROBLEMS OF COLLEGE STUDENTS—G. R. Kamman, St. Paul; B. C. Schiele, U. of Minn.; L. R. Gowan, Duluth; P. H. Heersema, Rochester.

YOUTH AND SOCIAL HYGIENE—R. R. Sullivan, U. of Minn.; H. G. Irvine, Minneapolis; W. E. Hatch, Duluth; P. A. O'Leary, Rochester.

THE NATIONAL HEALTH PROGRAM—George Earl, St. Paul; W. A. O'Brien, U. of Minn.; A. W. Adson, Rochester.

SKIN GAME (On cosmetic problems and skin diseases of students)—F. W. Lynch, St. Paul; C. W. Laymon, Minneapolis; F. T. Becker, Duluth; L. A. Brunsting, Rochester.

GETTING READY FOR MARRIAGE (On mental and physical preparation necessary for successful marriage)—J. J. Swendsen, St. Paul; L. A. Lang, Minneapolis; R. J. Moe, Duluth; J. A. Haugen, Minneapolis.

ONE STEP AHEAD (On good posture and foot health for students)—S. W. Shimonek, St. Paul; E. T. Evans, Minneapolis; M. H. Tibbetts, Duluth; H. B. Macey, Rochester.

PROCEEDINGS EIGHTY-SEVENTH ANNUAL SESSION

CHEMISTRY IN MEDICINE (Covering particularly the new drugs such as sulfanilamide and sulapyridine and others)—M. H. Hoffman, St. Paul; Harold N. Wright, U. of Minn.; F. J. Hirschboeck, Duluth; H. R. Butt, Rochester.

AFTER THE ACCIDENT—WHAT? (On First Aid in general and particularly first aid for fracture cases)—R. M. Burns, St. Paul; R. F. McGandy, Minneapolis; F. J. Elias, Duluth; H. B. Macey, Rochester.

Child Welfare

The Child Welfare Committee with Chairman R. L. J. Kennedy of Rochester held at least one meeting in St. Paul recently and a report of their work will be available later to the delegates.

Radio

The radio continues to be one of the most efficient means of influencing public opinion. The profession in Minnesota will never be able adequately to estimate the good that has come to our profession through the development of the broadcasting on medical subjects by Dr. William A. O'Brien. Since he has become engrossed in the graduate education feature in terms of the Continuation Courses at the University, he has been singularly equipped and in a position to sense the various needs of our guild, as well as to forecast the situation where newer scientific research points the way. With a simple but engaging technic and with a capacity for gentle humor antidoting any tendency to magnify fear (always so much associated with disease) he is able to disseminate useful information to ever increasing audiences. Chairman R. M. Burns of St. Paul with his committee have continued to serve most effectively. The report of his committee is attached.

Change Planned

I am unable to report at this time of the work of the Editorial Committee chairmaned by R. M. Hewitt of Rochester who has been ill. However, I know they are working and planning, it is understood, a change in the news service so long issued to country newspapers by this committee.

First Aid

A. B. Stewart of Owatonna, chairmaning the First Aid and Red Cross Committee, has been very active. I quote from his report as follows:

"As Chairman of the First Aid and Red Cross Committee of the Committee on Public Health Education I have little to report.

"I have statistics with detailed information in regard to the Red Cross activities in Minnesota, including First Aid instruction, Highway First Aid and Vaccination and Immunization. The latter has a separate committee, with Dr. Critchfield as chairman. I wrote to him some time ago offering him what information I had. I believe we might, each, accomplish more if we worked together.

"As the St. Louis Headquarters of the Red Cross have expressed pleasure in the activities that I have outlined to them I believe that I shall urge Red Cross chapters to push Immunization campaigns.

"Out of the 61 chapters in the state, only 14 have done so. I have not thought it advisable or necessary to call the committee together especially as we are so distant from each other."

Tuberculosis

Concerning tuberculosis, Chairman J. A. Myers of Minneapolis and his committee have been most active. A report of the work of this committee is also attached.

In passing I may state that the Minnesota Public Health Association has likewise been active concerning further ways and means of directing the anti-tuberculosis program. Dr. C. B. Wright of Minneapolis, chairmans a committee of the Public Health Association having to do with the period when previously treated subjects may safely be employed. To determine through mass methods the extent of infection, especially in the lower income employed groups, has been given much study. Out of all this some unified program will gradually evolve.

Packet

The Speakers' Library Service with the monthly packet dealing with various subjects and available through the State Medical office is very popular. Especial thanks is due the University and associated hospitals and their staffs and the State Department of Health for much of the material collected and used.

New Problem

Finally your Chairman feels that there is a great untouched field in the direction of the better organization of medical service through a study of the striking changes in the percentages of the population at various age levels. Gradually we are arriving at a point where without decisive decrease or increase in the prospective age groups under 20 we face a situation in which a tremendous increase is taking place and will continue to do so in the age levels over 60. In that group there is developing a much stronger trend toward octogenarianism among women than with men. In our courses of instruction in medical schools, in the organization of our hospitals, in the attitude of mind and the technics developing in our various specialties, in the daily rounds of the general practitioner, there is a great need for continuous discussion and among other things the need of familiarizing ourselves with the broader aspects of geriatrics.

E. L. TUOHY, M.D.

REPORT OF THE RADIO COMMITTEE

The radio program has continued to be carried on during the past year by Dr. W. A. O'Brien, director of postgraduate education at the University of Minnesota. A list of the subjects and the general plan of Dr. O'Brien's weekly broadcasts for the past year is attached to this report. It will be noted that the broadcast on the last Saturday of each month was on dental health and was sponsored by the Minnesota State Dental Association.

The radio program of the Minnesota State Medical Association is now 12 years old, one of the oldest of its sort in the entire United States, and, undoubtedly, one of the most popular.

The committee feels that the association and Dr. O'Brien are to be congratulated on this record and that our sincere appreciation should be extended to WCCO for its unfailing and courteous service. As far as possible, also, the committee hopes that the example of the St. Louis County Medical Society in securing these broadcasts over direct wire to their local station, KDAL, will be followed. It should be realized, of course, that WCCO has no direct affiliations with any other stations except WLB in Minnesota, at the present time, and that only by a special combination of circumstances would a direct wire be available over which the broadcasts could be carried. Dr. O'Brien has participated in individual broadcasts over WCCO, WLB, KSTP, and WTCN in addition to the regular program.

Offers of regular broadcast time have also been received by other stations not affiliated with WCCO, notably by KSTP, which is affiliated with a chain of smaller stations in Minnesota. The committee is of the opinion that the offer from KSTP, especially, should be accepted and several conferences have been held with members and with officials of KSTP on the matter. It is the general consensus that a different type of program should be developed for this purpose and several suggestions have been made. One is for the currently popular round-table type of program. Another is for a program series to be conducted by an Inquiring Reporter who collects the questions of average citizens on a given subject and submits them over the air to one or two experts, the experts to change from program to program. Details for some such program will be worked out in the near future and experiments will probably be made in series of weekly programs over this station and its affiliates.

In the meantime another experiment is now under way in connection with Dr. O'Brien's program which, if it is successful, will be made a definite part of the program. That is, to provide copies of Dr. O'Brien's talks, transcribed at the time of the broadcast, to any listeners who wish to send 10 cents for it to cover postage, cost of mimeographing, and mailing.

Arrangements for broadcasts by distinguished visitors, together with daily résumés of meeting events were made by the committee in connection with the Minneapolis meeting in 1939 and the total series covering many phases of medicine and of the work of organized medicine was undoubtedly of great public interest. Broadcasting arrangements in Rochester do not permit of so extensive a program in connection with the 1940 meeting, but similar arrangements will be made at the next big city meeting.

R. M. BURNS, M.D.

Medical Broadcasts

April 1, 1939—March 31, 1940

- April
 - 1 Cause of Cancer
 - 8 Cancer in Women

 16 Gout
 23 Injuries of Joints
 30 Exodontia

REPORT OF THE SUB-COMMITTEE ON TUBERCULOSIS

The Sub-Committee on Tuberculosis held its first meeting on February 24, 1940. The following were present:

- J. A. Myers, Minneapolis, *Chairman*
 B. S. Adams, Hibbing
 C. A. Stewart, Minneapolis
 H. Z. Giffin, Rochester
 H. E. Hilleboe, St. Paul
 E. J. Simons, Swanville
 L. H. Flancher, Lake Park
 E. A. Meyerding, St. Paul
 K. H. Pfuetze, Nopeming
 S. A. Slater, Worthington
 Mr. R. R. Rosell, St. Paul

Dr. Myers briefly outlined the history of the Committee on Tuberculosis, stating the objectives of the Committee when it was first formed and the present objectives. In connection, slides were shown, showing the comparison between the United States and England in the eradication of tuberculosis in cattle. Additional slides of x-rays, showing the different stages of tuberculosis in humans, were also shown.

Dr. Stewart submitted his proposed State-wide Anti-tuberculosis campaign, outlining both the Ideal and Economical Plans.

A general discussion of the plans followed, with Doctors Slater, Pfuetze, and Flancher relating their progress in TB work in their own respective counties.

Dr. Hilleboe outlined the program of the Division of Social Welfare and offered his cooperation with Dr. Stewart's plan, advising that they both work together.

Dr. Stewart suggested that the members present decide on certain major points of the plan, which they were to follow, and after the plan is under way, the details could be worked out. The following objectives were agreed on:

Ideal Plan:

1. Apply the TB test to the entire personnel of each household unit in every county.
2. X-ray every positive reactor.
3. Additional laboratory and medical examination to complete the diagnosis.
4. Provide adequate segregation and treatment for each case as long as he is infectious.

Economical Plan:

1. Concentrate x-ray studies particularly on the tuberculin sensitive adults present in each home in which tuberculin sensitive children are found.
2. X-ray adults who are positive reactors who have children who have negative reactions to tuberculin.
3. Reapply a TB test to all future members of population and all who were negative on previous survey at least annually.
4. Concentrate x-ray studies particularly on tuberculin sensitive adults in each home in which tuberculin sensitive children are found, who previously reacted negative to the test, and repeat them at least annually.

Dr. Stewart advised that financial aid would have to be solicited from different organizations such as the Minnesota State Medical Association, Hennepin County Medical Society, U. S. Public Health Service, and Foundations.

It was recommended that different groups such as the State Board of Health, Hennepin County Medical Society, American Medical Association be invited to send representatives to a meeting of the Tuberculosis Committee after the plan is under way.

It was agreed that a meeting be held March 26 of the members present and that Dr. Chesley of the State Board of Health be invited to attend.

The second meeting was held on March 26, 1940. The problem of the incorrigible tuberculous patient, that is, the one who has tuberculosis in the contagious stage, but who refuses to be admitted to a sanatorium, was discussed at some length by Drs. Slater and Flancher. Various methods of controlling them, such as quarantine, were considered and it was moved by Dr. Slater that the Committee go on record as favoring the state's sponsoring or providing an institution where the incorrigible tuberculous patient, or the one that might be considered a menace to the community, could be taken care of under such conditions so as to provide proper treatment and

at the same time retain the patient until it is safe for him to return to his community. The motion was seconded by Dr. Pfuetze and was carried.

The tuberculin test was discussed at some length and the Committee voted unanimously to recommend that the physicians of this state use the intracutaneous method of Mantoux. Considerable confusion has arisen concerning the reading of the tuberculin test. Inasmuch as there apparently has been a strong tendency to over-read the reactions, the following points were presented by Dr. Slater:

1. The tuberculin test should never be read until forty-eight or preferably seventy-two hours after administration.
2. Not more than one test should be given at a time.
3. When the first test is given with a small dose of tuberculin, a stronger dose may be administered in seventy-two hours, if there is no reaction from the first dose.
4. A tuberculin reaction consists of induration or edema. Redness of the skin at the site of administration, in the absence of induration, should never be considered as a reaction.
5. The degree of reaction depends on the extent of the induration and may be indicated as one, two, three, and four.

The Committee voted to recommend the ideal plan of tuberculosis control for the state which Dr. Stewart presented at the previous meeting. To supplement this, it was recommended that one county be selected to serve as a laboratory; that is, where an attempt be made to carry out in detail the ideal plan with reference to the tuberculin test, the x-ray film, and the complete examination for tuberculosis of everyone in the county.

The Committee voted unanimously to hold regular meetings, the next one to be during the convention of the State Medical Association in Rochester.

J. A. MYERS, M.D.

DR. R. M. BURNS: Your committee on Lay Education has made a thorough study of these reports. We wish, first of all, to commend the thoroughness and conciseness of these reports and heartily agree with their content. The Speakers' Bureau has had success and there is increasing demands for these talks. The radio has been a most effective means of influencing public opinion and we are happy to learn of the Duluth hook-up. We hope future stations will still be added. Dr. W. A. O'Brien is to be especially commended for his untiring work and the manner in which his talks are presented and the extent of the subjects covered.

The report of the Sub-Committee on Tuberculosis, headed by Dr. J. A. Myers, has been read. This report indicates that extensive study has been made of this subject, and the Committee endorses the recommendations of the Sub-Committee on Tuberculosis.

It was moved, seconded and carried that the report of the Reference Committee be accepted.

DR. W. W. WILL: We will now have the report of the Reference Committee on Medical Economics reports. The following committee reports were reviewed.

REPORT OF THE SUB-COMMITTEE ON PROFESSIONAL EDUCATION IN MEDICAL ETHICS AND SOCIAL AND ECONOMIC TRENDS

The last meeting of this committee took place on May 31, 1939, at which time the following members were present: Dr. H. S. Diehl, Minneapolis; Dr. J. J. Swenson, St. Paul; Dr. G. C. MacRae, Duluth; and Dr. Louis A. Buie, Rochester.

Inasmuch as other committees are taking care of social and economic problems, the duties of this committee should be limited, it has been felt, to problems of an ethical nature. It was suggested to the group meeting of the Economics Committee that the name of the subcommittee be changed and that henceforth it be known as the Subcommittee on Medical Ethics. It was also suggested that the number of members of the committee be reduced. There are now eight members and it is felt that three members should suffice. The group committee approved of the recommendation. This plan is therefore submitted to the House of Delegates for its approval.

Methods were discussed whereby information might be disseminated on the subject of Medical Ethics and it was decided that Drs. MacRae, Swenson and Buie should inquire of local medical societies regarding ethical problems of interest which have arisen in the past. It was agreed that helpful information concerning such problems should be published from time to time in MINNESOTA MEDICINE. This work has been planned and partially carried out. Your committee has found it advisable to proceed cautiously with this plan.

Dr. Diehl's program for undergraduate medical students was discussed and his work commended. The names of additional speakers were considered and several were recommended to Dr. Diehl for use in his program of lectures.

The committee has been active since its last meeting. Several important problems have come to its attention and have been handled satisfactorily. In each instance we have had the very fine cooperation of members of the Council, Mr. Brist and Mr. Rosell, and the advice and assistance of these men were largely

PROCEEDINGS EIGHTY-SEVENTH ANNUAL SESSION

responsible for the successful management of each case. Many ethical problems border very closely on those which are medico-legal and it is probable that there will be few ethical difficulties which can be analyzed and solved without the assistance of the above mentioned individuals.

The attached is a schedule of Dr. Diehl's lectures for the 1940 term.

L. A. BUE, M.D.

Orientation to Practice—Spring 1940 (Schedule of Lectures)

April 5 *Opportunities in and Preparation for Practice:*

General practice; specialization; industrial medicine; government service; insurance medicine; teaching and research; graduate and post-graduate training

Dr. H. S. Diehl

April 12 *Medical Licensure:*

State and National Boards; Basic Science Boards; reciprocity; Narcotic Licenses; responsibility of Licensure; revocation of license to practice medicine.

Dr. A. W. Adson

April 19 *Quackery, Fads, Cults and Patent Medicines:*

Definition and description; reasons for existence; relationship to the practice of medicine and to the public health; attempts at control; borderline types of practice by physicians.

Dr. W. A. O'Brien

April 26 *The Ethics of the Practice of Medicine:*

Responsibility of physicians to their patients and to each other; consultations; fee splitting; relationship to druggists, to nurses; euthanasia.

Dr. F. J. Hirschboeck

May 3 *The Management of the Public and Private Patient:*

Winning the patient's confidence; the diagnosis; the prognosis; cooperation of the patient in carrying out treatment; the patient's family; his job; his bills for medical and hospital care.

Dr. S. M. White

May 10 *Starting the Practice of Medicine:*

Choosing a location; problems of the young practitioner, relationship to other physicians; to hospitals; getting acquainted; determination of fees. Individual and group practice. Partnerships.

Dr. J. M. Hayes

May 17 *Malpractice:*

Definition; justified and unjustified malpractice suits; examples; safeguards against malpractice; malpractice insurance.

Dr. B. J. Branton

May 24 *The Physician in Court:*

In industrial compensation cases; as an expert witness in criminal suits; in personal injury suits; in malpractice suits.

Judge Paul Carroll

May 31 *Medical Care of the Indigent and of Low Income Groups:*

Cost of medical care; system of individualistic practice; free and pay clinics; state medicine; health insurance; hospital insurance; attitude of organized medical profession; trends in this country.

Dr. R. E. Scammon

June 7 *Medical Organizations:*

National, State and local; purpose; types of organizations; activities; advantages of membership.

Dr. C. B. Wright

REPORT OF THE MEDICAL ADVISORY COMMITTEE

It will be the purpose of the Chairman of the Medical Advisory Committee to give a verbal account of the work carried on by this Committee during the past year at the meeting of the House of Delegates. Because of the confidential nature of the contents, it is not being sent to the delegates at this time.

B. J. BRANTON, M.D.

REPORT OF THE SUB-COMMITTEE ON LOW INCOME AND INDIGENT PROBLEMS

During the past year our main project centered in the making of a survey of the state as regards the handling of relief, old age pension cases and dependent children. A complete survey was made of every county and nearly every township, also, at the same time, getting opinions from doctors. The report is now on file in the office of the secretary of the society. It did bring out many enlightening facts, many of which, I am quite sure, will be straightened out within the coming year.

During the past year a survey has been made by the Wright County Medical Society as to whether it wished to come under the Farm Security Administration program as far as medical care is concerned for clients of the Farm Security Administration. After very thorough study members of the Wright County Medical Society unanimously decided not to accept the plan. They expressed themselves as satisfied with the relief plan they have at the present time, and will take their own chances on making collections.

No other Farm Security proposals have been considered during the past year. Judging from the experience of neighboring states, we do not believe they will be necessary in this state in 1940.

As to the question of medical insurance plans to be carried out throughout the state, nothing has been very definitely proposed. We are perfectly willing to bide our time, and see what experiments are being carried out in the state of Wisconsin.

consin and some of our neighboring states, and we may learn a great deal from their efforts.

Mr. Finke, in charge of the welfare department throughout the state, is gradually formulating plans whereby there will be more uniform handling of relief matters than there has been in the past.

No grave complaints of methods of handling the low income group have been made during the past year. What the future may bring remains to be seen.

It is the recommendation of this Committee that the name of the committees now known as County Contact Committees be changed to County Medical Advisory Committees. The reason for the change is to better define the purpose and duties of these committees for associates and Welfare Boards in the counties.

W. A. COVENTRY, M.D.

REPORT OF THE COMMITTEE ON CONTRACT PRACTICE

Your Committee has held one meeting during the year, at which time several issues were discussed, the principal one being the case which has been pending for some time in regard to certain contract practices with the Eagles Lodge. There are some court actions on the docket in regard to this, but no definite information is available at this time.

It is the unanimous opinion of your Committee that it would be advisable for the Council collaborating with this Committee to reiterate their definitions and limitations of any and all so-called contract practices. There are a number of members who have contracts of various sorts with industrial firms and groups of various kinds and reiteration of the stand of the Council and the Officers of the Society at this time would not be amiss.

F. A. OLSON, M.D.

REPORT OF THE COMMITTEE ON INDUSTRIAL RELATIONS

The council of the City of St. Paul last fall announced the appointment of five physicians to take care of city employees injured in the line of duty. At the same time, employees were informed that medical fees would be paid only to these physicians.

Immediately, thereafter, members of the Ramsey County Medical Society passed a unanimous resolution in opposition to the action and expressed their willingness to continue to care for any city employees who might wish to come to them, pending final disposition of the matter.

Subsequently a St. Paul fireman was injured on duty and was treated, at his own request, by his family doctor. This doctor was not one of the five selected and the City Council refused to pay his fee though no question was raised as to its fairness.

The fireman's case was appealed to the Industrial Commission and the Commission upheld the city in this matter. Thereupon the St. Paul Trades and Labor Assembly took over the case for the fireman and appealed to the Supreme Court for a decision.

At the direction of the Council of the Minnesota State Medical Association, Mr. F. Manley Brist, attorney for the association, then filed a brief, as friend of the court, defending the right of the injured employee to his choice of physician. A brief in defense of this right was also filed by the Minnesota State Federation of Labor.

The case was heard by the Supreme Court on April 1 and no decision has been handed down as yet. It is hoped that the decision when it comes will be favorable.

STEPHEN H. BAXTER, M.D.

REPORT OF THE EDITING AND PUBLISHING COMMITTEE, MINNESOTA MEDICINE

For Period January 1, 1939, through December 31, 1939

The year 1939 proved to be a banner year for Minnesota Medicine from the standpoint of increase in revenue, the net surplus being the largest ever shown in its twenty-two years of publication. The net cash surplus amounted to \$1,679.32 as compared to \$934.76 for the previous year. The nearest approach to the 1939 surplus was that for 1929, which amounted to \$1,081.52.

During 1939 there were printed a total of 37,900 copies, or an average of 3,159 per issue. The total number of pages amounted to 1,208, or an average of 100.6 per issue. Of this number 890 were devoted to reading and 318 to advertising. The reading pages included 127 scientific articles, including those presented in the Proceedings of the Minnesota Academy of Medicine and the Minneapolis Surgical Society. In addition there were seven abstracts of papers and fifteen case reports. This number does not include the case reports appearing in the body of many of the scientific articles. Illustrations numbered 150, an average of 12.5 illustrations per issue.

The special sections devoted to Medical History of Minnesota and Medical Economics occupied 77 pages and 76 pages, respectively, or an average of about 6.5 pages per issue. Other special sections included editorials, reports and announcements of societies, news items, book reviews, the yearly roster and minutes of the annual meeting of the Association. There are now 158 pages of type matter relating to the Medical History of Minnesota. In accordance with our promise, we are holding this in page form.

At the close of 1939 our records showed the total number

PROCEEDINGS EIGHTY-SEVENTH ANNUAL SESSION

of paid membership subscriptions to be 2,503, with about 135 subscriptions carried the first part of the year as delinquent accounts. There were 204 non-member subscriptions. Miscellaneous distribution, including single copy sales, exchanges, complimentary copies, advertisers' checking copies, et cetera, numbered 351 copies, leaving a surplus of about 100 copies for possible distribution in filling orders for back copies and for sending sample copies to prospective subscribers and advertisers.

The outlook for 1940 is of course somewhat uncertain. However, there seems to be a general feeling that conditions will not be worse than in 1939 and possibly better, even though it is election year. In difficult times like these, no reasonable assurance can be given for any definite period of time.

It is encouraging, however, to know that the first quarter of 1940 shows a substantial increase over the corresponding period for last year, and the first three months shows an excellent condition.

Your attention is again called to the fact that a substantial volume of advertising has to be declined because the products have not been approved by the Council of the A.M.A. One Minneapolis firm recently offered a contract for \$100 an issue, or four full pages in each issue, which could not be accepted because of these restrictions. In the end, however, we feel that this policy commands the confidence and respect of readers as well as of national advertisers.

During the year Dr. J. T. Christison, for more than fifteen years a member of the Publication Committee, and for ten years its chairman, retired from practice and from his place on this committee.

The long, faithful and efficient service which Dr. Christison gave to MINNESOTA MEDICINE is deserving of the most sincere appreciation of every member of this Association. It was a work in which he was deeply interested, and to which he gave a considerable portion of his time. I feel that he should be given a vote of thanks for his splendid service.

In accordance with the authority of the Council a special feature was included with the January, 1940, issue of the Journal. This consisted of the publication of a 52-page supplement, and of 600 additional copies of that issue. The cost of this was charged against the net cash earnings for 1939. Other features may be included in the Journal during the year, with the approval of the Publication Committee and the authority of the Council.

E. M. HAMMES, M.D.

REPORT OF THE COMMITTEE ON SICKNESS INSURANCE

At a recent meeting of the Committee on Sickness Insurance of the Minnesota State Medical Association, a free discussion was conducted concerning the various plans that are being experimented with in different cities, counties and states, as well as a discussion of the general policy the committee should take concerning plans that might develop within our own state.

Members of the committee agreed that there was no need for the proposal of a state plan at the present time, but that the committee should keep on file in the Secretary's office copies and reports of all plans and the results of such plans for reference in the event that some city or county should feel inclined to develop some type of group sickness insurance.

In brief, the committee wishes to assure the House of Delegates that we are vitally interested in this subject, but we prefer to take a passive rather than an active interest in initiating any sort of plans.

The committee expressed itself as not favoring any plan which might be started by a few doctors in a community, unless it has the approval of the county society, and furthermore, any such plan should include the whole medical group in the county. It was thought advisable that any proposed plan should be first submitted to the Committee on Sickness Insurance which will refer it to the Council, for further consideration.

A free discussion took place concerning the advisability of carrying on a pro-medical publicity program. The committee concluded that it would be unwise to initiate such a program, but it should be prepared to counteract any unfavorable propaganda that might arise concerning compulsory state health insurance.

There appears to be an abundance of material on the affirmative side of socialized medicine and the question of the proper method of disseminating literature on the negative side was discussed. Mr. Crownhart's book on "Sickness Insurance in Europe" was one publication the committee felt should be given wide distribution. Furnishing libraries, particularly college libraries in towns of 10,000 population and over, was another means of distributing material. Doctor Adams was instructed to consult the Council of the Minnesota State Medical Association relative to the cost and advisability of furnishing libraries with this book.

It was also agreed that Doctor Adams and Mr. Rosell should make a survey of the situation with regard to material available on the subject of Socialized Medicine and also where this material should be distributed.

Doctor Cranmer explained in detail the Hennepin County Medical Society plan. Doctor Sivertsen discussed a proposed plan, and Doctor Alberts discussed the plans that Ramsey County has in mind.

Submitted by those in attendance at the meeting of the Committee on Sickness Insurance, in St. Paul, on March 22, 1940.

A. W. ADSON, M.D.

REPORT OF THE COMMITTEE ON MEDICAL ECONOMICS

Developments affecting the economic side of medicine have gone on apace. Probably of outstanding importance has been the tactical defeat of the Wagner Bill, largely due to opposition developed in the ranks of federal authorities themselves. The forces of the American Medical Association and their friends were arrayed against it, and their stand was undoubtedly a powerful obstacle. Nevertheless, the change in the attitude of "high-

er-ups" toward the proposed plans of the National Health Program apparently was the deciding factor. Of great importance is the recent change in attitude of federal authorities toward the representatives of organized medicine. Instead of the former ostracism from federal health councils, representative physicians of late have repeatedly been called on for counsel. The President's hospital bill, recently introduced in Congress, is a far cry from the National Health Program. It is quite probable that this bill will be modified according to the suggestions of officials of the American Medical Association. Some of the phases of Medicine are still playthings of social reformers and politicians, although for the time being at least there is a pause in their activities. It is barely possible that it has finally been realized that the physician is better equipped to make any necessary adjustments in medical distribution than the unholy alliance of social reformers and politicians. The idealistic stand of the physician toward Medicine seems to be rather difficult for some laymen to comprehend. That the physician will resist any changes which he believes will be detrimental to Medicine, even though they may be to his economic advantage, seems hard for the lay mind to grasp. The recent decision of the Appellate Court to the effect that Medicine is not necessarily a profession but can be regarded as a trade has imperiled the status of organized medicine. The case is now in the hands of the Supreme Court and its decision will be of great importance.*

During the past year several state and county medical societies have endeavored to solve the problem of the cost of medical care by voluntary sickness insurance, carried on under their supervision. The State Medical Associations in California and Michigan, with the consent of the legislatures, have already set up plans for voluntary sickness insurance. It is too early to determine the results, but disappointment has been expressed because of the small number of subscribers who are availing themselves of this opportunity. Largely those with an income which would place them well above that of the medically indigent have availed themselves of it. This is true in spite of the fact that the monthly rate asked by the California Medical Association is so low that in the minds of many physicians it would be impossible to deliver good medical care. It would seem that some of the people who want changes, want them at little or no cost to themselves.

Theoretically it would seem that some form of *voluntary* sickness insurance would be an ideal solution of the problem. However, such insurance has many faults to be overcome. It has been claimed that *compulsory* health insurance is the only way to insure widespread acceptance. Those who are at all familiar with compulsory insurance, however, realize that there are but few who would be willing to see it adopted. The solution of the financial problems of medical care is necessarily in the hands of the physician and it will gradually be worked out in the best interests of all concerned.

The Minnesota State Medical Association has wisely continued its policy of observing the various attempts made by state and county societies to find some solution. Fortunately for us, there is no urgent need in Minnesota for adjustments other than those which are already being made by the physicians of various communities. It can safely be said that our Council and the committees interested will keep themselves informed.

The Bureau of Medical Economics of the American Medical Association published during the year the report of the nationwide Survey of the Demand and Supply of Medical Care, in which many members of the Minnesota State Medical Association took part. Great credit is due to the Bureau for the completion of this monumental undertaking. While the report from Minnesota was not as voluminous or complete as might be desirable, nevertheless it contained many data which were of definite value. Some states, such as Pennsylvania, New Jersey and others, made very painstaking and complete reports. Some of the county societies, particularly Cook County, spent much time and money in completing the survey and as a result made recommendations which were definite contributions to the medical situation in their counties. It is unfortunate that more physicians could not be induced to participate actively in the survey. The time undoubtedly will come when the medical profession will be called upon again to make an inventory, possibly in a more simplified form. Now that the physicians have been awakened to the value of such a survey, a more enthusiastic response is to be hoped for.

A meeting of the Sub-committees on Medical Economics was held in St. Paul in December, at which some of the more recent economic problems were discussed. A report of some of the discussions was published in the January number of MINNESOTA MEDICINE. There is no doubt that a meeting of this kind acts as a stimulus to the various sub-committees and also permits of more adequate coöperation.

At the request of the Council, a Committee on Sickness Insurance was appointed last fall. The membership of this committee is as follows: Dr. A. W. Adson, chairman, Dr. E. D. Anderson, Dr. L. A. Buie, Dr. R. R. Cranmer, Dr. O. W. Holcomb, Dr. G. C. MacRae, Dr. O. I. Sohlberg, Dr. W. W. Will. This committee promises to correlate all the information on this vital subject and should be of practical value in forming any new plans which might seem advisable to solve the problems involving insurance in our own state.

Of outstanding economic interest is the recent appointment by the Minnesota Division of Social Welfare of an Advisory Committee to coöperate with the head of the Division, Mr.

Walter Finke, on matters affecting medical care of those groups classified as indigent or medically indigent. This Advisory Committee is composed of the following members: Dr. A. W. Adson, chairman, Dr. E. J. Simons, Dr. C. A. Stewart, Dr. L. L. Sogge, Dr. W. A. Coventry, Mr. Walter Finke, and two ex-officio members, Dr. A. J. Chesley and Mr. R. R. Rosell. With the generous coöperation of Mr. Finke this committee has been successful in effecting a definite improvement in the status of the physician dealing with this class of patients. The report of this committee, which was submitted to the county contact committee, contains an excellent résumé of the progress which has been made.

During the year an attempt has been made by the Editorial Sub-committees to keep the members of our state association informed in the economic section of MINNESOTA MEDICINE as to current developments of economic interest. A perusal of these columns, together with those of the section of Organized Medicine in the *Journal of the American Medical Association* will keep every physician abreast of recent developments in the medical problems of economic interest which are of such vital importance to the future of Medicine.

W. F. BRAASCH, M.D.

Dr. M. C. Piper: I would like to make a preliminary suggestion if it is not out of place. It has occurred to me that some time in this program, somebody should express an appreciation to the Committees who have so faithfully performed their work during the year and brought in these very nice reports for us. Furthermore, it seems to me that we crowd this report of a year's work into the last part of the evening when we are all tired and not giving due emphasis to it. I should like to suggest that we give this part of the program of the Delegates more time and attention.

We advise the adoption of the recommendation in the first paragraph of the report of the Sub-committee on Professional Education in Medical Ethics and Social and Economic Trends; that the number of the Committee be reduced from the present eight members to three members, and that it be known as the Sub-committee on Medical Ethics. The Reference Committee wishes to add its recommendation regarding the series of undergraduate lectures as outlined by Dr. Diehl of the University.

The Reference Committee has no comment to make regarding the report of the Medical Advisory Committee.

We recommend the adoption of the report of the Sub-committee on Low Income and Indigent Problems and suggest the continuation of the activities of the committee. It is suggested, if feasible, some provision be made to acquaint the various County Medical Societies with the findings of the state survey referred to with suggestions regarding the relationship between County Medical Advisory Committees and County Welfare Boards. Of course, this resolution was drawn up before we heard this excellent discussion this evening.

We recommend the adoption of the report of the Committee on Contract Practice with the suggestion the Chairman be given the privilege of the floor for further amplification of a supplemental report.

The Reference Committee recommends the adoption of the report of the Committee on Industrial Relations.

The Reference Committee recommends the adoption of the report of the Editing and Publishing Committee, with this suggestion: that a vote of thanks be given on the part of the Association to Dr. Christison for his meritorious service on this committee. Furthermore, the Reference Committee wishes to compliment MINNESOTA MEDICINE on the publication of the supplemental issue of January, 1940, as well as for the favorable financial standing at this time.

The Reference Committee recommends the adoption of the report of the Committee on Sickness Insurance.

The Reference Committee recommends the adoption of the report of the Committee on Medical Economics and wishes to call attention to the statement in Paragraph 4 that there is no urgent need in Minnesota for adjustments other than those that are already being made, but feels that in a state, fortunately situ-

*Editor's Note: The case has now been remanded for trial to the District Court.

ated as Minnesota is said to be, some definite plan of solution of the care of the indigent and of the people not on relief but unable to afford adequate medical care should be inaugurated by this Association.

Dr. F. A. Olson, Chairman of the Committee on Contract Practice, and Mr. F. Manley Brist, Attorney for the State Medical Association, gave supplemental reports but their remarks were not recorded. Dr. B. J. Branton and Dr. L. L. Sogge likewise gave supplemental but unrecorded reports.

It was moved, seconded and carried that the report of the Reference Committee on Medical Economics Reports be accepted.

A Committee on Resolutions, composed of Dr. D. P. Head, Dr. E. M. Hammes and Dr. E. C. Bayley, was appointed by Dr. Will to report at the next meeting of the House.

At the request of Dr. Will, the Necrology report was then given by Dr. B. B. Souster, Secretary, as follows:

NECROLOGIST'S REPORT

MEMBERS

Olav N. Birkeland, Hibbing. Born 1887. Northwestern University 1917. Died February 2, 1940. Aged 52.

Ernest H. Bohland, St. Paul. Born 1874. Minneapolis College Physicians and Surgeons 1903. Died January 10, 1940. Aged 65.

A. C. Jacobs, Elmore. Born 1852. Minnesota Hospital College 1886. Died June 28, 1939. Aged 87.

Benjamin W. Kelly, Aitkin. Born 1874. University of Michigan 1897. Died June 4, 1939. Aged 65.

Charles A. Lapierre, Minneapolis. Born 1870. Laval University 1892. Died June 29, 1939. Aged 69.

William J. Mayo, Rochester. Born 1861. University of Michigan 1883. Died July 28, 1939. Aged 76.

James McCrea, Fulda. Born 1863. McGill University 1894. Died December 19, 1939. Aged 76.

Martha B. Moorhead, Minneapolis. Born 1865. Women's Medical College of Pennsylvania, 1892. Died October 13, 1939. Aged 74.

Howard McI. Morton, Vincentown, N. J. Born 1868. University of Pennsylvania 1891. Died July 19, 1939. Aged 71.

Timothy J. Moynihan, St. Paul. Born 1878. Minneapolis College of Physicians and Surgeons 1906. Died March 8, 1940. Aged 62.

Fred H. Neher, St. Paul. Born 1891. Marquette University 1915. Died December 6, 1939. Aged 48.

Leonard J. Nilles, Rollingstone. Born 1902. University of Minnesota 1936. Died February 2, 1940. Aged 37.

Lida Osburn, Mankato. Born 1875. University of Minnesota 1900. Died March 11, 1940. Aged 65.

Edward L. Paulson, Minneapolis. Born 1883. University of Minnesota 1909. Died October 7, 1939. Aged 56.

Victor Rosseau, Maple Lake. Born 1872. University of Minnesota 1905. Died October 15, 1939. Aged 77.

Jacob C. Rothenburg, Springfield. Born 1860. University of Michigan 1885. Died October 1939. Aged 79.

Fred H. Stangl, St. Cloud. Born 1893. Rush Medical College 1919. Died March 19, 1940. Aged 46.

Eugene S. Strout, Minneapolis. Born 1862. University of Michigan 1891. Died June 25, 1939. Aged 77.

Lincoln A. Sukeforth, Duluth. Bowdoin 1886. Died April 8, 1940.

Theodore Thordarson, Minneota. Born 1865. University of Illinois 1897. Died August 2, 1939. Aged 74.

James A. Watson, Minneapolis. Born 1867. Manitoba Medical College 1895. Died June 17, 1939. Aged 72.

Thomas T. Warham, Minneapolis. Born 1866. Minneapolis College Physicians and Surgeons 1897. Died March 28, 1940. Aged 74.

FORMER MEMBERS

Guy R. Caley, Princeton. Died September 26, 1939.

Charles R. Christenson, Starbuck. Died January 14, 1940.

C. T. Granger, Rochester. Died July 30, 1939.

George A. Kohler, Minneapolis. Died January 8, 1940.

Owen McKeon, St. Paul. Died December 29, 1939.

Dr. W. W. Will: I would like to ask the House of Delegates to stand in memory of the departed. (Delegates stood as requested.)

The House of Delegates will reconvene at the Cafe in the Kahler Hotel tomorrow.

The meeting adjourned.

HOUSE OF DELEGATES

Monday, April 22, 1940

Dr. W. W. Will introduced Dr. H. Z. Giffin, Chairman of the Council.

Dr. H. Z. GIFFIN: I have noticed from time to time that the Speaker of this House has considerable difficulty in getting the House to come to order. It occurred to me the House of Delegates had no gavel and also that we had an artist in wood in our membership, who might be persuaded to make the gavel for us. Accordingly, I approached Dr. Lemon on the matter and Dr. Lemon not only agreed to make a gavel but he worked assiduously at it and he has produced a work of art. I would like to have Dr. Lemon tell you about it. (Dr. Lemon's speech in full is published elsewhere in this issue.—Editor.)

Dr. W. W. Will: Dr. Lemon, on behalf of the Minnesota State Medical Association and this House of Delegates, I accept the gavel with a great deal of pleasure.

Upon being informed that a quorum of certified delegates was present by Chairman E. S. Boleyn of the Credentials Committee, Dr. Will then asked Dr. B. S. Adams of Hibbing to read a telegram from St. Louis (Missouri) Medical Society asking Minnesota delegates to the American Medical Association to vote for St. Louis for the 1943 convention of the Association. The motion was then made and seconded and carried to dispense with the reading of the minutes of the previous meeting.

Dr. W. W. Will: I see, sitting before me, a man before whom I appeared many, many years ago, as a student in fear and trembling. Perhaps the reason that I felt like a little boy in his presence was because he took such a fatherly interest in my class. They tell me he has grown older; I admit that his hair is a little bit grayer though he parts it just as he did all those years ago. He has been a president; he has been a member of the House of Delegates of the American Medical Association; he has done yeoman service in the Editing and Publishing Committee. Someone has said that he has retired. Now ordinarily, I would believe anything that a member of this House of Delegates might say, but when anyone tells me that Dr. J. T. Christison has retired, especially when there is a fight on in the interest of organized medicine, I must ask them to prove it. I am sure that this House of Delegates agrees with me that Dr. Christison has been one of the most valuable members of our Association, and don't ever let anyone tell you that Dr. Christison has retired. He has not; he is here with us today and we will hope that he will stand up at least and take a bow if he is given the opportunity. Perhaps you, yourselves, would like to express your feelings about Dr. Christison.

Dr. C. A. Stewart: Mr. Chairman, I would like to have the privilege of expressing my appreciation and genuine admiration for Dr. Christison. In the year that I was born, 1890, Dr. Christison received the degree of Doctor of Medicine from Long Island College. There is a story connected with his graduation. His final examination included a practical exam-

ination in which he was assigned the sphenoid bone. It is said that he took the bone into the proctor and it is said that the proctor did not recognize the bone and passed him.

In 1895, Dr. Christison became Clinical Professor of Pediatrics at the University of Minnesota and as such, he enjoyed the distinction of being the first Clinical Professor of Pediatrics west of the Mississippi River. It was he who appointed Dr. Walter Ramsey and Dr. Julius Parker Sedgewick to the Department of Pediatrics. And in so doing he became, in truth, the father of Pediatrics in the state of Minnesota.

Dr. Christison has been identified with the Minnesota Medical School for something in excess of forty-seven out of the fifty-one years of its existence. In addition to these statistics, he has been president of this Medical Association; he has also been our delegate to the American Medical Association. And in addition, as it has already been mentioned, the guidance of MINNESOTA MEDICINE has been in his hands for many years. I consider it a pleasure here to be able to announce that an endowment fund derived from the earnings of MINNESOTA MEDICINE has been established. This endowment insures the future of the journal which he has fathered through all these years. This year the fund will receive something in excess of \$1,000. And we may well look upon this endowment as the J. T. Christison Endowment Fund. I thank you.

DR. E. M. HAMMES: Being one of Dr. Christison's old students, and living in his neighborhood, I would like to be allowed to say a few words about him.

I do not understand the Speaker of the House when he says that he approached Dr. Christison (we liked to call him Christy when we were students) with fear and trembling. I think he must have been the only student who ever approached Dr. Christison with fear and trembling. Dr. Christy has many pet babes and among them was the Pediatrics Department of the University of Minnesota, the State Medical Association, the American Medical Association and last but not least MINNESOTA MEDICINE.

It was in 1916 when the Council first talked about publishing a medical journal. In 1917, the president appointed a committee consisting of Drs. Scofield, Finkler, Hill and Buckley and one other member to consider the report on an offer made by the *St. Paul Medical Journal* to turn over this journal with all its assets to the Minnesota State Medical Association. Through the efforts of Drs. Buckley and Emmett Farr, both of whom are now deceased, and Dr. Christy, the offer was accepted and MINNESOTA MEDICINE was born.

It was in 1919 that Dr. Christy became a member of this committee and for at least the past ten or eleven years he was Chairman of the Committee. Through his untiring efforts, we now have a journal second to none, I believe, in this country.

Dr. Christy has traveled extensively to Europe and South America and I said to him a little while ago: "Christy, what are your hobbies now?" He replied, "My hobbies are to see America last."

Of all the members of the medical faculty of the University, Christy was not only one of the most popular among the medical students—I do not know if Christy knows that or not, although it is true, but the friendship and affection which began in those days has continued and grown throughout the years, and we, his own students, still hold him in high esteem.

Dr. Christy, we want you to come here regularly for our meetings, every year for years to come. We still need your counsel and we still need your advice.

DR. W. H. AURAND: Mr. Speaker, there aren't many members of the old class of 1901 here, but I happen

to be one of them. We thought so much of Dr. Christison in those days, that we made him a member of our class of 1901.

DR. L. L. SOGGE: Sometimes we admire a tree because it produces beautiful flowers, and sometimes because it produces fruit. Those among us who attended Dr. Christy's classes feel that he was a flower to us medical men and that he produced fruit that we have enjoyed as long as we have known him.

I was a farmer boy when I went into his classes. Some of us were pretty discouraged at times; we thought it an almost impossible task to go through and complete the course, but I remember as plainly as if it were yesterday how Christy encouraged me. He is one of the men who helped me to get the courage to go through medical school and I shall never forget him.

DR. WILL: I am sure that there are many more of you who would like to express your thoughts in regard to Dr. Christy. I think, however, that I ought to offer a word of explanation as to why the fear and trembling. I, too, was a farmer boy, and Dr. Christy was a very distinguished looking man; he has never gotten over it either. He was like a father to us, too, but stand me up alongside of him now and you couldn't tell which was the father. Dr. Christy would say, "It's the way you live, of course." I think we ought to give you a little chance to say a word for yourself, Dr. Christy.

DR. J. T. CHRISTISON: Mr. Speaker and Gentlemen of the House: Just give me a minute to get the lump out of my throat.

I received, when I returned home a few days ago, a letter from that imp, couched in such terms that I could not resist the temptation to come to this meeting. It never occurred to me that you were going to put up a job like this on me. I was going to say that it is downright cruelty because "there ain't any such thing."

It is true enough that I probably passed a lot of you fellows when I shouldn't have done it; but at the same time, you were all boys to me and you always will be. Some years ago, at a meeting of this Association in Minneapolis, I took the liberty of saying that the members of the State Medical Association of Minnesota were, individually, the finest lot of men I have ever known, but collectively, you weren't worth a damn.

Since that time, many things have happened.

We had under consideration, at that time, the plan of selling the State Society to the County Societies and our dear, beloved friend, Herman Johnson, was the sponsor of the movement. He enlisted the services of Dr. Savage, Dr. Sogge, myself and some others, and I think, between us, we put it over. So that today, Minnesota is recognized by the American Medical Association as one of the outstanding subordinate societies in its entire membership. The little things that I have done I regard as simply my duty.

When I first entered the teaching service of the Medical College, it wasn't much of a school to tell the truth. But the students were earnest, hardworking boys, and they deserved what they got.

Speaking of Herman Johnson, I remember an examination I gave to the class of 1901, of which he was a member. I wrote the question on the board and told the boys I was going over to smoke a pipe with Westbrook. They might write until they got tired and I would be back in an hour and a half. When I came back, there was only one man in the room. He was on the top row in the benches in Millard Hall, writing away for dear life. I tiptoed up and looked over his shoulder; he had about seven or eight pages of foolscap closely written. I said to him, "Herman,

(I knew most of the boys then, you know, by their first name), what on earth are you doing?" So intent had he been on his writing that he jumped when I spoke to him. "I'm trying to complete this examination because getting through medical school means a lot to me," he said. "Herman," I said, "let me see what you have got there."

He handed me the sheaf of papers and I looked at them. "Well, Herman," I said, "I don't know if you are trying to write a book, or what you are trying to do, but if you expect me to read all that stuff, you are jolly well mistaken." I took the test, and folded it up, marked "B" on it, and handed it back.

This comprehensive business that they have now at the end of the year did not appeal to us fellows at all. After we had had a group for six weeks, we knew who was going to pass and who wasn't. We interrogated them as we went along, and we found out if they were getting any good out of our lectures and whether the clinics, which we were giving them, were bearing fruit. And perhaps you got what you deserved after all.

Perhaps if I had known what was contemplated, I might have skipped out; but no one, I am sure, could appreciate more than I, the kindly feelings that prompted these remarks, and from the bottom of my heart, I thank you.

Dr. W. W. WILL: I am going to depart from the usual proceedings and call at this time for election of officers.

The Speaker then called for nominations for the office of President-elect.

Dr. B. J. Branton of Willmar was nominated for the position of *president-elect* by Dr. S. A. Slater of Worthington. There being no further nominations, it was moved, seconded and carried that the nominations be closed and that the secretary cast a unanimous ballot for Dr. B. J. Branton for the office of President-elect.

In response to a request from the Speaker, Dr. Branton acknowledged his election to the position of president-elect and recalled that he had graduated from medical school with Dr. Sogge and Dr. Will and many others who were present among the delegates. He hoped to be able to follow worthily in their footsteps as president of the Minnesota State Medical Association. He declared that to be elected president by colleagues in the same profession is the greatest honor that could come to any man in a lifetime. He thanked the delegates from the bottom of his heart and expressed the hope that he would be able to measure up to the men who preceded him in office. He foresaw pitfalls for medicine in 1941 and bespoke the coöperation of all to avoid them and to maintain the high standards of medicine in Minnesota.

Dr. Albert Fritsche of New Ulm was nominated for the position of *first vice president* and there being no further nominations, it was moved, seconded and carried that the nominations be closed, and the secretary be instructed to cast the unanimous ballot for Dr. Fritsche for first vice president.

Dr. F. J. Heck of Rochester was nominated for the position of *second vice president*, and there being no further nominations, it was moved, seconded and carried that the nominations be closed, and the secretary be instructed to cast the unanimous ballot for Dr. Heck for second vice president.

Dr. B. B. Souster of St. Paul was nominated to succeed himself as *secretary*, and there being no further nominations, it was moved, seconded and carried that the nominations be closed and that the president be

instructed to cast the unanimous ballot for Dr. Souster for secretary.

Dr. W. H. Condit of Minneapolis was nominated to succeed himself for the position of *treasurer*, and there being no further nominations, it was moved, seconded and carried that the nominations be closed and that the president be instructed to cast the unanimous ballot for Dr. Condit as treasurer.

Dr. W. W. Will of Bertha was nominated to succeed himself as *Speaker of the House of Delegates*. Dr. E. A. Meyerding, vice speaker, was asked by Speaker Will to take the chair. There being no further nominations, it was moved, seconded and carried that the nominations be closed and that the secretary be instructed to cast a unanimous ballot for Dr. Will to succeed himself as Speaker of the House of Delegates.

Dr. Will resumed the chair and Dr. E. A. Meyerding of St. Paul was nominated to succeed himself for the position of *vice speaker*. It was moved, seconded and carried that the nominations be closed and that the secretary be instructed to cast a unanimous ballot for Dr. Meyerding for vice speaker.

Dr. Carl M. Johnson of Dawson was nominated as *Councilor of the Third District* to succeed Dr. B. J. Branton, previously elected to the position of President-elect, and it was moved, seconded and carried that the nominations be closed and that the secretary be instructed to cast a unanimous ballot for Dr. Johnson as Councilor of the Third District.

Dr. E. M. Jones of St. Paul was nominated to succeed himself as *Councilor of the Fifth District*. There being no further nominations, it was moved, seconded and carried that the secretary be instructed to cast a unanimous ballot for Dr. Jones as Councilor of the Fifth District.

Dr. E. J. Simons of Swanville was nominated to succeed himself as *Councilor of the Seventh District*. There being no further nominations, it was moved, seconded and carried that the nominations be closed and that the secretary be instructed to cast a unanimous ballot for Dr. Simons as Councilor of the Seventh District.

Dr. W. A. Coventry of Duluth and Dr. W. F. Braasch of Rochester were nominated to succeed themselves as *Delegates to the American Medical Association* with Dr. J. C. Hultkrans of Minneapolis and Dr. W. L. Burnap of Fergus Falls as *Alternates*. There being no further nominations for any of these offices, it was moved, seconded and carried that the nominations be closed and that the Secretary cast a unanimous ballot for these four men as Delegates and Alternates to the American Medical Association.

Dr. W. W. Will then called for Dr. T. B. Magath to present a resolution to the House of Delegates.

Dr. T. B. MAGATH: I am speaking not as a member of the State Board of Health but as Chairman of the Executive Committee of the American Society of Clinical Pathologists, and a member of the organization of Pathologists of this state.

For many years, the Pathologists have been cognizant of the fact that the entering wedge in Corporate and State Medical Practice was through their specialty. Three problems have confronted us through these years. One is the practice of laboratory medicine by lay-groups, which came to a head in Pennsylvania this year when the court decided that the practice of laboratory medicine was the practice of medicine and that in

order to practice medicine in Pennsylvania, you had to have a license.

The second is the practice of pathology, and anesthesia, and radiology by the hospitals. We have maintained that the hospitals have no right to practice medicine. They therefore have no right to practice radiology, pathology, and anesthesia, or any other specialties of medicine.

The third is the State Board of Health situation, which is not very serious in this state, but which has reached enormous proportions in many other states. As a matter of fact, even in this state, there are no private practitioners of pathology who get their living by the practice of pathology alone. Through Federal grants in aid, the Federal Government is able to dictate to State Departments of Health how funds shall be spent, and there have been many federal grants in aid to state laboratories. The only way to avoid such dictation is to refuse to receive the money. As a matter of fact, three states have refused to receive federal money in certain maternal welfare programs and in certain other situations. But because their funds are so large in proportion to state funds, it has been impossible for state laboratories or state boards of health to refuse them in the majority of cases for perfectly obvious reasons.

The situation thus created is extremely critical for the practice of clinical laboratory medicine. We are faced with a kind of parting of the ways. If the situation is to continue, there will be no practice of pathology as such, and one has only to cite the fact that at the present time, there are from eight to ten jobs open for one pathologist who is able to take them. To show how serious the situation is, naturally young men will not go into pathology unless there is a possibility of remuneration in private practice in that particular field.

As pathologists, we feel that if this tendency continues, and if this is to be the order of the day, there is no reason why State Boards of Health or other state or municipal organizations may not practice any form of medicine. We see, according to newspaper accounts, that Surgeon General Parran has advocated that future diagnosis in cancer must be made available free of charge to anyone who wants it. Why he has not said that the operation for the removal of the cancer should be free I cannot understand.

In any case, pathologists feel that it is time now to have on record some resolution by the American Medical Association, pointing out the principle on which pathology should be practiced by State Boards of Health. It should be said in the beginning that there is absolutely no contention on the part of any pathologist that the State Board of Health should not control communicable disease in any way that it sees fit. That is the prerogative of the Board and must not be interfered with by anyone.

They do not believe, however, that the state laboratory has any right to do laboratory medicine for people who are able to pay for it. And that is the only principle on which we base this resolution. We believe that the same policy applies to all branches of medicine and that it is fundamental to the practice of medical arts as we know it today.

It may interest you to know that there are probably less than one thousand pathologists in the United States qualified to practice pathology today. The situation has been presented to the Board of Trustees of the American Medical Association, and the Trustees have suggested that we return to our several states and present to them resolutions of the character of the resolution which I am about to read you now. Similar resolutions will be presented to other state medical societies throughout the United States.

"WHEREAS the continued growth and development of that branch of medicine known as clinical pathology is necessary for the proper diagnosis and treatment of the sick and is essential to the science of medicine; and

"WHEREAS the natural growth of laboratories of state boards of health has been greatly augmented by grants-in-aid from the federal government; and

"WHEREAS the effect of these grants-in-aids is to extend these services to all citizens without regard to their ability to pay; and

"WHEREAS the excessive development of laboratory medicine by state boards of health serves as an entering wedge for state medical practice which apparently will include all medical specialties; and

"WHEREAS these tendencies result in the curtailment of the private practice of clinical pathology, which practice is essential for the continued growth and development of clinical pathology;

"BE IT THEREFORE RESOLVED that the House of Delegates of the State Medical Society recommends to the authorities of the State Board of Health that they consider limiting the services offered by the laboratories of the Board. In general, laboratory services by the State Board of Health Laboratories should be confined to requests made by health officers or others in authority representing municipal, township, county and state organizations, and requests from physicians whose patients find it difficult or impossible to pay the cost of laboratory services of this kind in the usual and customary manner. In general, laboratories of the State Board of Health should not provide services at the tax payers' expense to persons who are able to provide for themselves."

I should like to say in conclusion that the State Board of Health in Minnesota does not extend its services to clinical pathology and into other such services. It has confined itself rather generally to the control of communicable diseases. However, it is time that somebody in authority took the position that certain principles must be adhered to in the practice of medicine, and these principles apply to all specialties.

At this time Dr. W. W. Will called upon Dr. H. Z. Giffin, Chairman of the Council, to present a report of the day's Council meeting.

DR. H. Z. GIFFIN: The resolution just presented by Dr. Magath was considered by the Council today and approved and referred to the House of Delegates for action. The Council met with the State Board of Health this morning and several matters discussed were referred to the various committees and need not be presented at this time to the House of Delegates.

One other matter, that of the resolution sent by the Oregon State Medical Society, concerning the exhibit of the Mayo Foundation at the Fair in San Francisco and also the story and pictures about the Mayo Clinic which appeared in *Life* magazine, was considered by a committee of the Council consisting of Dr. Jones, Dr. Elias, Dr. Sogge, and Dr. Earl, who have presented a report and formulated a letter which received the unanimous approval of the Council this morning, and which will be referred at this meeting to the House of Delegates.

Other matters that were considered this morning need not, I believe, be referred to the House of Delegates.

Dr. J. P. McDowell inquired if the resolution involved in any way the question of nurses giving anesthetics in hospitals, and Dr. P. C. Leck of Austin asked if the resolution affected in any way the present practice of the State Board of Health in the matter of Wassermann tests.

DR. T. B. MAGATH: As you probably notice, the resolution is couched in the most general terms. As I said, the immediate effect in this state will certainly be nil because at the present time, this state has no laboratory that is set up on the basis of giving free laboratory tests to all.

If the principle is enunciated, however, we are hoping and expecting that ultimately young men who will practice pathology will come into this state. I am quite familiar with all of the obvious arguments and objections to this plan, not the least of which is that Wassermanns may be done in large quantities in a central place, done well and done efficiently. That is only one side of the argument.

We are maintaining that a pathologist is still a useful animal and that if he is around, he will do other things besides Wassermanns. If he can't make a living by doing Pathology, he won't be in Pathology, and you won't have any Pathologists. That is all there is to the whole problem.

It was moved, seconded and carried that the resolution be approved. At the request of the Speaker of the House, Dr. D. P. Head read the following resolutions which were approved by the Committee on Resolutions, and presented for action by the House of Delegates.

RESOLUTION ON THE STATE BOARD OF HEALTH

WHEREAS the State Board of Health and its secretary and executive officer, Dr. A. J. Chesley, have consistently worked with the Council of the Minnesota State Medical Association, not only in carrying out all branches of their established program, but in the inauguration of new activities made possible by federal appropriation; and

WHEREAS they have made invaluable contributions to the program of this association including the important statistical studies prepared especially for our monthly packets, and

WHEREAS they have used a considerable portion of federal funds allotted to Minnesota for the postgraduate education of our members out in the field and at the Center for Continuation Study on the University Campus,

BE IT THEREFORE RESOLVED that this House of Delegates express its deep appreciation to Dr. Chesley and his associates both for his cooperation in matters of policy and for his aid to our program and members, and

BE IT FURTHER RESOLVED that this House commends the Board and Dr. Chesley and their aids for their outstanding achievements in public health in Minnesota.

* * *

The courtesy extended our members and guests and the fine accommodations provided by the Rochester hotels, have greatly added to the comfort and enjoyment of all who attended this outstanding meeting. The House of Delegates extends its thanks and appreciation to managements and staffs of all of these institutions and to the people of Rochester who cooperated with them in providing added accommodations for guests.

* * *

Five distinguished out of state speakers have appeared before this convention through the courtesy of the following special societies: Minnesota Society of Internal Medicine, Northwestern Pediatric Society, Minnesota Radiological Society, Trudeau Society and the Northern Minnesota Medical Association.

In sponsoring these speakers the special societies have made inestimable contribution to our meetings which is gratefully acknowledged by this House.

* * *

Most of the credit for the fine arrangements made for this meeting goes to our host society, the Olmsted-Houston-Fillmore-Dodge County Medical Society and its active local arrangements committee under the chairmanship of Dr. F. J. Heck. To Dr. Heck and his committee and to every member of the Society, the House of Delegates in session here expresses its warm appreciation and gratitude.

* * *

WHEREAS a new policy by which the advice of physicians is sought by the Division of Social Welfare at each step in the re-organization of welfare work in the state, wherever medical care is involved; and

WHEREAS by this policy medical care of the needy is now being established on a better basis than ever before in the state; and

WHEREAS this new policy has been put into effect by Mr. Walter Finke, Director of the Division, and Dr. H. E. Hilleboe, Medical Coordinator, and their aids, he it therefore

RESOLVED that this House of Delegates profoundly appreciates the sympathetic cooperation of Mr. Finke and his associates and endorses his plan of close cooperation between physicians and welfare workers to the end that the welfare clients may have the best possible medical care in Minnesota.

BE IT ALSO RESOLVED that this House of Delegates offers Mr. Finke and his aids the fullest cooperation and support.

* * *

The House of Delegates wishes to express its obligation to the *Rochester Post Bulletin* and to the *Minneapolis, St. Paul and Duluth* papers including the *Minneapolis Star Journal*, *The Minneapolis Times Tribune*, *The St. Paul Dispatch* and *Pioneer Press*, and the *Duluth Herald and News Tribune* for their excellent reporting and treatment of scientific sessions held in connection with the meeting of the Minnesota State Medical Association at Rochester and for their generous contribution of space to advance announcements. The importance of accurate reporting of medical news is well recognized by the members of this House and the cooperation of these newspapers is thoroughly appreciated.

* * *

Radio time for three statewide broadcasts by distinguished guest speakers was generously provided by KROC, KSTP and affiliated stations of the Minnesota network. These broadcasts contributed much to the interest and value of the meeting of the Minnesota State Medical Association at Rochester and the warm thanks of the House of Delegates to stations KROC, KSTP and associates is hereby extended.

The grateful appreciation of this House is accordingly extended to every member of the Clinic Staff for the fine entertainment in which the Clinic acted with the Olmsted-Houston-Fillmore-Dodge County Medical Society as host, for their courtesy and helpfulness in every detail of this meeting and especially for their kindness in opening their homes to convention visitors who were unable to secure reservations in the hotels.

* * *

The Speaker then called for discussion of these resolutions.

Dr. C. R. DRAKE (Minneapolis): I second the resolution concerning Dr. Chesley most heartily. Last time I saw Dr. Chesley, outside this meeting, was down in St. Louis at a meeting of the National Association of Administrators of Schools. School people have many ideas about health; some of them good and some are poor; some of them are ridiculous. However, Dr. Chesley was on the job and I feel that our group put up the best argument all along the line. As a result of Dr. Chesley's work, I feel sure the organization will be guided largely by the medical profession.

It was moved, seconded and carried that the resolution be accepted.

The Speaker then called for the report of the Special Committee of which Dr. E. M. Jones of St. Paul was Chairman.

DR. E. M. JONES:

We have carefully reviewed the report of the Reference Committee on Executive Session of the Oregon State Medical Society pertaining to two matters of so-called "MAYO CLINIC PUBLICITY" and which report was forwarded to the Council of the Minnesota State Medical Association by Morris L. Bridgeman, M.D., Secretary of the Oregon State Medical Society, and, by Olin West, M.D., Secretary and General Manager of the American Medical Association.

The first of these two matters concerns certain alleged publicity regarding the Mayo Clinic and Mayo Foundation scientific exhibit at the San Francisco Fair in 1939, it being the claim of the House of Delegates of the Oregon State Medical Society that the exhibit "while ostensibly of a scientific character, is presented in such form as to make it a means of attracting patronage and hence commercial in nature."

We beg to most respectfully report that we have very carefully examined the facts and circumstances leading up to the participation by the Mayo Clinic and the Mayo Foundation in this scientific exhibit and we find the facts to be undisputed that the Mayo Clinic and the Mayo Foundation received numerous and repeated requests to assist in the presentation of such scientific exhibit at that Fair from members and officers of the California State Medical Society; that these requests were rejected by the Mayo Clinic and the Mayo Foundation; that following repeated renewal of such request the Mayo Clinic and the Mayo Foundation out of courtesy to those making the request reconsidered the matter and after discussing it with members and officers of the California State Medical Society and others, agreed to participate in such scientific exhibit provided that the exhibit first met with the approval of the members of the California State Medical Society with the distinct understanding that the exhibit would be maintained at the Fair only during 1939; that upon termination of the Fair, and before any decision was reached as to whether or not the Fair would reopen in 1940, this scientific exhibit was ordered dismantled by the Mayo Clinic and the Mayo Foundation and returned in spite of repeated requests to have it remain during the Fair in 1940.

This committee is thoroughly convinced that this exhibit was purely of a scientific nature and that the Mayo Clinic and the Mayo Foundation were actuated solely by a desire to present such scientific exhibit in acquiescence to the repeated requests from persons of high repute and standing in the profession of medicine in the State of California and who had no interest in the Mayo Clinic or in the Mayo Foundation and who were not motivated by any desire of attracting patronage to the Mayo Clinic or the Mayo Foundation, and who were interested solely in having at the California Fair a high type of scientific exhibit in the field of medicine that would interest visitors to the Fair.

Consequently, this committee is convinced following careful examination of the facts, including correspondence and telegrams in reference to the exhibit, that the exhibit was neither commercial in nature nor was the Mayo Clinic or the Mayo Foundation motivated by anything except the highest ideals and principles underlying the practice of medicine in their participation in this exhibit.

This Committee most respectfully wishes to inform the Council that it has carefully considered the second matter referred to by the House of Delegates of the Oregon State Medical Society concerning the Mayo Clinic and the Mayo Foundation, to-wit, the claimed impropriety of an article that appeared in *Life* magazine for September 4, 1939. It is the position of the House of Delegates of the Oregon State Medical Society that this article which makes reference to a

specified number of physicians on the staff of the Mayo Clinic and also makes reference to the alleged number of patients who register in one day at the Mayo Clinic and claimed approximate number of operations performed in one year by members of the staff of the Mayo Clinic is improper, it being claimed that the article in question "is generously illustrated with various photographs and charts outlining the organization and operation of the Clinic and Foundation," and the conclusion on the part of the House of Delegates of the Oregon State Medical Society that the "obvious effect of this type of publicity in a lay publication is to attract patients," and the further expression of opinion on their part that "publicity of these types has obvious commercial implications and is not in the best interests of the medical profession and is to be condemned," the recommendation of the House of Delegates of the Oregon State Medical Society being "that this publicity of the Mayo Clinic and the Mayo Foundation be called to the attention of the American Medical Association and all the constituent state medical associations. . . , the inference being that this so-called publicity was inspired and approved by the Mayo Clinic and the Mayo Foundation.

Your committee has made a most painstaking examination of the facts leading up to the publication of the article referred to in *Life* magazine and we find that the evidence is overwhelming; that this article was neither inspired nor approved by the Mayo Clinic or the Mayo Foundation. In fact, the facts show that the Mayo Clinic and the Mayo Foundation at no time furnished *Life* magazine nor any one connected with that magazine directly or indirectly, with any material or with any pictures to be used in such an article and furthermore, upon learning the *Life* magazine intended to publish such an article, immediately conferred with the officers of the Minnesota State Medical Association and with a number of officers and trustees of the American Medical Association and in addition sought legal advice to determine if there was not some way in which the Mayo Clinic and the Mayo Foundation could dissuade or stop through legal means, the publication of any such article. It was then discovered that no amount of persuasion would deter *Life* magazine from obtaining such an article and it was also learned that no legal steps could be taken to enjoin *Life* magazine from publishing such material, correct or otherwise, as they had been able to gather through their own employees.

The facts disclose that a number of the pictures are outdoor pictures, candid snapshots taken in the lobby and in the halls together with sketches that were made by employees of *Life* magazine showing diagrammatic outline of the floor plan, the responsibility for which can in no manner be attributed to the Mayo Clinic or the Mayo Foundation.

It is quite apparent from the article itself and the pictures that were published that it is a simple matter for any publication, magazine or otherwise, to obtain such information and views without the consent or even the knowledge of the Mayo Clinic, the Mayo Foundation or any one else in the practice of medicine similarly situated.

Your committee believes that the medical profession of the State of Minnesota would be the first ones to criticize and publicly condemn any professional impropriety, either by way of misconduct or publicity motivated through any selfish desires. We also believe that careful examination of the facts in respect to both of these matters clearly demonstrates the lack of merit in the position taken by the House of Delegates of the Oregon State Medical Society and also indicates conclusively their lack of knowledge of the true facts.

The Mayo Clinic in presenting their case invite suggestions from any state or national medical organization to assist them in avoiding any future similar occurrences.

In conclusion your committee would recommend to the Council and to the House of Delegates that they have reviewed the facts pertaining to the resolution presented by the House of Delegates of the Oregon State Medical Society in reference to both these matters and find that the facts themselves refute the position taken by the House of Delegates of the Oregon State Medical Society and clearly show no improper motive whatsoever in respect to the scientific exhibit at the California Fair, and, also show that the article that appeared in *Life* magazine was neither inspired nor approved by the Mayo Clinic or the Mayo Foundation and the publication of any article was disapproved of by them in advance of its publication; that this committee is not unmindful of the contribution made by the Mayo Foundation to the education and training of physicians and surgeons who practice throughout the world and to the specific benefit that accrues to the State of Minnesota and the University of Minnesota by virtue of the Mayo Foundation and we would most respectfully recommend that suitable action be taken by the Council and by the House of Delegates of this Society setting forth the opinion of both such bodies in reference to this matter and that copies thereof be furnished the Oregon State Medical Society, the American Medical Association and any other constituent state medical association that was the recipient of the report of the House of Delegates of the Oregon State Medical Society in reference to this matter.

DR. W. W. WILL: Thank you, Dr. Jones. I hope that we may have more discussion of this matter. First of all, I would like to ask Mr. Harwick, Secretary of the Board of Governors of the Mayo Clinic, to say a few words.

MR. H. J. HARWICK: Mr. Speaker, Gentlemen: I have quite a complete file here and I'll try to condense it, taking the *Life* matter first.

In May, 1938, Miss Dorothy Larson, representing *Life*, came to the Clinic and requested permission to publish a pictorial story regarding the Clinic. At that time she was seen by Dr. Balfour and myself, and we persuaded her not to proceed. She, at that time, brought up the question of a series of picture articles, picture stories, of medical centers throughout the United States. We gave her no assurance of our participation in that but referred her to the officers of the American Medical Association. She told me at that time that she was going to see Dr. Fishbein. I attended the meeting of the American Medical Association in San Francisco in June, 1938, and happened to be on the same train with Dr. Fishbein; I discussed this matter fully with him, and he agreed to follow it through with Miss Larson when he got out in San Francisco.

We heard no more about the matter until September, 1938, when Dr. Balfour received a request directly from the publisher of *Life*, Mr. Roy Larson, no relation to Miss Larson, again requesting permission to publish this story. To this Dr. Balfour replied as follows:—"I'll skip part of it here—"We appreciate the compliment entailed in wishing us to do this, and know that your staff would set out to prepare something which would avoid as much as possible any criticism; but we have always endeavored to adhere to what the medical profession believes to be the fundamental principles of the practice of medicine, and we would feel that regardless of how such a story is pictured we would be placed in a false position.

"In spite of the fact that you have published pictorial stories of scientific institutions which you mentioned in your letter, the primary function of the Mayo Clinic is the care of the sick and since these patients are, to a large extent, private patients, we strive to live up to those principles governing their care. We hope you will see our position in the matter, etc."

Then he adds: "If in the future, the American Medical Association should desire to cooperate with you in the preparation of an article in which we might be of assistance, we would be glad to give it consideration."

We heard no more of that; that was in September. We heard no more until July, 1939, when Miss Larson appeared in Rochester without advance notice and told us, Dr. Balfour, and myself, she had been sent by the editorial board of *Life* to get a story, the photographers were on their way and that her instructions were to proceed with the story regardless of our opposition. Dr. Balfour, Dr. Mussey, Chairman of our Board of Governors, and myself had no success in attempting to persuade her that the article should not be done. We were very definite in stating to her that we would not grant permission for pictures inside the Clinic.

It was then decided to seek the advice of the Minnesota State Medical Association and the American Medical Association. Accordingly, Dr. Giffin of the Clinic Staff, Chairman of the Council of the State Society; Dr. Braasch, a delegate from Minnesota to the A.M.A., asked Dr. Earl, President of the State Society; Dr. Savage, Delegate to the A.M.A., and Dr. C. B. Wright of Minneapolis, Member of the Board of Trustees, to come to Rochester for a conference, which they very graciously agreed to do. Dr. Balfour also communicated with Dr. Fishbein by telephone. We pointed out that we could not prevent *Life* from publishing the story on Rochester and including photographs of the outside of the Clinic. He emphatically advised against giving permission to take pictures inside the Clinic. Dr. Fishbein also said he would see the Editors of *Life* about the middle of August and would present to them the viewpoint of the medical profession and of the Clinic.

He communicated immediately with one of the higher officials of *Life* who later telephoned Dr. Balfour and also telephoned me again asking permission to proceed with the story and pictures. He was definitely told by both of us that this could not be done. Dr. Wright, Dr. Earl and Dr. Savage and Dr. Henderson of Louisville, another member of the Board of Trustees of the A.M.A., who happened to be in Rochester at the time, had dinner with Miss Larson and discussed the matter at length. Following that meeting Dr. Braasch, Dr. Giffin and myself, met with them and with Miss Larson. These gentlemen had expressed themselves as seeing no objection, if *Life* planned a series of articles regarding medical institutions of this kind, to the Clinic's being portrayed as one of such institutions.

The result of this conference was presented to the Board of Governors of our Clinic on Wednesday, July 26. By the way, Miss Larson was present at that meeting; we asked her to be there; after discussion, the Board unanimously decided that the Clinic could not give permission for, nor sponsor such publicity. It was further decided that a disclaimer, denying any responsibility for any article that appeared in *Life* should be prepared; and I wrote Mr. Larson, the publisher of *Life*, as follows: "After several conferences with Miss Dorothy Larson, the officers of the State Medical Association, and after communicating with Dr. Fishbein of the American Medical Association, and two trustees, Dr. Wright of Minneapolis and Dr. Henderson of Louisville, the Board of Governors of the Clinic met today and reviewed with Miss Larson the entire situation. It was the unanimous opinion of the Board that we could not authorize a story on the Mayo Clinic nor pictures to be taken within the Clinic. Since the purpose of such a plan would be entirely contrary to our ideals of how a medical practice should be conducted and not in accordance with the ideals of the medical profession, since we cannot give approval, we hope some way can be found to make our position in this matter clear, should you not respect our wishes in this as you have so courteously done in the past."

To this letter, Mr. Larson replied as follows, and this is a gem: "Thank you for your kind letter of July 26th. We are indeed distressed that the Board of Governors of the Mayo Clinic were unable to cooperate with us in producing what we hope will be a very fine essay on one of the great medical centers of the world. If and when we use the pictures of Rochester as a medical city, we shall certainly attempt to make it clear to the reader that the story was neither sponsored nor sanctioned by your Board of Governors." Now that was not done. This last sentence is a gem, too. "I hope that the day will come when *Life* and the Mayo Clinic can work together in promoting the interests of medicine." (Laughter.)

We then wrote and thanked these gentlemen that so kindly came down. We didn't know when they left that the article was going to come out; we didn't know it until the day before it appeared. I think, Dr. Giffin, that you acquainted the Council at different times with what was going on, did you not?

Now our file in connection with the Exposition is not so complete. I have to rely on memory for part of it. As I recall, first in 1937, certain members of our staff received letters from various officers of the California State Medical Society, inquiring as to whether we would be willing to show an exhibit on clinical medicine at the California Exposition. The matter was brought up to our Board of Governors, and we felt that we had better not participate. We didn't know what the Fair was going to be; we didn't know much about the scientific exhibits that were going to be out there. We had had the exhibit at Chicago which had been a good deal of grief and a heavy expense to us, and we didn't feel that we wanted to go ahead. The pressure kept getting harder and hard-

er. Finally the retiring president of the association called Dr. W. J. Mayo and told him that the members of the California Association were very much interested in having this exhibit, that they were having difficulty getting any clinical institution out there to exhibit, that they felt it would be unfortunate if the Exposition went on without some exhibit of clinical medicine, that we were the only people that they could see in the country who might be willing and able to do it, and that they felt it was our duty to medicine to put it on. Dr. Will agreed to do it. However, we did not sign the contracts; the thing dawdled along until, I think it was April or May of 1938, and meanwhile we had consulted with the people of the American Medical Association in Chicago and had explained the thing to them. They had told us that they could see no reason why we should not exhibit; in fact, they rather urged us to do so and arranged so that our space would be adjacent to theirs.

The American College of Surgeons were also going to exhibit, but in April or May—I don't recall the exact time—they decided not to exhibit. Meanwhile, we had not signed any contract; so I went to San Francisco, and I talked with the man who was President of the American College of Surgeons. He told me the reason they had decided not to exhibit. First, that they didn't have the funds on hand to use for that purpose; and greater than that, they couldn't find anyone in their organization who was willing to go to the grief and trouble of preparing an exhibit. He said that there was nothing in their decision involving the ethical position. They felt it was perfectly sound, and that they could see no reason why we shouldn't exhibit; in fact, he expressed himself as being sorry that the American College was not going to exhibit. I talked to him about the gentleman who had been delegated by the State Society as the Scientific Director, Dr. Silverman, and he spoke of him in the very highest terms, stating that he would feel perfectly confident of anything that this man proposed to put on as an exhibit. I then consulted another old friend of ours out there, Past President of the American Medical Association and a Past President of the State Society and a member of one of their important committees, and he said very much the same thing in stronger terms. He very much urged us to exhibit, and he spoke in the highest terms of Dr. Silverman, the Director of the Exhibits; he made this comment, however: "If you do exhibit, I hope you don't put it up in too high faluting a way." He said, "I think you should put up an exhibit of clinical medicine in a way that lay public can understand. If you put a lot of charts and other scientific things, the public won't be interested and it will be of no instructive value."

We discussed the exhibits of the University of California and Stanford University which were in the same corridor, and he strongly urged us to exhibit. We, Dr. Mussey and I, went all over the building, then half completed, and found where our space was going to be, got a diagram and a story of what the other exhibits were going to be there. Meanwhile at the A.M.A. meeting we talked with many members of the California Society and members of the American Medical Society from other states and almost without exception they urged us to participate. We finally signed a contract in November, I think—and the Fair was to open in February. As Dr. Jones mentioned, we made it clear that we would not exhibit more than one year, that we would not come in for the second year. We did not. We dismantled our exhibit and had it sent home, and in January we received a telegram from the Secretary of the California State Society urging very strongly that we continue our exhibit for 1940; we have also had several telegrams and letters from the Director of the Public Health Service in California since then urging us to exhibit in 1940. But we have not done so, and do not intend

to do so. I think that in a rough way covers it. (Applause.)

It was moved and seconded that the House of Delegates adopt the resolution as read by Dr. Jones. Carried.

Dr. Will then called for discussion.

DR. GEORGE EARL: Last year in my capacity as an officer of the State Medical Association, I was called to a meeting in Rochester, along with Frank Savage, Delegate to the American Medical Association, and C. B. Wright, Trustee of the American Medical Association, to meet Miss Larson, representative of *Life* magazine.

Miss Larson presented the statements that have been given you; namely, that representatives of *Life* magazine had been to Rochester on a former occasion; that they had taken pictures previously; and that they were now ready to go ahead and publish. They had been persuaded to hold up publication for a year, Miss Larson said, but she was of the opinion that the editorial board of *Life* would now release the pictures. They had sent her out to secure more pictures if possible, and as much more information as she could secure. The members of the Clinic, as well as those of us who represented the State Society and the American Medical Association tried to point out to Miss Larson that this would be a difficult matter for organized medicine in Minnesota. We sensed from what she said that *Life* magazine would go ahead anyway so then we tried to compromise and suggested that she begin with a series of articles reflecting the beginnings of American medicine; that she start first with Philadelphia, go on to Boston, New York, Baltimore, Chicago, taking in Rochester, of course, since it would have to be taken in any review of American medicine, and going on to the coast, giving in this matter a cross section of the history of medicine in which the torch was carried ever westward.

Miss Larson promised to present our ideas to the editors of *Life*. We went further; we said that as long as the Mayo Clinic felt as it did about the matter, and they expressed themselves very strongly in our presence as opposing the publishing of pictures in *Life*, would it not be wise if *Life* should publish a Minnesota issue. We suggested that they might relieve the situation considerably by having pictures of the University and possibly other medical developments in Minnesota as well as of the Mayo Clinic.

Miss Larson listened attentively and said that she would present the matter to her employers. We spent an entire evening with Miss Larson and I have never seen more persuasive methods used in trying to prevent publication. No one was more surprised than we were when the article finally came out. We thought that *Life* would surely listen to our representations.

I have given you this account of the occasion because the delegates should have first hand information from someone who was there and who is not connected with the Mayo Clinic.

DR. P. C. LECK, Austin: Mr. Chairman, I also had advance information that this article was to appear in *Life*. I am an independent practitioner in Austin, fifty miles from here. I have no interest in the Mayo Clinic, either to condemn or whitewash their publicity. It is a wonderful place to have close by when you are in a pinch, but sometimes not so good when the patient thinks that he is the only one who is in a pinch.

With that preliminary, I might say that a patient of mine who has been a friend of our family for many years visited in our home last summer, having just returned from a visit to New York City, where her daughter and her daughter's husband are in the newspaper business. A *Life* photographer visited in her daughter's home while she was there and gave quite a story about her efforts in securing pictures and information about the Mayo Clinic. The photographer, a

girl reporter, said that she was having no success whatever in getting permission from the Mayo Clinic; that she had spent a great deal of time there; and that she had finally failed completely to get any cooperation from the Clinic itself. She said that she was going ahead to make what she could out of Rochester. So it was with great interest that I looked at the article that finally appeared in *Life*. And with that forewarning it was very obvious to me that if the Mayo Clinic had been cooperating with the magazine, it would certainly have made a much better job of it.

On this other matter of the Fair, I personally think that the State Medical Association would make a mistake if they went on record favoring that type of exhibit. My personal feeling is that all such exhibits should be shown in the name of the American Medical Association which in turn could secure the cooperation of the Mayo Clinic or any other group in assembling the exhibit material.

At the request of Dr. F. J. Elias of Duluth, Mr. Harwick told the following episode:

MR. HARWICK: This is something that Dr. Olin West called our attention to. Dr. Mussey and I were in Chicago discussing the *Life* matter with him, and this whole question of publicity. We had just been besieged by moving picture people that wanted to make scripts based on the life of Drs. Will and Charlie in the development of the Clinic, and he got to reminiscing about some of the troubles that we had. We have appealed to him so often because it seems that we are down there about every month on some article or another and we manage to kill off about 99 $\frac{99}{100}$ per cent of them, but we do get caught on about $\frac{1}{10}$ of 1 per cent. Dr. West said to me, "You don't need to tell me about your efforts. I recall one instance where the *Chicago Tribune* sent a special feature writer up to Rochester, and he wrote up an article on the Clinic; when he had it completed—he hadn't consulted anybody here—he went in to show it to Dr. Will. Dr. Will read it very carefully and complimented him on the article and then said to him, 'I hope you're not going to publish it.' He outlined the reasons why it should not be published, that it would be unethical and subject us all to criticism and he went to some lengths trying to get this fellow to stop it. Then the writer said that he couldn't do that, that that would be up to his publisher. He had instructions to write the story and he had written it and he was going to turn it in to his publisher. Then Dr. Will wrote Colonel McCormick a letter in which he outlined the reasons he had given this writer for not publishing it, and asked him also to consult with the American Medical Association to verify his viewpoint. He enclosed a blank check signed by himself and Dr. Charlie and told Colonel McCormick to fill it in for whatever amount he thought that the story would bring him by publishing it, and then not publish it."

And Dr. West recalls that Colonel McCormick came into his office in a rage and told him that neither the A.M.A. nor the Mayos or any other man could buy the *Chicago Tribune* and tore the check up. (Laughter.)

DR. E. A. MEYERDING: During my term as Secretary, these things came up frequently. For instance there was the rabies trouble in Minneapolis. A newspaper man, you know, is always looking for something that will attract people's attention. The minute that you try to hide something, he is after you, surmising that where there is smoke, there must be fire, and hoping that somewhere he will get a break. They made use of a break in the rabies business. So far as Minnesota newspapers are concerned, there is only one way I know to handle the situation; that is to have a committee to confer with the editorial association so as to work out some agreement as to what shall and what shall not be published. The newspaperman must have

news and he is going to get it and the minute that you try to conceal something, he is going to look for a nigger in the woodpile.

DR. W. W. WILL: I think Mr. Rosell has had some experience with the Minnesota Editorial Association which might be enlightening to the House of Delegates. Mr. Rosell:

MR. R. R. ROSELL: During the past year we have had several meetings with the representatives of the Editorial Association and have offered our services in every way possible to assist them in getting authentic medical news. Recently we released from our office to every member of the Editorial Association a card to be used in their offices notifying their staff that they could call us long distance, reversing the charges, for authentic medical news and information. A few papers have accepted the offer and have made use of the service; but as Dr. Meyerding said, newspaper men are after a scoop and they will not lay down on the job if the news is available.

I may say that the Committee of the Editorial Association is very friendly to us. Mr. Benshoof, Chairman of that Committee, from Detroit Lakes, has worked with us closely, but if the newspapers are on the track of a really big story, they will get it if possible. The best policy is to give them freely everything that it is possible ethically to give them, and

never to antagonize them by sweeping prohibitions. Whenever we do that, there is a bad situation and it is very difficult to straighten out afterwards.

DR. W. L. BURNAP: I just wanted to say one word; so far as publicity is concerned, it seems to me that Minnesota is very clean. I think that we all agree that our committee has carried on successfully and that the state as a whole is pretty good. Certainly there is nothing very bad about it.

The motion made previously to accept the report of Dr. Jones' Committee was seconded and carried unanimously.

It was moved by Dr. D. P. Heed, seconded and carried, that the House of Delegates instruct the Ethics Committee upon plans to curb all unwarranted publicity in the public press.

DR. W. W. WILL: There is one other matter that must be considered at this meeting; the place of meeting of 1941.

DR. E. M. HAMMES: Mr. Speaker: As Chairman of the delegates from Ramsey County, I extend to you an invitation to hold your meeting for next year in St. Paul. We have the hotels; we have the Auditorium; and if we have the usual good attendance, we'll have a good many doctors in St. Paul.

It was moved, seconded and carried that the 1941 meeting be held in St. Paul. The meeting adjourned.

CLASSIFIED ADVERTISING

FOR SALE—X-ray shockproof portable, with mobile stand. Will do all work. Will sacrifice. Address C-26, care MINNESOTA MEDICINE.

FOR SALE—Medical and surgical instruments and office equipment of late Dr. J. O. F. Kraushaar, Aberdeen, South Dakota, for portion of cost. Will include practice and case records covering 30 years. Present location obtainable. Good hospital. Population 18,000; large surrounding territory. Knowledge of German an asset but not essential. Address—Minnesota Teacher's Service, 1209 Northwestern Bank Building, Minneapolis; or Mrs. J. O. F. Kraushaar, Aberdeen, South Dakota.

WANTED—Locum tenens last two weeks in August. Address D. V. Moen, Medical Resident Physician, Ancker Hospital, Saint Paul, Minn.

FOR SALE—One used Victor Mobile Unit, 30 MA capacity and one used Victor Vertical Fluoroscope. Excellent condition. Reasonable. Address: Standard X-Ray Sales Company, 768 Lowry Bldg., Saint Paul, Minnesota.

PHYSICIANS ATTENTION!

Office space available in central location in Minneapolis. Reduced rent while getting established. Opportunities to assist in surgery. X-ray and clinical laboratories with technician. Be prepared to give complete examination in your own office. Address C-27, care MINNESOTA MEDICINE.

PHYSICIAN WANTED: Swedish or Polish physician wanted. Location established for 15 years. Share reception room with dentist, Dr. A. A. Stromwall. Can occupy at once. Good reasons for vacancy. Call or write C. C. Gerber, Arcade & Case Sts., Saint Paul, Minnesota, telephone Tower 7340.

PRESENT TRENDS IN THE STUDY OF ARTHRITIS AND RHEUMATISM*

RUSSELL L. CECIL, M.D.

New York, N. Y.

RHEUMATOID arthritis and rheumatic fever constitute two of the last remaining unsolved problems in the field of the infectious diseases. For this reason they possess exceptional fascination to the investigator, so much so that today a small-sized army of bacteriologists, physiologists and chemists are attempting to dispel the mystery which still surrounds the etiology of these conditions. It must not be inferred, however, that when we call the arthritis problem unsolved we mean to deny the progress which is being made every year in our knowledge and understanding of the disease. If we must admit that the etiology of rheumatoid arthritis and rheumatic fever is still unknown, we may add, in the same breath, that recent investigations are throwing more and more light into this dark corner of medicine and that there is good reason to believe that within another decade, students of rheumatism will have a much clearer conception of the pathogenesis of these two great diseases than we have today.

In the present discussion I propose to touch only the high spots of recent research and will exercise the prerogative of every investigator in dwelling especially on those phases of the problem which have been studied in our own laboratories at the Cornell Medical College.

First let us discuss a very fundamental aspect of the problem, namely terminology and classification. Students of arthritis are beginning to demand more accurate criteria for the identification of the various forms of arthritis. This is particularly so of rheumatoid arthritis,

a disease which has been very much abused so far as terminology is concerned. In the past, vague and desultory joint pains of all kinds have been casually glorified by the designation of rheumatoid arthritis. So many young physicians who have had no training or background in morbid anatomy fail to realize that rheumatoid arthritis is a very definite disease entity, characterized by well defined pathological changes in the joints and in the subcutaneous tissue when nodules are present, and that unless some of the genuine features of the disease are present, the diagnosis of rheumatoid arthritis should never be made. Such carelessness in terminology is particularly unfortunate when clinical reports of some form of therapy are being made. If one includes under rheumatoid arthritis the various arthralgias and psychoneuroses that one sees so frequently in arthritis clinics, the statistical value of the report from the therapeutic standpoint is completely nullified. In my clinic I am constantly being surprised by some of the conditions which are filed under rheumatoid arthritis. For example, osteoarthritis may be mistakenly classified under rheumatoid arthritis, just because the patient shows a high sedimentation rate. The arthralgias of menopause are frequently termed rheumatoid.

The New York City Committee on Arthritis Clinics has been working this winter on a classification of arthritis, and the classification shown in Table I, though provisional, seems to me to be as satisfactory as any.

Briefly I should say that the clinical criteria for the diagnosis of rheumatoid arthritis would be the following:

*Mayo Foundation lecture delivered at the Annual Meeting of the Minnesota State Medical Society, Rochester, Minnesota, April 22, 1940.

(1) Some of the joints must be swollen, and preferably some one or more of the knuckles or the proximal interphalangeal joints of the fingers.

(2) The disease is practically always polyarticular and tends to remain in the joints already involved as it spreads to new joints.

(3) There is a strong tendency to symmetrical distribution of the affected joints. In my opinion the typical fusiform finger is the most characteristic feature of the disease. I always hesitate to make a diagnosis of rheumatoid arthritis when the swelling of the hand and fingers is of a diffuse character.

(4) There is usually evidence of general systemic infection, as indicated by slight fever, anemia, and loss of weight and strength. The vasomotor disturbances are quite characteristic, especially excessive perspiration and rapid wasting of the muscles.

(5) The sedimentation rate of the red cells is practically always increased quite markedly.

(6) The x-ray appearance of the bones and joints is highly characteristic. One of the earliest changes is the osteoporosis of the bones adjacent to the affected joints. As the disease progresses, there is narrowing of the interarticular space and blurring of the whole joint architecture. Small punched-out areas are sometimes seen about the head of the bone adjacent to the affected joint.

(7) The agglutination test with the patient's serum against the streptococcus hemolyticus is positive in 65 to 75 per cent of cases.

(8) In well established cases of several years duration, characteristic ankylosis and deformity of the affected joints renders the diagnosis very simple.

Pathology of Rheumatoid Arthritis.—In 1929 A. G. Timbrell Fisher²³ pointed out certain microscopic features in the synovial membrane in rheumatoid arthritis. He particularly stressed the numerous agglomerations of small round cells which form rounded masses in the region of the blood vessels. In 1931 Allison and Ghormley² published a monograph on arthritis in which they stressed still more strongly the presence of focal collections of lymphoid cells in the synovial membrane. To quote these writers: "Histologically the tissues show a definite picture, which is as clear cut as is that of

tuberculosis, namely a proliferative change in the synovial membrane and marrow which is characterized by focal collections of lymphocytes. This microscopic picture will, we believe, be enough to establish the diagnosis of proliferative (rheumatoid) arthritis." It is true that these collections of lymphoid cells are nearly always present in the synovial membrane of the affected joint in rheumatoid arthritis. Furthermore, in a recent study from our laboratory, in collaboration with Angevine and Rothbard,⁹ we were able to produce an experimental hemolytic streptococcus arthritis in rabbits which presented a picture very similar to that described by Allison and Ghormley. In other words, the same collections of lymphoid cells were found in the synovial membrane of the rabbit as were found in human tissue. However, further experiments showed that a similar picture could be produced in experimental pneumococcus arthritis, and Jordan³² has recently shown that when turpentine is injected into the synovial tissue of rabbits, a lesion can be produced which is indistinguishable from the experimental streptococcal arthritis and quite similar to that seen in human rheumatoid arthritis.

Interesting reports have appeared in recent years on the pathology of subcutaneous nodules in rheumatoid arthritis and rheumatic fever. Here again we encounter peculiar agglomerations of cells about central areas of necrosis which are not seen in any other disease. However, Dawson¹⁷ has shown that the histopathology of the subcutaneous nodule of rheumatoid arthritis differs little, if any, from that of the subcutaneous nodule of rheumatic fever.

Summarizing then, we may say that the synovial membrane and the subcutaneous nodules in rheumatoid arthritis presents interesting and characteristic histological changes, but that these changes are not absolutely specific for rheumatoid arthritis.

Etiology of Rheumatoid Arthritis.—It must be admitted that the theory of focal infection, so popular a few years ago, is very much on the wane in so far as it applies to the etiology of rheumatoid arthritis. The theory of focal infection was first invoked by Frank Billings⁷ as an explanation for the pathogenesis of rheumatoid arthritis. However, if one goes back to Billings' original article and reviews the ten

cases on which his study was based, it is at once evident that some of them today would not be classified as typical rheumatoid cases. Not only Billings, but most of the earlier writers on arthritis, failed to differentiate clearly between infectious and rheumatoid forms. However, the most significant feature of this problem is the fact that while foci of infection were being rapidly disposed of, rheumatoid arthritis remained as prevalent as ever. Two years ago we were so impressed with this fact that Dr. Angevine and I⁸ analyzed 200 cases of rheumatoid arthritis with special reference to the incidence of focal infection. In analyzing these carefully studied cases, we found definite evidence of infection in only 20 per cent of the series, and a questionable focus in 10 per cent. We were surprised to find that 70 per cent of the patients revealed no demonstrable focus of infection. But this was not all. Even when foci of infection were present, their removal seemed to have no permanent beneficial effect on the course of the disease. For example, tonsillectomy had no influence on the disease in eighty-eight cases, and caused a severe exacerbation of the disease in two instances. In no case was the course of the disease arrested or the patient cured. Extraction of the teeth gave no benefit in forty-seven cases, and three patients reported a flare-up of pain in their joints following teeth extraction. The results following drainage of infected sinuses were quite ineffective. As a result of our study, we concluded that internists must exercise a more conservative attitude regarding infected tonsils, sinuses and teeth than they have in the past, and not leave a decision regarding the treatment of these so-called foci to specialists. Evidently the time has arrived for a complete revaluation of the focal infection theory. Focal infection undoubtedly plays an important part in a number of ailments, and we were convinced from our study that there is a type of infectious arthritis, not rheumatoid in character, which is related to focal infection and which is benefited by the removal of infected foci. In this type of arthritis one or more large joints are affected. The patient runs a fever and the picture is not unlike that of rheumatic fever. However, the symptoms do not yield to salicylates and there are no cardiac complications.

TABLE I—CLASSIFICATION OF ARTHRITIS

- I. Infectious Arthritis
 - (a) Of proved etiology.
- II. Probably Infectious; etiology unproved.
 - (a) Arthritis of rheumatic fever.
 - (b) Rheumatoid arthritis (atrophic arthritis; chronic infectious arthritis)
 1. Adult type.
 2. Juvenile type (Still's disease)
 3. Ankylosing spondylitis (Marie-Strumpell)
 4. Psoriatic arthritis.
 - (c) Arthritis associated with various infections.
- III. Degenerative arthritis (osteoarthritis; hypertrophic arthritis)
 - (a) Generalized; etiology unknown.
 - (b) Localized.
 1. Secondary to trauma.
 2. Secondary to structural abnormality.
 3. Secondary to previous infectious arthritis.
 4. Etiology unknown.
- IV. Arthritis associated with disturbance of metabolism.
 - (a) Gout.
 - (b) Arthritis manifestations of other metabolic diseases.
- V. Arthritis of Neuropathic origin.
 - (a) Secondary to tabes dorsalis.
 - (b) Secondary to syringomyelia.
 - (c) Secondary to peripheral nerve lesions.
- VI. Miscellaneous forms.
 - (a) Arthritis of serum sickness.
 - (b) Arthritis of hemophilia.
 - (c) Intermittent hydra-arthritis.

Bacteriology of Rheumatoid Arthritis.—The earlier students of focal infection, particularly Rosenow³⁸ and his co-workers, emphasized the frequency with which streptococci were recovered from focal infections and from this they made the inference that rheumatoid arthritis was probably a streptococcal disease. This theory has enjoyed wide popularity for years. In 1929 the writer, in collaboration with Nicholls and Stainsby¹⁰ undertook a detailed study of the bacteriology of the blood and joints in patients with rheumatoid arthritis. By using a special culture method, streptococci were recovered from the blood in 62 per cent and from the joints in 67 per cent of 154 patients with rheumatoid disease. Most of the strains recovered in this series were attenuated streptococci. Control cultures on other normal individuals or patients suffering from other diseases yielded negative results. This work was repeated in

numerous laboratories with variable results, some confirming, others failing to confirm these observations. However, in the majority of instances, negative results were obtained. More recently Dr. Angevine and Dr. Steffen have endeavored to repeat the work of Nicholls and Stainsby, but their results have been entirely negative. As a result of these negative findings, one is forced to suspect that the streptococci recovered in earlier studies were contaminations, but this of course can not be absolutely proven.

In 1931, Cecil, Nicholls and Stansby¹² first noted the presence of specific agglutinins for the streptococcus hemolyticus in the sera of patients with rheumatoid arthritis. In a series of 103 cases of this disease, ninety-seven showed agglutination with the hemolytic streptococcus at a dilution of 1:640 or higher, while in a series of fifty normal controls, the serum in every case failed to give a strong agglutination reaction. The presence of these agglutinins has been confirmed by Dawson, Olmstead and Boots¹⁸ and a number of other investigators. The percentage of patients showing a positive reaction has varied according to different observers from 40 to 90 per cent. In the opinion of the writer, the percentage of cases showing this positive reaction will depend on the duration and severity of the disease. In well-established cases of several years duration and with active swelling of many joints, the percentage of positive reactions should be about 90 per cent. If all patients, including incipient cases, are included, the percentage of positive reactions will run between 55 and 60 per cent.

It was interesting to observe that the agglutination reaction is often strongly positive in patients whose cultures fail to reveal hemolytic streptococci, and this statement applies not only to blood and joint cultures, but to cultures from the throat, stools, etc. Because of this fact the question has been raised as to whether this is a truly specific agglutination reaction or a non-specific phenomena similar to the Felix-Weil agglutination of the proteus bacillus by the serum of patients with typhus fever. In the last year or so bacteriologists have shifted their interest from the streptococcus group of organisms to the so-called pleuropneumonia-like group. These peculiar micro-organisms are very tiny, varying from .5 μ down to 0.2 μ or less in diameter. From such granules slender threads may grow

out, which form a single filament, or they may bud out from several parts of the granule to form delicate star-shaped structures. These threads become branched and form a dense mycelial-like network. About the margins of the colonies the threads become enlarged to form coarse globular or club-shaped bodies. These organisms have been found to exist in symbiosis with the *Streptobacillus moniliformis*, the organism which Klieneberger³³ frequently obtained by inoculating mice with the pharyngeal exudate of rats. Recently Findlay²² and his co-workers have cultivated the pleuropneumonia-like organism from the joint tissue of rats suffering from a type of polyarthritis. They were able to reproduce the disease in mice by injecting into the foot pads filtered or unfiltered suspensions of joint tissue, or cultures grown from them, along with a bit of agar. Sabin³⁹ has also produced a chronic arthritis in mice by intravenous or intraperitoneal injections of cultures of the strain he isolated from the brain of a normal mouse. He described this as a progressive, proliferative polyarthritis, resembling rheumatoid arthritis in man. The process often goes on to ankylosis of one or more joints. Sabin was able to recover the organism in cultures from the joints as late as seventy days after inoculation by blind passages, that is, by a series of subcultures repeated at short intervals without waiting for evidence of growth to appear.

Another interesting etiological theory which has received considerable attention has to do with the role of vitamin deficiency in rheumatoid arthritis. This applies particularly to the studies of Rinehart³⁷ in relation to vitamin C deficiency. Rinehart found that chronic vitamin C deficiency in the guinea pig produces an arthropathy with many similarities to rheumatoid arthritis, and that in certain instances superimposed infection accelerates and accentuates the pathological process. In Rinehart's study on guinea-pigs the experimental infection, in the presence of adequate vitamin C, failed to produce arthritis. Rinehart points out that the general atrophic changes in rheumatoid arthritis, involving the bony skeleton, muscle and skin, are seen also in chronic vitamin C deficiency. Rinehart concludes that vitamin C deficiency may operate as a factor in the etiology of rheumatoid arthritis. It must be admitted that Rine-

hart has presented an intriguing theory, but one which does not receive much support from practical experience. In other words, there is very little clinical evidence to support the idea that patients with rheumatoid arthritis are suffering from a deficiency of vitamin C, and certainly vitamin C in large doses does not cure the disease.

Psychic Shock.—Several interesting articles have appeared recently on the relation of psychic trauma to the onset and recrudescence of rheumatoid arthritis. It seems quite likely that this is merely a predisposing cause, but the fact remains that a good many patients trace the onset of their disease to a psychic shock and many others give a history of some emotional disturbance preceding relapse. Cobb, Bauer and Whiting¹³ made a careful study on the relationship between the onset of exacerbations of arthritis and the emotional or environmental factors, and found that environmental stress, especially poverty, grief and family worry seem to bear a definite relationship to the onset of exacerbations of rheumatoid arthritis.

Treatment of Rheumatoid Arthritis.—The therapy of rheumatoid arthritis continues to be empirical, with new cures constantly coming in and going out. A revival of sulphur therapy has been attempted on the theory that the cells of an arthritic patient have lost the ability to retain sulphur. Sullivan and Hess,⁴² for example, expressed the belief that the cystine content of the finger nails of arthritic patients is definitely low, an indication of disturbed metabolism of sulphur. Freyberg,²⁵ however, has taken issue with this theory and has shown pretty clearly that the sulphur metabolism in arthritis is entirely normal.

So far as treatment of rheumatoid arthritis by medication is concerned, gold salts are now attracting the greatest interest. Gold therapy for arthritis was first instituted twelve years ago by Forestier.²⁴ It soon became quite popular in Europe, but was disregarded almost entirely by American students until quite recently. The mode of action of gold in arthritis is unknown. Intramuscular injections seem to be quite as effective as intravenous injections, and are probably safer. The drug is given in courses in much the same way as bismuth and arsphen-

amin in syphilis. The usual method of treatment is to begin with 25 to 50 milligrams, and work the dose up to 100 milligrams. There is some difference of opinion as to what constitutes a course, but most authorities advise a total dosage of 1 to 2 grams, depending on how the patient reacts to the drug. Injections are usually given once a week, deep into the buttock with a long needle. Most writers recommend several courses, believing that relapses and failures result when only one course is administered. Patients on gold therapy should be followed with frequent blood counts, urinalyses and sedimentation tests.

Of the number of different gold products on the market, the most popular ones in this country are sodium gold thiosulfate, Solgonol B, and Myochrysine. Reactions to gold are numerous and some of these may be quite serious. Occasionally fatal results have been noted. Many patients have an immediate vasomotor disturbance, which is not serious but unpleasant, following the injection. Undoubtedly the commonest form of toxic reaction is drug dermatitis, which appears as a dry scaly itching erythema or morbiliform rash. Occasionally severe exfoliative dermatitis is encountered. Next to dermatitis, the writer has found stomatitis the commonest toxic manifestation, showing itself as a loss of taste, sore tongue and gums, or an ulcerative stomatitis. A few patients develop acute gastro-intestinal symptoms with fever, vomiting, epigastric pain and diarrhea. Occasionally acute hepatitis with jaundice is encountered, and rarely acute yellow atrophy. Occasional instances of glomerular nephritis occur, and finally purpura hemorrhagica, aplastic anemia and agranulocytosis. While exfoliative dermatitis is extremely unpleasant and may occasionally be serious, it is the disturbances of the hematopoietic system which are the most to be feared. Some observers believe that the toxic manifestations of gold therapy can be avoided by simultaneous injection of calcium gluconate; others recommend liver extract or glucose.

In spite of the dangers attendant to gold therapy, most investigators who have had extensive experience with the gold salts are quite enthusiastic over the results obtained. Hartfall and Garland²⁹ saw results which were little short of miraculous on patients showing various grades of disability. They also noted improved

general health and appetite, gain in weight and reduction in sedimentation rate. The writer has now treated over 200 cases of rheumatoid arthritis with gold therapy. Unfortunately time has not been yet available for a careful analysis of these figures. Like many others, my earlier experiences with gold were discouraging. A severe case of exfoliative dermatitis was encountered quite early, and this engendered a fear of the drug which prevented adequate dosage being administered to other patients. With increasing experience, however, I came to place a high value on gold, particularly Myochrysine, with which I have done most of my work. I have encountered no serious disturbances in the blood. There have been three cases of exfoliative dermatitis; two have been quite severe. I have seen a few quite remarkable recoveries and many others that were striking, particularly when the drug was administered early in the disease. In conclusion, I think it is fair to say that gold therapy marks an important advance in the treatment of rheumatoid arthritis. It is a dangerous agent, but in the hands of an experienced therapist it can be used with great benefit in the treatment of rheumatoid patients. Perhaps the greatest objection to the drug is that a good many patients simply cannot take it without developing a skin rash. With the development of dermatitis, of course, the drug has to be discontinued, sometimes only temporarily, at other times permanently.

Vaccine therapy is still popular in many arthritis clinics, but has lost some of its vogue because of the growing popularity of gold therapy. However, in the writer's opinion, streptococcus vaccine still has a place in the treatment of rheumatoid arthritis. In our clinic we use it on those patients who cannot take gold, and occasionally it is used in combination with gold.

Fever therapy has been extensively tried and there are now numerous reports in the literature. The results are fairly consistent. The majority of the patients receive relief from fever therapy, but in most cases this benefit is only temporary. However, there remains about 10 per cent of patients who are really greatly benefited by fever therapy. These are usually early cases, and in such patients I am always tempted to try fever therapy at least once or twice, just to discover how they react to treatment.

Vitamins have become an integral part of the routine therapy of rheumatoid arthritis, most of the physicians giving generous quantities of A, B, C and D to arthritic patients. I have already referred to Rinehart's studies on vitamin C in relation to rheumatoid arthritis, though of particular interest is the work of Dreyer and Reed,¹⁹ who strongly advocate massive daily doses of vitamin D for the treatment of rheumatoid arthritis. The doses recommended of 200 to 250 thousand U. S. P. units a day frequently excite toxic symptoms, chiefly nausea, anorexia, lassitude, diarrhea and severe gastrointestinal pain. Some writers, notably Irons,³ offer objections to this massive vitamin D therapy on the plea that some permanent injury might be done by such doses. Massive vitamin D therapy has not met with an enthusiastic response from the profession. Slocum and Hench⁴¹ were unable to obtain any benefit from this therapy on twenty-five rheumatoid patients, and similar negative results have been reported by Bauer.¹ The writer's own personal experience has also been disappointing.

A word must be said here about the studies of Hench³⁰ on the relation of jaundice to rheumatoid arthritis, and its application in the use of bile salts. It has been known for some time that an attack of catarrhal obstructive jaundice would produce a remarkable amelioration in the symptoms of rheumatoid arthritis. Hench³⁰ studied thirty-one cases of atrophic arthritis and fibrositis in relation to jaundice. In most instances the jaundice was caused by the toxic action of cinchophen, but the patients who had simple catarrhal jaundice expressed similar relief. In the majority of cases, marked reduction of pain and swelling and a striking increase in motion accompanied the more or less complete analgesia, and the rheumatic process appeared to have suddenly become inactive for varying periods, sometimes only for days or weeks, occasionally for months or years. Only a few weeks ago the writer had an opportunity to study one of these cases at close range. A young woman, aged twenty-four, with typical rheumatoid arthritis of four years duration, was put on gold therapy. After she had had about ten injections of Sanochrysine, she developed a toxic hepatitis with headache, jaundice and bile-stained urine. The jaundice appeared about two months after the last injection.

tion of gold and lasted four to five weeks. Previous to the onset of the jaundice, she had considerable arthritis in various joints, with swollen wrists and ankles, several fusiform fingers and swelling of the right knee. Within a week or so after the onset of jaundice, the swelling and pain disappeared entirely from her joints and there was complete restoration of function. This period of inactivity lasted three months, when the symptoms in her joints gradually returned to the state they had been in previous to the attack of jaundice. These observations on jaundice and its effect on rheumatoid arthritis has led to the administration of bile salts to patients with this disease. Thompson and Wyatt⁴⁷ employed bile salts alone and bilirubin alone without any beneficial effect. However, the *combination* of bilirubin and bile salts seemed to have a favorable influence on the symptoms. Hench,³⁰ however, was unable to confirm these observations. Margolis³⁵ has employed autolyzed liver which, in his experience, produced exacerbation of the symptoms. Davis,¹⁶ working in our Department of Physiology at Cornell, believes that crude liver extract, when given in large doses, has a favorable effect on the course of arthritis, but I have not been able to confirm this observation on a very limited number of cases. Everyone seems to be agreed that jaundice, either natural or experimental, is not a cure for arthritis, but is only a temporary palliative.

Rheumatic Fever

Coming now to the subject of rheumatic fever, we find a situation quite similar in many respects to that which exists in rheumatoid arthritis, particularly in so far as studies on etiology are concerned. The disease is still classified as probably infectious, though of unknown origin, and the weight of opinion still favors the hemolytic streptococcus as the causative agent. The reasons for this opinion are obvious enough and have been particularly stressed by Coburn¹⁵ and others in their studies on the relation of rheumatic fever to acute respiratory infections.

Green²⁷ has recently cultured the throat of patients with acute rheumatic fever and compared his results with cultures from nonrheumatic controls. Hemolytic streptococci were recovered in 58 per cent of the rheumatic cases and from only 30 per cent of the nonrheumatic

cases. More recently Green²⁸ claims to have actually recovered hemolytic streptococci from cardiac vegetations of patients dying of rheumatic fever. We have not been able to corroborate this work, however, in our own investigations. A decade ago the writer, in collaboration with Nicholls and Stainsby,¹¹ recovered streptococci of various types from the blood and joints of patients with acute rheumatic fever. These results, however, have not been confirmed by recent studies in our laboratory and the previous findings are therefore open to the same criticism that has been made of the positive cultures obtained in rheumatoid arthritis.

Positive skin reactions to extracts of hemolytic streptococci are present in a considerable percentage of rheumatic fever patients, and this has been stressed recently by Goldie,²⁶ who obtained positive reactions in 77 per cent of rheumatic fever cases and in only 32 per cent of controls.

It has been shown by numerous observers that rheumatic fever is particularly prone to follow hemolytic streptococcal infections of the throat or tonsils or accessory sinuses. Coburn and Pauli¹⁸ found that agglutination and complement fixation reactions of sera from patients with rheumatic fever pointed definitely towards streptococcus infection. Furthermore they found that precipitin tests indicated that at the time of the rheumatic attack, patients develop in their blood specific precipitins to the protein fractions of the streptococcus hemolyticus. Finally, these same authors demonstrated that at the onset of rheumatic fever there occurs in each instance a rise in the antistreptolysin titer of the patient's serum. The authors consider this rise in antistreptolysin as particularly strong evidence of recent infection by the hemolytic streptococcus. These studies of Coburn have been repeatedly confirmed in various laboratories and certainly point strongly towards a streptococcal factor in the disease.

Virus Theory.—So-called virus bodies have been found in the exudates from various cases of rheumatic fever by Eagles,²⁰ Schlesinger⁴⁰ and others of the English school. These so-called elementary bodies are agglutinated by the patient's serum, but apparently possess no pathogenesis for animals. Until some definite proof of pathogenicity has been established, bacteriol-

ogists are not likely to give these studies very serious consideration. In our laboratory Dr. Angevine and Dr. Rothbard⁴ have made repeated efforts to cultivate a virus from the blood and exudates of patients with rheumatic fever, but always without success.

With respect to the rôle of vitamin C deficiency in rheumatic fever, others have followed the original studies of Rinehart³⁷ and have thrown additional light on the subject. There seems to be some vitamin C deficiency in the blood of patients with rheumatic fever, but this has been found to be the case in almost any febrile infection, all of which militates against the theory that vitamin C deficiency plays an important part in the etiology of rheumatic fever.

It seems fitting at this point to say something further about the so-called pleuropneumonia-like organisms in their relation to rheumatic fever. Swift and Brown⁴⁵ have reported the finding of pleuropneumonia-like organisms in the joint fluids of cases of acute rheumatic fever. This was accomplished first by cultivation on the chorioallantoic membrane of chicks by frequent serial passages. After about five passages, characteristic lesions appeared which were not obtained with exudates from other sources and from which pleuropneumonia-like organisms were cultivated on suitable media. Secondly, by intranasal inoculation of mice with exudate or with suspensions of inoculated chorioallantoic membranes, they produced a pneumonia free from ordinary bacteria from which, directly or after filtration, they could produce the characteristic lesions on chorioallantoic membranes and could recover pleuropneumonia-like organisms by direct culture. In their article, however, they do not report the production of arthritis with these strains, and in a recent report by Swift⁴³ before the International Congress on Microbiology in New York City, he expressed serious doubt concerning the findings in his previous report.

In our investigations on rheumatism at Cornell, Angevine and Rothbard,⁵ using the methods of Kleiueberger,³⁴ have made repeated efforts to cultivate pleuropneumonia-like organisms from the blood, exudates, and pathological tissue of patients with rheumatic fever, but always without any success.

Treatment of Rheumatic Fever.—There have been no outstanding new developments in treatment. Something, however, should be said about chemotherapy in relation to both rheumatic fever and rheumatoid arthritis. Swift, Moen and Hirst⁴⁶ have tried sulfanilamide in the treatment of chronic recurring rheumatic fever. No benefits were noted; indeed, the rheumatic manifestations were intensified. Disappointing results were also reported by Massell and Jones,³⁶ who treated 58 patients with rheumatic fever, including 7 with chorea. Quite negative results have been reported by other observers, and the drug is equally disappointing in the treatment of rheumatoid arthritis.

Of special interest, however, in the prevention of rheumatic fever are the recent studies of Coburn and Moore,¹⁴ who have recently published an interesting study on the value of sulfanilamide in the prevention of rheumatic fever. Rheumatic children were given maintenance doses of the drug (about 2 Gm. daily) over a period of months and were observed with respect to the incidence of hemolytic streptococcus infections and recurrences of rheumatic fever. No toxic effects from the drug were observed. Only one of the twenty-six patients so treated contracted an infection with hemolytic streptococci in the throat flora, and only one of the twenty-six highly susceptible rheumatic children developed active rheumatism. However, sulfanilamide administered to rheumatic subjects after the onset of streptococcic throat infections did not prevent rheumatic recrudescences. This important contribution to the prophylaxis of rheumatic fever seems to offer real promise as a practical measure of preventing recurring attacks of the disease.

Experimental Arthritis.—Bacteriologists continue to be interested in the study of experimental arthritis. In our own laboratory the writer, in collaboration with Angevine and Rothbard,⁹ have recently published the results of extensive study on experimental arthritis in rabbits produced with streptococci and other organisms. Experimental arthritis was produced successfully with both streptococcus hemolyticus and streptococcus viridans. However, we were also able to produce an arthritis with staphylococcus aureus, pneumococcus, and paratyphoid bacillus A. The pathological picture produced

by these bacteria was very similar to that produced by streptococci.

In the February number of the *Journal of Experimental Medicine* Angevine and Rothbard³ have called attention to the mechanism by which bacteria become localized in the tissues of the joints and eyes. Histological examinations of sections from the eyes and joints of large numbers of rabbits injected with hemolytic streptococci has clearly demonstrated that when arthritis or cyclitis occurs, the synovial villi and ciliary processes are the most frequent and usually the primary sites of inflammation. By special methods for demonstration of bacteria, it has been shown that bacteria which found lodgment in either an eye or a joint were demonstrable first in the vessels of ciliary processes or synovial villi. A localized synovitis or iridocyclitis is brought about by the localization of bacteria in the synovial villus and ciliary process. These experiments, which give a clearer insight into the pathogenesis of infectious arthritis and iritis, explain why both may occur in association with certain infectious diseases.

The streptococcal theory of arthritis and rheumatism still seems to me to be the favorite theory. Perhaps eventually, however, we may find that the joints are not actually infected, but become sensitized in some way which we do not yet quite understand. Faber²¹ in 1915 sensitized the joints by intra-articular injections of killed green streptococci, and stated that subsequent intravenous injections of the same organism lodged more readily in the prepared joints. He regarded this sensitization as specific within set limits, although he did not claim that the sensitization was specific for various strains of streptococci. Swift and Boots⁴⁴ in 1923 sensitized the joints of rabbits by intra-articular injections of nonhemolytic streptococci and subsequently infected the animals with intravenous injections of streptococci. They concluded that, because arthritis developed in many nonsensitized as well as in sensitized joints, sensitization was not an important factor in the development of arthritis. More recently Dr. Angevine⁶ has returned to this problem and has obtained some interesting results. Rabbits were injected either intravenously or intradermally with heat-killed hemolytic streptococci and subsequently injected intravenously with living organisms. Arthritis was produced in the intravenously immunized

rabbits with a smaller number of bacteria than was required to produce the disease in normal or intradermally immunized animals.

In another series of experiments the right knee joints of rabbits received repeated injections of small amounts of either heat-killed streptococci or a nucleo-protein fraction. When the animals were subsequently infected intravenously with living cultures of the same organism, the previously injected joints were more susceptible to infection than were joints that had been injected either with heat-killed staphylococci or horse serum. In these studies, which have not as yet been published, it would appear that the relation of bacterial allergy to joint infection is a subject which has not yet been completely elucidated.

CLINICAL ASPECTS OF VITAMIN B DEFICIENCIES*

NORMAN JOLLIFFE, M.D.

New York, N. Y.

THE vitamin B complex is known to contain at least a dozen fractions, four of which are available in crystalline form in amounts adequate for clinical use. These are thiamin chloride (B_1), riboflavin (B_2), nicotinic acid (p-p factor), and pyridoxin (B_6). Another factor, pantothenic acid (filtrate factor), has recently been synthesized and is just now becoming available for clinical investigation. Through the controlled use of these crystalline B-vitamins, the clinical investigator has made progress hitherto impossible when only concentrates were available. This progress has been mainly in three directions:

1. In recognizing the particular clinical manifestations of deficiency of each of the crystalline B-vitamins.

2. In recognizing the true etiology of certain clinical syndromes.

3. In recognizing that deficiency diseases in man are usually not single but multiple.

The diagnosis of deficiency in the B-vitamins depends, at the present time, upon a clinical eval-

uation of the history and the signs and symptoms presented by the patient.⁶ A vitamin B deficiency should be suspected in the following groups of persons:

1. *The Indigent and Low Income Groups.*—The average American diet affords a small margin of safety in the B-vitamins. In vitamin B_1 this margin amounts to only 20 to 80 per cent.⁵ This safety margin, though below the optimum, provides sufficient amounts of the B-vitamins to protect against deficiency disease under ordinary physiologic conditions. As this diet is average, it follows that a considerable fraction of the American population must consume a super-average and a considerable fraction a subaverage amount of the B-vitamins.

2. *Persons Who Have Erroneous Dietary Habits and Food Idiosyncrasies.*—Regular consumption of extra-dietary supplements of vitamin-free calories as obtained from sugar, corn syrup, alcohol, candy, pastries, or soft drinks, may render a marginal diet inadequate. In evaluating the adequacy of a diet we must always scrutinize the dietary of any subject who remem-

*From the Department of Medicine, New York University College of Medicine, and the Medical Service of the Psychiatric Division, Bellevue Hospital, New York. Read before the annual meeting of the Minnesota State Medical Association, Rochester, Minnesota, April 24, 1940.

bers what he has eaten. The average person consuming a mixed and varied dietary not limited by idiosyncrasies or restrictions rarely remembers this. The more varied the diet, the less likely it is to be inadequate.

3. *Alcohol Addicts*.—These subjects often consume amounts of vitamin-free alcohol sufficient to lower the vitamin calory ratios significantly, even when an otherwise adequate diet is maintained.^{7,8,10} A smaller consumption of biologically good calories, and impaired absorption or utilization of the vitamin, are additional factors leading to vitamin deficiency in these subjects.

4. *Patients Having Diseases Altering the Vitamin B Requirements*.—The better known of these are listed in Table I. This table indicates the wide possibilities for the development of secondary vitamin deficiencies.

Thiamin Deficiency

The signs and symptoms attributed to vitamin B₁ deficiency are legion, the most definite being anorexia, fatigue, a neurological and a circulatory syndrome. Anorexia and fatigue are non-specific. In their presence the possibility of vitamin B₁ deficiency should be considered and confirmatory signs should be sought. When these symptoms occur without supporting objective signs, and do not definitely respond to thiamin therapy within seventy-two hours, they are probably not due to vitamin B₁ deficiency alone.¹⁴

The neurological manifestations of vitamin B₁ deficiency are those of bilateral and symmetrical polyneuritis involving first and predominantly the lower extremities. Peripheral neuritis that involves a single nerve, or that is not bilateral and symmetrical, or that does not involve first and predominantly the lower extremities is, in our experience, probably not due to vitamin B₁ deficiency alone. For such neuritides other etiological agents should be sought.

For the purpose of clinical investigation we have classified the neurological manifestations according to severity into four groups: suggestive, mild, moderate, and severe. Heaviness of the lower extremities, and calf muscle cramps are usually the first symptoms. These are followed by paresthesias in the toes and fingers, burning of the feet, and pains in the legs. It should be emphasized that pain, though nearly always pres-

ent, can often be elicited only by a leading question. Calf muscle tenderness and plantar hyperesthesia are as a rule the earliest objective signs. The hyperesthesia may extend up the ankles and legs in a sock distribution. Vibratory sensation may be lost in the toes. These signs we classify as suggestive, and a positive diagnosis of polyneuritis is not made, as circulatory disturbances may cause these or very similar findings. When, however, in addition to these signs, the ankle jerks are absent, a diagnosis of mild polyneuritis can be made. As the deficiency continues, the sensory and motor changes advance, the knee jerks disappear, position sense in the toes becomes impaired, calf muscle atrophy develops, and foot drop follows. We classify this degree of involvement as moderate, provided the signs are confined to the lower extremities. When there is also involvement of the upper extremities, the spinal cord, or the cranial nerves, or when a "central neuritis" is present, we classify the polyneuritis as severe.

The circulatory manifestations of vitamin B₁ deficiency do not form a rigid clinical picture.^{4,9,11} They may occur in a person whose circulatory system is otherwise normal, or they may be superimposed on one previously damaged by degen-

crative, hypertensive, or inflammatory disease. These circulatory manifestations, as observed by Weiss and Wilkins,^{23,24} Jones and Sure¹⁵ and in our clinic, may be classified as follows:

1. Edema and serous effusions occurring in the absence of congestive heart failure, enlarged heart, or recognized etiologic factors producing edema and serous effusions.

2. Edema and serous effusions occurring with supporting signs and symptoms of congestive heart failure, usually with definite roentgenographic evidence of cardiac enlargement.

3. Sudden circulatory collapse which may be the first manifestation of circulatory failure or may occur after other signs of circulatory failure are well advanced.

The circulatory manifestations of vitamin B₁ deficiency occur in about one-third of vitamin B₁ deficient subjects manifesting definite polyneuritis. They are more likely to occur in patients with suggestive or mild involvement than in those having advanced neuritis. This factor is related to the ability of persons with mild neuritis to perform muscular exertion.

Some of the more characteristic diagnostic features of the circulatory manifestations of vitamin B₁ deficiency are:

1. Mild nature of the polyneuritis.
2. Increased or normal velocity of the blood flow in the presence of congestive heart failure.
3. Rapid response to specific therapy with complete and permanent reversibility of the circulatory manifestations.

Riboflavin Deficiency

Riboflavin is a necessary constituent in the diet of many animals. In the rat its lack leads to failure in growth, to a senility, alopecia, a non-specific dermatitis and keratitis; in the dog an acute deficiency leads to spasticity, generalized weakness, circulatory collapse and a "yellow" liver, while a chronic partial deficiency results in signs characterized clinically by ataxia. Although riboflavin is presumably present in every living cell and is concerned with the chemical reactions involved in cell respiration, no distinct clinical syndrome in man had been attributed to its deficiency prior to Sebrell and Butler's¹⁹ report.

The lesions produced by Sebrell and Butler in ten of eighteen women maintained on the diet

of Goldberger and Tanner appeared ninety-four to 130 days after the beginning of the experiment. They began "as a pallor of the mucosa of the lip in the angles of the mouth without involvement of the buccal mucosa. This pallor was soon followed by maceration, and within a few days superficial transverse fissures appeared, usually bilateral, and exactly in the angle of the mouth. These fissures extended somewhat downward from the angle. . . . In some instances the fissures continued to extend onto the skin for a distance of as much as half an inch. These lesions resemble those described as *perlèche*. At about the time the fissures were seen, the lips became abnormally red along the line of closure. This was due apparently to a superficial denudation of the mucosa. In addition to the cheilosis, there was also seen a fine, scaly, slightly greasy desquamation on a mildly erythematous base in the nasolabial folds, on the *alæ nasi*, in the vestibule of the nose and on the ears."

Under the conditions of the experiment these lesions were alleviated by the administration of synthetic riboflavin, but not by nicotinic acid. The authors' conclusion that the condition is a manifestation of riboflavin deficiency seems warranted. Since then, Oden, Oden and Sebrell¹⁸ have reported three patients from rural Georgia with similar lesions which responded promptly to 5 mg. of synthetic riboflavin given daily. They believe, since the Odens have seen many similar cases in their practice in rural Georgia, that ariboflavinosis is in all probability a common deficiency disease in the southern United States. Sydenstricker²² thinks that these lesions are "even more frequent than frank pellagra." Sydenstricker's¹⁶ group has reported, in addition, a keratitis associated with these signs of riboflavin deficiency in ten subjects.

We¹³ have reported fifteen subjects having lesions due, we believe, to ariboflavinosis. Thirteen of these subjects were alcoholic, one had advanced pulmonary and intestinal tuberculosis and one was an epileptic. In this group of fifteen patients, thirteen had nicotinic acid deficiency, seven had vitamin B₁ deficiency and three had vitamin C deficiency. Only one patient had no clinical evidence of another vitamin deficiency. Since then, however, we have observed three additional subjects, all university students, who presented no clinical evidence of another deficiency disease. The facial lesions seen consisted of filiform

excrescences of a seborrheic nature, apparently derived from the sebaceous glands, varying in length up to 1 mm., closely to sparsely scattered over the skin of the face. Their characteristic location was in the nasolabial folds, but in addition they occurred frequently on the *alæ nasi*, occasionally on the bridge of the nose and sometimes on the forehead above the eyebrows. The skin on which the excrescences were located was the seat of a fine, scaly, greasy desquamation. On casual inspection these filiform lesions resembled urea frost, but they could not be brushed off by rubbing with the fingers. In addition, most of the patients showed fissures and maceration at the angles of the mouth, and a degenerative crust-like formation on the epithelium of the lips, most marked on the lower. The fissures at the angles of the mouth were bilateral and extended laterally 1 to 3 mm. onto the mucous membrane of the mouth and 1 to 10 mm. onto the skin. They were usually very shallow but were sometimes 0.5 mm. deep, and their bases as a rule showed little or no increased redness. Extending for 5 to 20 mm. from the angle of the mouth onto both lips, the mucous membrane was macerated and wrinkled and pearl-gray. The lips, particularly the lower, frequently showed a marked increase in the vertical fissuring, often without a break in the mucous membrane. Occasionally, the vestibule of the nose was involved, with lesions similar to those on the lips. We observed no lesions on the ears.

Our first ten subjects, all of whom were pellagrins, were maintained with the diet of Goldberger and Tanner. After a control period of three to fifteen days, during which neither the facial lesions nor the cheilosis improved, various preparations then being tested for their value in the treatment of pellagra were given. Preparations which produced a cure of the stomatitis of pellagra were followed also by disappearance of the facial and lip lesions now ascribed to riboflavin deficiency. These were vegex, brewers' yeast and liver residue. Highly concentrated liver extract effective in pernicious anemia, as well as cod-liver oil, linseed oil, cevitic acid and thiamin chloride were ineffective not only in pellagrous stomatitis but also on these facial and lip lesions. For this reason we believed that the lesions were all part of pellagra.

When, however, we began the treatment of our pellagrins with nicotinic acid while still main-

taining them on the diet poor in the vitamin B complex, although we obtained dramatic responses in the oral, gastrointestinal and mental manifestations of pellagra, the facial and lip lesions were not affected. After the response to nicotinic acid, two of these patients were given a full diet supplemented with 18 gm. of vegex daily by mouth. The characteristic facial and lip lesions promptly improved.

At this time Sebrell and Butler's report appeared. Their description of the lesions which they had produced experimentally suggested to us that the lesions we had been observing in our subjects were probably signs of more advanced states of riboflavin deficiency. If true, this observation would explain their failure to respond to nicotinic acid and their response to a full diet plus vegex, brewers' yeast or liver residue, substances rich in riboflavin. We, therefore, determined to test the effect of synthetic riboflavin on the lesions occurring in our subjects.

By maintaining patients having these characteristic lesions of riboflavin deficiency with a diet poor in the B complex we demonstrated that these lesions respond to synthetic riboflavin, but not to thiamin chloride, nicotinic acid or vitamin B₆.

Nicotinic Acid Deficiencies

The signs and symptoms of partial chronic nicotinic acid deficiency, particularly those occurring in pellagrins, are so well known from the work of Spies, Sydenstricker and Smith and their co-workers that it is not necessary to describe them in detail. The complete picture consisting of a scarlet-red stomatitis and glossitis, diarrhea, bilateral symmetrical dermatitis and mental aberrations form in combination such a characteristic syndrome that they are widely recognized and should never go unrecognized. It is not so well understood, however, that the oral lesions, the gastro-intestinal lesions, the mental changes or the skin lesions may each occur alone or in any possible combination. For example, the patients having the stomatitis of nicotinic acid deficiency are too frequently considered to have only the superimposed Vincent's infection. The primary diagnosis is not considered and specific therapy is neglected. If nicotinic acid therapy is instituted not only is the scarlet-red stomatitis blanched within 24 to 48 hours, but the Vincent's infection heals without

other general or local therapy. The mental changes may precede the skin, gastrointestinal or oral changes and the patient may be labeled as a neurasthenic, neurotic or psychoneurotic. Similarly, gastrointestinal manifestations may precede all the others, and the diagnosis may be missed for many weeks.

We¹² have reported 150 cases of an "encephalopathic syndrome," a condition heretofore almost always fatal, which we believe is caused by nicotinic acid deficiency. This syndrome may occur as the only clinical manifestation of a deficiency disease or it may occur in association with pellagra, polyneuritis due to vitamin B₁ deficiency, the oculomotor disturbances of a "central neuritis," or scurvy. The clinical picture of this encephalopathic syndrome is more or less well defined and is characterized by clouding of consciousness, cogwheel rigidities of the extremities, and uncontrollable grasping and sucking reflexes.

Bender and Schilder,² who have described its clinical picture, included this syndrome as one of a group of five which they called collectively "encephalopathia alcoholica." Their classification of the types of encephalopathia alcoholica was related to the most prominent manifestations: (1) clouding of consciousness and changing rigidities, (2) cerebellar symptoms, (3) catatonia, (4) alcoholic delirium, and (5) polyneuritis. Groups 1 and 5 were clinically similar, the difference being that in group 1 the polyneuritis was minimal or absent while in group 5 the polyneuritis was so marked as to constitute the most prominent manifestation. We believe that these two groups are identical, differing only in the degree of clinical vitamin B₁ deficiency superimposed on a nicotinic acid deficiency or vice versa. Groups 2, 3 and 4 present different clinical pictures distinct from the specific encephalopathic syndrome reported herein. We also believe that the oculomotor disturbances when they occur are a manifestation of a disease process distinct from this specific encephalopathic syndrome. Likewise to be excluded are the encephalopathic manifestations of groping, grasping and sucking which may occur during the course of delirium tremens, acute alcoholic hallucinosis, expanding intracranial lesions, infectious diseases with delirium, advanced cerebral arteriosclerosis and other diseases.

The encephalopathic syndrome does not occur exclusively in alcoholic patients. Both Spies²⁰

TABLE II. RELATION OF THERAPY ON 150 SUBJECTS HAVING THE ENCEPHALOPATHIC SYNDROME*

Treatment	Cases	Deaths		Died Corrected	
		No.	Percent	From Other Causes	Mortality Percent
House diet, dextrose and saline solution	47	45	95.7	3	89.4
House diet, dextrose and saline solution, thiamin chloride...	15	15	100.0	0	100.0

Basal diet, dextrose and saline solution, nicotinic acid	22	7	31.8	4	13.6

*Reproduced through courtesy of the *Jour. A.M.A.*

and Sydenstricker²² have observed this syndrome in endemic pellagrins. Some of the cases of pellagra described by Matthews¹⁷ (cases 2 and 9) may very well have manifested this encephalopathic syndrome, although his report does not include recorded observations of grasping and sucking reflexes or of cogwheel rigidities of the extremities. Cleckley, Sydenstricker and Geeslin³ have studied a group of subjects having stupor which responded to nicotinic acid therapy. We believe that several of their protocols are probably descriptions of the encephalopathic syndrome which we are reporting here. Prior to 1933, patients admitted to our service having this encephalopathic syndrome almost invariably died irrespective of the treatment given. Since most of the patients were dehydrated, it seemed reasonable to attempt hydration by infusions of 5 per cent dextrose in physiologic solution of sodium chloride. A total of forty-seven patients were thus treated (Table II), forty-five of whom died while exhibiting the encephalopathic syndrome. Three of these patients had other diseases which were probably fatal (pneumococcal pneumonia, ruptured duodenal ulcer, subarachnoid hemorrhage); if these are discarded a corrected mortality of 89.4 per cent is obtained.

Most of these subjects had polyneuritis due to vitamin B₁ deficiency. A considerable number had stomatitis, which in fifteen instances is now recognized as having been similar to the stomatitis of patients with pellagra. Its frequent association with known deficiency diseases suggested that the encephalopathic syndrome too might be a manifestation of some nutritional lack. If so, then from its commonest associations the defi-

ciency would most likely be of one or more fractions of the vitamin B complex. That the encephalopathic syndrome also occurred independently, in the absence of other clinical evidence of deficiency disease, suggested the possible lack of a distinct and perhaps as yet unidentified nutritional element. Since polyneuritis was the commonest associated disease, we studied the effect of parenteral administration of from 50 to 200 mg. of thiamin chloride daily while continuing the routine treatment of hydration. The fifteen consecutive patients thus treated all died without improvement in the encephalopathic syndrome. The next group of these patients was treated with vitamin rich diets supplemented by oral and parenteral administration of large amounts of preparations rich in the B vitamins: vegex, brewers' yeast, an aqueous whole liver extract and various fractions of liver. Of the total of sixty-six patients thus treated, thirty-three had other signs now recognized as due to deficiency of nicotinic acid. Twenty-five, or 37.8 per cent of these patients recovered; the rest died while manifesting the encephalopathic syndrome, a mortality of 62.2 per cent. Seven patients in this group, however, had in addition a probably fatal disease (three advanced pulmonary tuberculosis, two pneumococcic pneumonia, one streptococcus hemolyticus sepsis, one cirrhosis of the liver); discarding these, we obtain a corrected mortality of 51.5 per cent. This experience supported our hypothesis that the responsible factor or factors must be sought in the vitamin B complex, excluding thiamin chloride.

Shortly after nicotinic acid became available, we began to test the effect of nicotinic acid on our patients having the encephalopathic syndrome. Twenty-two consecutive patients with the encephalopathic syndrome were treated with nicotinic acid, seven of whom died, giving a mortality of 31.8 per cent. This death rate should be compared with the mortality of 95.7 per cent in forty-seven subjects treated by hydration alone, the mortality of 100 per cent in fifteen subjects treated by hydration plus thiamin chloride and the mortality of 62.2 per cent in sixty-six subjects treated by hydration plus the entire vitamin B complex. In the three groups not given nicotinic acid each subject who died did so without prior recovery from the encephalopathic syndrome. In the group treated with nicotinic acid, four of the seven subjects who died did so

one, two, four and ten days respectively after the disappearance of the encephalopathic syndrome and of diseases probably independently fatal (pneumococcic pneumonia, cirrhosis of the liver, streptococcus hemolyticus sepsis, multiple lung abscesses). On this basis the "corrected mortality" in the group treated with nicotinic acid is 13.6 per cent, as compared with 89.4, 100 and 51.5 per cent corrected mortality in the groups of patients not treated with nicotinic acid.

It seems unlikely that the response obtained for the patients treated with nicotinic acid could be due to some other factor. Hydration alone failed, hydration plus thiamin chloride failed, hydration plus vitamin B complex was partially effective but hydration plus nicotinic acid was successful in a large majority of cases. Assuming that nicotinic acid is the effective therapeutic agent, the significant decrease in mortality in the group treated with preparations containing the vitamin B complex can be attributed to the nicotinic acid content of those preparations. The failure of the same preparations in more than half of the treated subjects can be attributed to their relatively small content of nicotinic acid. That the results in the group treated with nicotinic acid were due to chance seems unlikely. Each group seems large enough for the results to be significant. It is noteworthy that before the use of nicotinic acid we had never witnessed recovery in four consecutive cases but had witnessed death in more than fifteen consecutive cases of the encephalopathic syndrome.

The fact that only about half of our subjects presented other signs of deficiency of nicotinic acid, and the fact that in endemic pellagra the encephalopathic syndrome occurs only in the more advanced and severe cases does not necessarily contravene the evidence that this encephalopathic syndrome is a manifestation of deficiency of nicotinic acid. Our explanation, which of course, is speculative, is as follows: As a complete deficiency of riboflavin leads to a different clinical picture than partial riboflavin deficiency, there may well be a similar difference in nicotinic acid deficiency. The encephalopathic syndrome represents, we believe, a complete nicotinic acid deficiency, while the pellagra syndrome (stomatitis, the gastro-intestinal, the common psychic symptoms and possibly the dermatitis) represents a partial deficiency of nicotinic acid not complete enough to produce the encephalo-

pathic syndrome. If this is so, patients having both pellagra and the encephalopathic syndrome would represent the picture of a partial deficiency of nicotinic acid of sufficient duration to cause the structural changes recognized as pellagra, on which has been superimposed a complete nicotinic acid deficiency, while patients showing the encephalopathic syndrome without signs of pellagra would represent a complete nicotinic acid deficiency which develops so rapidly that the structural changes in the mouth and skin characteristic of pellagra do not have time to occur.

Whether this explanation of the *modus operandi* is the correct one or not, it seems to us entirely justifiable on the basis of our observations, to attribute the etiology of the encephalopathic syndrome which we have described to nicotinic acid deficiency; as such, its proper label should be "nicotinic acid deficiency encephalopathy." By this designation we do not mean to imply that there are not other causes of encephalopathy, for disturbances in brain metabolism may and do occur as a result of other factors than lack of nicotinic acid. It is not to be expected that nicotinic acid should be effective in those cases or that its administration in appropriate instances will always result in cures, for the deficiency may be advanced to an irreversible stage.

Pyrodoxin

A specific syndrome in man attributable to a deficiency of vitamin B₆ or pyrodoxin has not as yet been reported. In rats, a deficiency of this vitamin is known to cause "rat acrodynia," foci of degeneration in striated and cardiac muscle and changes in the nervous system, particularly of the columns of the spinal cord. Antopol and Schotland¹ have recently suggested that vitamin B₆ through its pyridine structure may be involved in the enzyme system concerned in muscle metabolism. In this connection it is interesting to note that Spies²¹ and his co-workers noted increased muscle strength in patients with pellagra following its administration; Antopol and Schotland have reported on its beneficial effect on muscle strength in six patients having pseudo-hypertrophic muscular dystrophy, but warned that "it is not to be implied that this group of muscular dystrophies are due to avitaminosis B₆." In addition we have accumulated evidence that vitamin B₆ plays some part in the acne syndrome.

Syndromes collectively labeled paralysis agi-

tans, while not directly fatal, usually pursue a progressive course, and eventually the victims become helpless and seek hospitalization. Since muscular rigidity and weakness is characteristic of paralysis agitans, and since vitamin B₆ is involved in muscle metabolism, it seemed worthwhile to test its effect in this syndrome. We, therefore selected fifteen patients having paralysis agitans, all of whom were bedfast or chairfast, ten of these for more than three years. Six of our patients gave a history of encephalitis. All the patients received 50 or 100 mg. of vitamin B₆ hydrochloride by intravenous injection, either daily or every other day. Of the fifteen patients, four showed subjective and definite objective improvement. Two additional patients were subjectively improved. The following case histories are reported:

Case 1. A seventy-eight-year-old retired business man, was seen on November 15, 1939, because of aches and pains of ten days' duration, in all the extremities. Significant findings were stooped posture, expressionless face, and paucity of associated movements. An intention tremor of the hands was present. There were no rigidities. He was treated with diet, vitamin B-complex by mouth, liver extract and thiamin chloride parenterally. By January 2nd, the patient was worse, rising from a chair was a task, and rigidities of the extremities were now present. Thiamin chloride and liver extract were discontinued. Belladonna preparations were administered and continued at limit of tolerance until April 1. By March 1 the patient had to be helped in and out of bed, to dress, to shave and to bathe. He could rise from a chair only with difficulty but continued to feed himself. From that time he has been given 100 mg. of nicotinic acid three times daily. On March 23, as no improvement had been noted, he was given 100 mg. of vitamin B₆ by intravenous injection. This dosage has since then been repeated every other day. Within half an hour after the first dose, the patient could rise from a chair without difficulty, the rigidities became indiscernible, he could walk and he climbed stairs without assistance. By March 31, expression was again evident in the patient's face, and he was able to take short strolls outdoors. By April 6, he was able to bathe, shave and dress himself, and had gone to church. His posture is fairly erect. The associated movements have not returned and the intention tremor remains unaffected.

Case 2. A sixty-two-year-old white night watchman was admitted to Bellevue Hospital on March 13, 1940 because of helplessness of one week's duration and with a tremor of twenty years' duration. One week prior to admission, while at work, the patient fell and found himself helpless. Important findings were unintelligible speech, mask face, coarse tremors of the hands, and rigidities of all extremities. He was unable to rise in

bed or move his legs on command. He was given tincture of stramonium to point of tolerance. On March 25, his condition was unchanged and treatment with 100 mg. of vitamin B₆ daily by intravenous injection, plus 300 mg. of nicotinic acid and vitamin B-complex by mouth was begun. By April 8, the patient could feed himself, rise from a chair, and avail himself of toilet privileges. His face is mobile and his speech intelligible. The tremor is unimproved, the posture is bent, and the poverty of associated movements remains.

Case 3. A forty-seven-year-old laborer, was transferred to Bellevue Hospital on July 22, 1939, from the Farm Colony, where he had been a patient for two years. He was never ill until he had "influenza" in 1926 which lasted one week and was associated with drowsiness and double vision. Within three months the patient noticed tremor of the upper extremities. For seven years prior to admission to the Farm Colony he had been treated as an out patient at another hospital. Significant findings were expressionless face, unintelligible speech, half moon posture, paucity of associated movements, constant coarse tremors, and cogwheel rigidities of the upper extremities. He was treated with tincture of stramonium. During the following eight months the patient's condition remained unchanged. On March 25, he was transferred to this service, given vitamin B-complex plus nicotinic acid by mouth, and intravenous administration of 100 mg. daily of vitamin B₆ was started. During the first week no improvement was noticed. By April 8, there was subjectively an increase in strength, the tremor seemed diminished, and an increase in the emotional play of the face was commented on by all observers. The rigidities, posture, gait and poverty of associated movements seemed unchanged.

These cases represent examples of the so-called "arteriosclerotic," "idiopathic" and post-encephalitic types of paralysis agitans. The first two are examples of degenerative diseases, the third of a sequel of an acute infection. The first two subjects represent in terms of function (as measured by ability to perform their normal occupation, disability of four months and four weeks respectively; the third nine years of disability. These factors may explain the prompt response of the first two subjects and the failure of the treatment in the third. The two patients whose histories are not detailed here, in whom definite objective improvement was noted, were both in the seventh decade. Neither gave a history of encephalitis, and both had disability for less than three years. Of the eleven patients who showed no objective improvement, ten had complete disability for more than three years, and half of these gave a history of encephalitis; the other had a disability of six months but gave

a history of encephalitis. It is, therefore, emphasized that thus far objective beneficial results in helpless patients have been limited to lessening of rigidities and increase in strength in patients whose complete disability is of less than three years' duration, and who give no history of encephalitis.

In summary, the syndrome of paralysis agitans appears to include a group of persons whose manifestations, particularly the rigidities and weakness, respond to vitamin B₆.

Treatment of Vitamin B Deficiencies

In the treatment of deficiencies of the B vitamins I wish to stress two points:

1. Specific signs and symptoms of a specific deficiency responds promptly to adequate amounts of the specific chemical substance if the pathologic changes are not so advanced as to be irreversible.

2. Complete recovery of the patient does not always follow and adequate treatment does not consist of the administration of these specific chemicals either singly or in combination.

To illustrate these two points a case record is presented.

V. B., a thirty-four-year-old white female, was transferred to the Medical Service of the Psychiatric Division of Bellevue Hospital from an institution for the care of epileptics where she had been a patient for the past five years. When admitted she complained of weakness, bleeding gums, sore mouth and tongue, and a rash on the face and hands, all of some few weeks' duration. Her history included epileptic convulsions since the age of three, a craniotomy in 1932 without improvement in the convulsions, and an appendectomy in 1921. Her diet consisted chiefly of the following: Breakfast—oatmeal, coffee, and white bread; lunch—white bread and butter, potatoes, and a portion of stew; supper—tea, white bread and butter, prunes and apricots. She received one egg each week. The meat in the stew was never eaten by the patient, but given to others. In addition, she consumed daily large amounts of cake furnished by her parents so that the main constituents of her diet were cake and white bread.

Examination on admission showed a thin, undernourished, chronically ill female. She was coöperative, and oriented as to time, place and person. The epithelium of the lower lip showed degeneration with scaling and desquamation (cheilosis). There were fissures at the angles of the mouth extending about 2 mm. laterally in each direction from the mucocutaneous junction. There was moderate maceration of the tissues in the angles of the mouth. In the nasolabial folds and across the bridge of the nose there

was a seborrheic lesion consisting of filiform excrescences about 0.5 mm. in length, which appeared to protrude from the sebaceous glands. Superficially this lesion resembled urea frost, but it could not be rubbed off, and the underlying skin felt greasy. It was not present on the upper lip, vestibule of the nose, forehead or ears. In addition to this lesion there was an acneiform eruption over the face. The upper jaw was dentureless. The gums of the lower jaw were red and markedly piled up, consisting of bags of blood which bled on light touch. The tongue was clean, bald, and reddened as were the oral mucous membranes. Along the frenulum of the tongue were ulcerations covered by a pearl-gray exudate. On the right hand there was deep pigmentation over the second interphalangeal joint and thumb, a small ulceration over the knuckles, and a bracelet-like pigmented dermatitis of the wrist. The left hand exhibited a bracelet-like pigmented dermatitis and slight dermatitis over the second interphalangeal joint. There was increased keratosis of the elbows. There were no "necklace lesions" and no perineal lesions. There was no evidence of peripheral neuritis. A diagnosis of riboflavin, nicotinic acid and cevitic acid deficiency, and epilepsy, was made.

The patient was maintained with the diet poor in vitamin B complex. Studies of the blood revealed total absence of cevitic acid. The patient was then given 300 mg. of cevitic acid daily by intravenous injection, and 100 mg. four times a day by mouth. On the second day of this regimen there was definite improvement and on the following day the gums were natural in color. The stomatitis and glossitis had remained unchanged. The dosage of cevitic acid was then reduced to 200 mg. daily by mouth, and the diet poor in the vitamin B complex was continued. From the sixth day of hospitalization the patient was given 500 mg. of nicotinic acid daily, in doses of 100 mg. each, by mouth. By the eighth day of hospitalization the abnormal redness of the tongue and mucous membranes of the mouth had disappeared, the frenulum ulcer had healed, and the dermatitis of the hands was clearing. The lesions on the face and lips, however, were unchanged.

After eleven days of nicotinic acid therapy there seemed to be no significant change in the filiform lesions on the face or the lip lesions. Beginning on the seventeenth day of hospitalization administration of nicotinic acid was discontinued, but the patient was still maintained with the diet poor in the vitamin B complex; in addition, 10 mg. of synthetic riboflavin was administered daily by mouth. On the fifth day of this regimen a definite and marked improvement was noted. The degenerative epithelial lesions of the lips and the fissures at the angles of the mouth had cleared entirely, and the filiform lesions on the naso-labial folds and bridge of the nose had disappeared; the acneiform rash had also improved. The patient, however, now showed definite signs and symptoms of a mild peripheral neuritis characteristic of vitamin B₁ deficiency. She was then given 50 mg. of thiamin chloride daily by intramuscular injection. This was followed by complete disappearance of the signs and symptoms of peripheral

neuritis within three days. At this time (the twenty-seventh day of hospitalization) the patient was given the house diet supplemented daily by 200 cc. of orange juice and 18 Gm. of vegex, and the administration of riboflavin, cevitic acid and thiamin chloride were discontinued. The strength of the patient now markedly improved, and her weight increased from 84 pounds (on the twenty-seventh day of hospitalization) to 111 pounds when she was discharged on the fifty-third day of hospitalization.

These results demonstrate that the specific signs and symptoms of a deficiency disease respond to the appropriate pure chemical substances. By the use of these chemical substances the clinical investigator has learned that complete recovery of the patient does not always follow, and adequate treatment does not consist of the administration of these specific chemicals whether singly or in combination. This fact is amply demonstrated by this patient, for complete recovery, that is, gain in strength and weight, and disappearance of the acne, did not occur until a full diet supplemented by the entire vitamin B complex was administered. We believe, however, that a full diet plus the autolyzed brewers' yeast (vegex) furnishes other factors, both known and unknown, that cannot as yet be supplied by any known combination of pure chemical substances.

The vitamin B-complex preparations used in these studies were kindly furnished by The Vegex Co., New York; Lederle Laboratories, Pearl River, New York, and the Fleischman Laboratories, New York; the thiamin chloride, riboflavin, pyridoxin and nicotinic acid by Merck and Co., Rahway, New Jersey.

RECENT ADVANCES IN THE TREATMENT OF HEPATIC DISEASE*

ALBERT M. SNELL, M.D.

Rochester, Minnesota

IT has often been said that fundamental ideas of the nature of a disease determine to a greater extent than any other factor the manner of its treatment. If a condition is regarded as hopeless from the outset, an element of defeatism colors our therapeutic efforts. The various types of cirrhosis of the liver have been regarded for years as practically beyond the reach of treatment; they are, in fact, considered as affections which by their very nature "are above the powers of the constitution."⁸

Before considering some of the advances which are being made in the treatment of primary disease of the hepatic parenchyma, it is first necessary to establish the fact that hepatic lesions of this type are capable of making a response to therapy. One must survey the normal course of the disease to see what turn of events may be expected and what factors seem to influence prognosis. In this connection a study of experimentally produced hepatic disease brings out some interesting and important facts. Bollman and Mann were the first to show that only a very small part of the parenchyma of the liver is necessary to carry on normal metabolic functions, and that the body, therefore, contains hepatic tissue greatly in excess of the amount necessary to maintain normal activity. They have also been able to remove as much as 80 per cent of a dog's liver at one time without any particularly abnormal results. In addition to the

anatomic and physiologic reserves possessed by the liver, an unusual degree of regenerative capacity is also apparent. When from a fifth to three-quarters of the liver has been removed from a dog, regeneration of a mass of hepatic tissue equal to or greater than the weight of the removed portion is completed in from six to eight weeks. Several factors, however, may be shown to diminish or to inhibit completely regeneration of the liver after removal of portions of its substance. Diversion of portal blood by the establishment of an Eck fistula, ligation of the common bile duct or the presence of pre-existing damage to the parenchyma will exert such an effect.

If specific hepatotoxic substances, such as carbon tetrachloride, are given to the experimental animal, similar regenerative and reparative properties of the liver may be shown. By the use of repeated doses of such poisons, animals can be carried to a point that corresponds to the complete picture of atrophic portal cirrhosis in the human being. Even when this late stage of the disease is reached these animals can then be restored to normal health and a state of normal hepatic function. Naturally, one may ask whether under similar conditions, recoveries ever occur in the human being and whether the reserve and regenerative capacity of the liver of human beings ever reach the same extent. Because of the various stages at which the clinical disease is detected and because of differences in the type of treatment employed, it is difficult

*From the Division of Medicine, The Mayo Clinic, Rochester, Minnesota. Presented at the annual meeting of the Minnesota State Medical Association, Rochester, Minnesota, April 22, 1940.

to find statistics on this point which are entirely satisfactory. In 1892, White reported that a review of the literature up to that time did not reveal a single case of uncomplicated cirrhosis of the liver with ascites which had long survived paracentesis; in his own series of cases, the time between the onset of symptoms and death averaged only about two months. In 1931, about forty years after White's report, Chapman, Rowntree and I reported a study of 112 cases of portal cirrhosis with ascites, encountered at The Mayo Clinic during the preceding six years. Eighty-four of these patients were treated according to a regimen that involved the use of a limited intake of fluid and salt and certain diuretic remedies. This plan of treatment, which was primarily directed at the removal of ascites and edema, was not without some beneficial effect. Of the 112 patients, eighty-four died and twenty-eight were alive at the time of the report. In the group in which survival did not occur, the average length of life after the development of ascites was sixteen months; of the twenty-eight patients living at the time of the report, the average length of life after the appearance of ascites was somewhat more than three years.

A more recent survey of the course of portal cirrhosis which is being carried out by Fleming at the clinic includes a study of the group of patients observed here from 1930 to 1937, inclusive. During this period, relatively less attention was paid to the matter of ascites and more to the maintenance of a high carbohydrate intake and to the improvement of the nutrition of the patient. There were 150 patients in Fleming's series of whom 128 are dead; the average duration of life after the appearance of ascites was about fourteen months, approximately the same as in the series studied by Chapman. Twenty-two of the patients in the more recently studied group are living, however, an average of almost six years after the first appearance of ascites. It is apparent from these two groups of figures that a not inconsiderable number of patients may survive even the more serious types of primary hepatic disease and that some ultimately regain a reasonably normal state of health. In both series of cases aforementioned, the greatest mortality appears to develop during the first six to twelve months after the appearance of ascites. Once this period has been passed the chances

for survival, or even ultimate cure, appear to be considerably improved.

Because of the comparatively encouraging interpretation which may be placed on these two statistical reviews, we have attempted to initiate the same type of program for our patients who have clinical hepatic disease, a program which has been used successfully for experimental animals poisoned with carbon tetrachloride. This, in brief, consists of feeding an adequate diet of a composition which is regarded as optimal for the normal regeneration of hepatic tissue. For use in clinical subjects, vitamin supplements have been added to this regimen for reasons which will be considered in later paragraphs. The diet which has been used is high in carbohydrate, low in fat and rich in proteins not derived from meat sources. The food value is approximately 500 gm. of carbohydrate, 110 gm. of protein and about 60 gm. of fat with a total fuel value of about 3000 calories. The protein component of the diet has been derived chiefly from vegetables, milk and egg white, meat being kept at a minimum. The reason for this change in the protein composition was based entirely on experimental evidence. It has been shown by Bollman² that, although animals with experimentally produced hepatic injury are made worse by the administration of meat or meat extracts, the administration of protein from other sources is without harmful effect.

Our interest in the matter of vitamin supplements was stimulated primarily by the observations of Patek¹³ who reported the effect of a high vitamin intake in a series of thirteen cases of alcoholic cirrhosis of the liver with ascites. Ten of these patients experienced remarkable improvement in respect to both clinical and laboratory findings; a few of the patients had spontaneous diuresis and the ascites disappeared. The vitamin supplements recommended by Patek, which we have used with various modifications, consisted of percomorphic acid (vitamins A and D), orange juice or pure ascorbic acid (vitamin C), Valentine's liver extract orally (as a source of riboflavin) or parenteral liver extract and yeast or a yeast concentrate plus thiamin chloride (to supply other portions of the B complex). In order to facilitate the absorption of the fat soluble vitamins, patients have been given 5 to 15 grains (0.3 to 1.0 gm.) of animal bile salts with meals.

Fleming has recently surveyed the results in a group of fifty cases in which this program was instituted during 1938 and 1939. The results are not entirely conclusive since hardly enough time has elapsed for the proper evaluation of this form of treatment. It appears, however, that about a half of the patients are living; about a third of the whole group are considerably improved and some appear to be making a complete recovery. This is a very satisfactory percentage of survival, especially since it includes patients treated during the critical first year after ascites developed. A few remarkable "cures" with disappearance of ascites have been encountered in this review, one of the most striking being in a man, aged seventy-two years, who after two years of almost weekly paracentesis has been free from ascites for one year and in good health. A number of patients have also made definite temporary improvement and later succumbed to hemorrhage from esophageal varices or from intercurrent infections. A review of the course of some of these cases indicates that the degree of improvement attained by the individual patient was to a great extent dependent on the regularity with which the program of therapy was followed.

These results and those previously reported by Patek are encouraging, especially because they concern a disease which has been regarded as virtually hopeless. It may be, of course, that coincidence and good luck have something to do with the matter. As Lennox has said of "cures" in cases of epilepsy, even the bloodiest of battles has thousands of survivors. The rationale of the therapeutic program has, however, something to recommend it. The dietary advised needs no defense, since all investigators of the clinical and experimental aspects of hepatic disease agree on its essential points. The use of vitamin supplements in large doses has recently been advised for almost all known ailments of human beings and their employment for hepatic disease may, of course, be referred to in the vernacular as "shot-gun" therapy or something worse. There is, however, a perfectly sound basis for this treatment in cases of hepatic disease which is not so widely known as it should be. The liver is a great storage depot for vitamins and perhaps for provitamins; its normally high content of vitamins A and D is well-known, as is the fact that it is one of the principal storehouses for vitamin C. It likewise stores the B

complex or at least certain portions of it, and is essential in the utilization of vitamin K to form prothrombin. It is natural to suppose that in hepatic disease of advanced degree a state of deficiency in respect to one or more of these vitamins may develop.

Since it has been learned that the liver may be concerned in the metabolism of vitamins, a search has been made for vitamin deficiencies that develop in the course of hepatic disease, especially cirrhosis. It has been found that these states of deficiency are neither so rare nor so poorly defined as one might expect. For instance, vitamin A deficiency as characterized by absolute night blindness has been noted several times; an excellent study of the subject made by Patek¹⁴ has shown that very large doses of vitamin A will gradually correct it whereas a diet that contains sufficient amounts of vitamin A to correct an ordinary deficiency state will not affect the condition. This observation implies that the ability of the cirrhotic liver to utilize vitamin A is definitely less than normal. Vitamin D deficiencies have also been demonstrated in hepatic disease chiefly as a form of osteoporosis; a few patients have been seen with advanced hepatic disease who show evidence of extensive loss of calcium from the bones. Disturbances of metabolism of another fat-soluble vitamin, the anti-hemorrhagic coagulation vitamin K, are well known and will be considered in a later paragraph. Defects in the utilization and storage of water-soluble vitamins are also apparent in certain cases. Deficiencies of vitamin C are rare; at least they seldom reach a degree sufficient to produce scurvy; but reductions in the concentration of ascorbic acid in the plasma and urine have been demonstrated. The relation of the B complex to cirrhosis requires consideration from a number of angles. It is, of course, a well-known fact that the patient with alcoholic cirrhosis has, ordinarily, subsisted on a diet deficient in the B complex. Recently, it has been shown by Rich and Hamilton that a diet adequate in respect to all its essential constituents and containing adequate amounts of thiamin chloride, nicotinic acid, riboflavin and vitamin B₆ was nevertheless capable of producing a marked cirrhosis in rabbits. Animals fed exactly the same diet but with yeast given instead of the various individual components of the B complex did not experience the development of hepatic lesions of any conse-

quence. In other words, a deficient intake of some unknown component of the B complex was capable of causing cirrhotic changes in the rabbit's liver. It is of interest to note in this connection that diets deficient in riboflavin will produce fatty metamorphosis of the liver in dogs, and that thiamin chloride (B_1) will maintain the liver glycogen of rabbits poisoned with carbon tetrachloride as well as favor normal regeneration (Hirata). When one examines the records of patients with hepatic cirrhosis for evidence of secondary B complex deficiencies, the typical clinical syndromes of peripheral neuritis, pellagra and cheilosis are found to be rare. Glossitis is occasionally noted but the oral lesions that one encounters in cases of pellagra are uncommon. Peripheral neuritis has also been observed; riboflavin deficiency (as characterized by cheilosis) has been observed by Jolliffe in the mouths of patients suffering from alcoholism and presumably from fatty changes in the liver. None of the usual clinical evidences of deficiency in vitamin B complex, however, are sufficiently marked to warrant attention for themselves alone and they are hardly numerous enough to indicate that ordinary types of avitaminosis-B play a significant part in the symptomatology of advanced hepatic disease.

There are, however, certain obscure and poorly understood features of portal cirrhosis which may have a bearing on the matter of deficiency of the vitamin B complex. It is now generally held that the liver has a very important rôle in the handling of thiamin. A few attempts have been made to determine whether or not normal storage of thiamin chloride obtains in persons who have cirrhosis; the results so far are not entirely conclusive but it does appear from the recent report of Robinson, Melnick and Field that patients with advanced hepatic injury have a low urinary output of thiamin and that they respond to a test dose of the material in a manner indicative of impairment of storage.

With pellagra, which represents a chronic form of deficiency of nicotinic acid, it is not uncommon for the urine to contain an abnormal concentration of porphyrin. There is a comparable large excretion of porphyrin after exposure to various hepatic and general poisons, notably alcohol.⁴ Porphyrinuria is common in hepatic disease and during episodes of hepatic insufficiency the amounts of porphyrin in the

urine may increase materially. This analogy with the state of affairs existing in the pellagrous subject suggests that a possible deficiency of nicotinic acid may enter into the production of certain symptoms of hepatic disease.

It should also be recalled that encephalopathic states have been seen associated with nutritional deficiencies which respond in a specific manner to the administration of nicotinic acid (Jolliffe). Various types of cerebral disturbances, of course, have been seen in both acute cases of pellagra and in acute cases of alcoholism. A somewhat similar type of disturbance of the central nervous system (coma hepaticum) may be seen in the course of hepatic cirrhosis; the condition is characterized by mental confusion progressing to deep stupor and muscular spasticity and evidences of cerebral irritation are associated features. At least three such patients in hepatic coma have been observed to respond in a striking manner to the continuous intravenous administration of glucose with large doses of thiamin chloride (100 to 150 mg.) and nicotinic acid (250 mg.). Whether such large doses are necessary is, of course, debatable but the results in the few cases studied have not been obtained from the therapy (glucose, oxygen) previously used. It may seem, at the moment, of little advantage to be able to revive a patient from hepatic coma and then be unable to prevent his death from some other form of hepatic insufficiency; however, patients have been known to survive one or more attacks of coma for long periods of time. One cannot, of course, draw conclusions from these isolated observations as to the effects of nicotinic acid and thiamin chloride but they are not entirely without significance.

There is one final reason to justify the use of the vitamin B complex and its various constituents for cirrhosis. Patients who have this disease derive an abnormally large proportion of calories from carbohydrate and therefore, presumably make unusual demands on the various enzyme systems which assist in the breakdown of glucose. Two of these enzymes (co-enzymes) which are active in the metabolism of glucose, are the phosphopyridine nucleotides, each of which contains a molecule of nicotinic acid. These are believed to be concerned with the metabolism of hexosephosphate. It has been established that this enzyme system is exhaustible; in fact, there is evidence to indicate that a high carbohydrate diet

will exaggerate a deficiency of nicotinic acid for this reason. Another stage of glucose metabolism which is affected by an analogous enzyme system is the breakdown of pyruvic acid. The co-enzyme in this reaction (cocarboxylase) is the pyrophosphate of thiamin. It has long been known that thiamin depletion is easily attained and that the process may be hastened by a pure carbohydrate intake (at least in some experimental animals). Finally, riboflavin enters into the composition of the Warburg-Christian respiratory enzymes which are active in cellular oxidation reactions. Thus, there are three enzyme systems dependent for their functional activities on constituents of the B complex. If storage of these various fractions of the vitamin B complex is reduced by hepatic disease and if the diet used in the treatment of the disease makes unusual, if indirect, demands on these fractions, it is logical to attempt to supply them in increasing amounts. In actual practice our attempts to apply this principle, especially to the care of patients who have acute hepatic damage and patients who have evidence of hepatic insufficiency in the postoperative state, have been productive of some encouraging results.

The Control of Hemorrhage from Esophageal Varices

One of the most feared complications in the course of chronic hepatic disease is the rupture of an esophageal varix. This accident is one of the leading causes of mortality in cases of atrophic cirrhosis and is all too frequently responsible for the death of a patient who may otherwise be making good progress. No entirely satisfactory means of dealing with these varicosities, which because of their situation are peculiarly vulnerable, has yet been devised. Omentopexy may possibly serve to divert some of the blood from these channels and thus reduce the chances of rupture; direct ligation of the coronary veins of the gastrohepatic omentum and even splenectomy have a similar and more direct chance of accomplishing a similar reduction in blood flow. The risk of the performance of all these procedures and the technical difficulties of the last two have militated against their general use.

For some time, the suggestion has been made that direct injection of these varices through the esophagoscope be considered but, until recently,

no successful procedure of this type has been reported. In 1939, Crafoord and Franckner of Stockholm reported the successful treatment of varices in this way and, more recently, H. J. Moersch has treated a patient in this manner. In the case which he described the varices were of such a size as to occlude almost completely the lumen of the gullet. After four injections of a 2.5 per cent solution of sodium morrhuate, the veins were greatly reduced in caliber and showed evidence of local thrombotic processes. The lumen of the esophagus had returned to almost normal caliber and the mucous membrane was distinctly less congested. It seems likely that treatment of this type may prove to be the most satisfactory method of controlling bleeding from the esophageal vessels.

The relationship between vitamin K and the hemorrhagic diathesis of hepatic disease is now well-known. The condition depends on a deficiency in prothrombin which in turn is not so much due to a lack of vitamin K as to a primary inability of the liver to form prothrombin even if adequate amounts of vitamin K are available. Prothrombin deficiencies have been produced experimentally by intoxication with chloroform and by partial hepatectomy. In the clinical field, analogous prothrombin deficiencies have been seen in cases of subacute and acute atrophy of the liver and in portal and biliary cirrhosis. Early attempts to manage such deficiencies in the same manner as had been found effective in cases of obstructive jaundice, that is, with vitamin K and bile salts, were found to be almost totally ineffective in some cases and only partially successful in others. This has also been the experience of other investigators.

With the introduction of the various naphthoquinone derivatives that exhibit vitamin K activity, it was hoped that this difficulty could be overcome and that, with the aid of these potent materials which could be administered parenterally, the prothrombin deficiency of primary hepatic disease could be corrected. This hope, however, has not been realized; even the use of the most active material employed to date (2-methyl-1, 4-naphthoquinone) has failed to control entirely the condition. This compound, and others of similar chemical composition, may, however, maintain the level of prothrombin at a point sufficiently high to prevent gross bleeding even in the presence of advanced hepatic injury.

The patient may thus be tided over a period of danger until time has been allowed for regeneration of hepatic cells. Bollman¹ has noted that a high carbohydrate intake enhances the protective effect of these quinone compounds to a considerable extent. The use of naphthoquinones along with every reasonable effort to expedite the process of liver regeneration may be expected to save a considerable number of patients from a fatal prothrombin deficiency. Failures are to be expected but at least partial control of the hemorrhagic state is now possible.

Summary

The experimental and clinical evidence cited indicate that the possibilities of survival or clinical cure in cases of primary chronic hepatic disease are not inconsiderable. One may suggest that the poor therapeutic results noted by earlier observers were due to the practice of limiting the diet, purging and administering diuretic remedies of various kinds. The scheme of treatment now advocated is based entirely on an attempt to secure optimal conditions of nutrition for the patient and to provide all vitamins in sufficient quantities to ensure adequate supplies for all enzymatic and cellular activities that are necessary to health. Until more is known of the specific requirements for the various "protective substances" in the presence of injury to the liver, such treatment will necessarily be on an empiric basis. The many studies on vitamin metabolism in respect to the liver which are being reported lead one to believe that there may be certain

specific features of hepatic disease which will respond favorably to certain known components of vitamins. Much further study will be required to establish the soundness of the present plan of therapy; in the meantime it may be offered on the basis of its comparatively favorable record and because no other therapeutic attack offers as good a prospect for success.

A PRELIMINARY SURVEY OF THE ANOPHELINE MOSQUITO FAUNA OF SOUTHEASTERN MINNESOTA AND ADJACENT WISCONSIN AREAS*

RICHARD H. DAGGY, OSWALD J. MUEGGE and WILLIAM A. RILEY

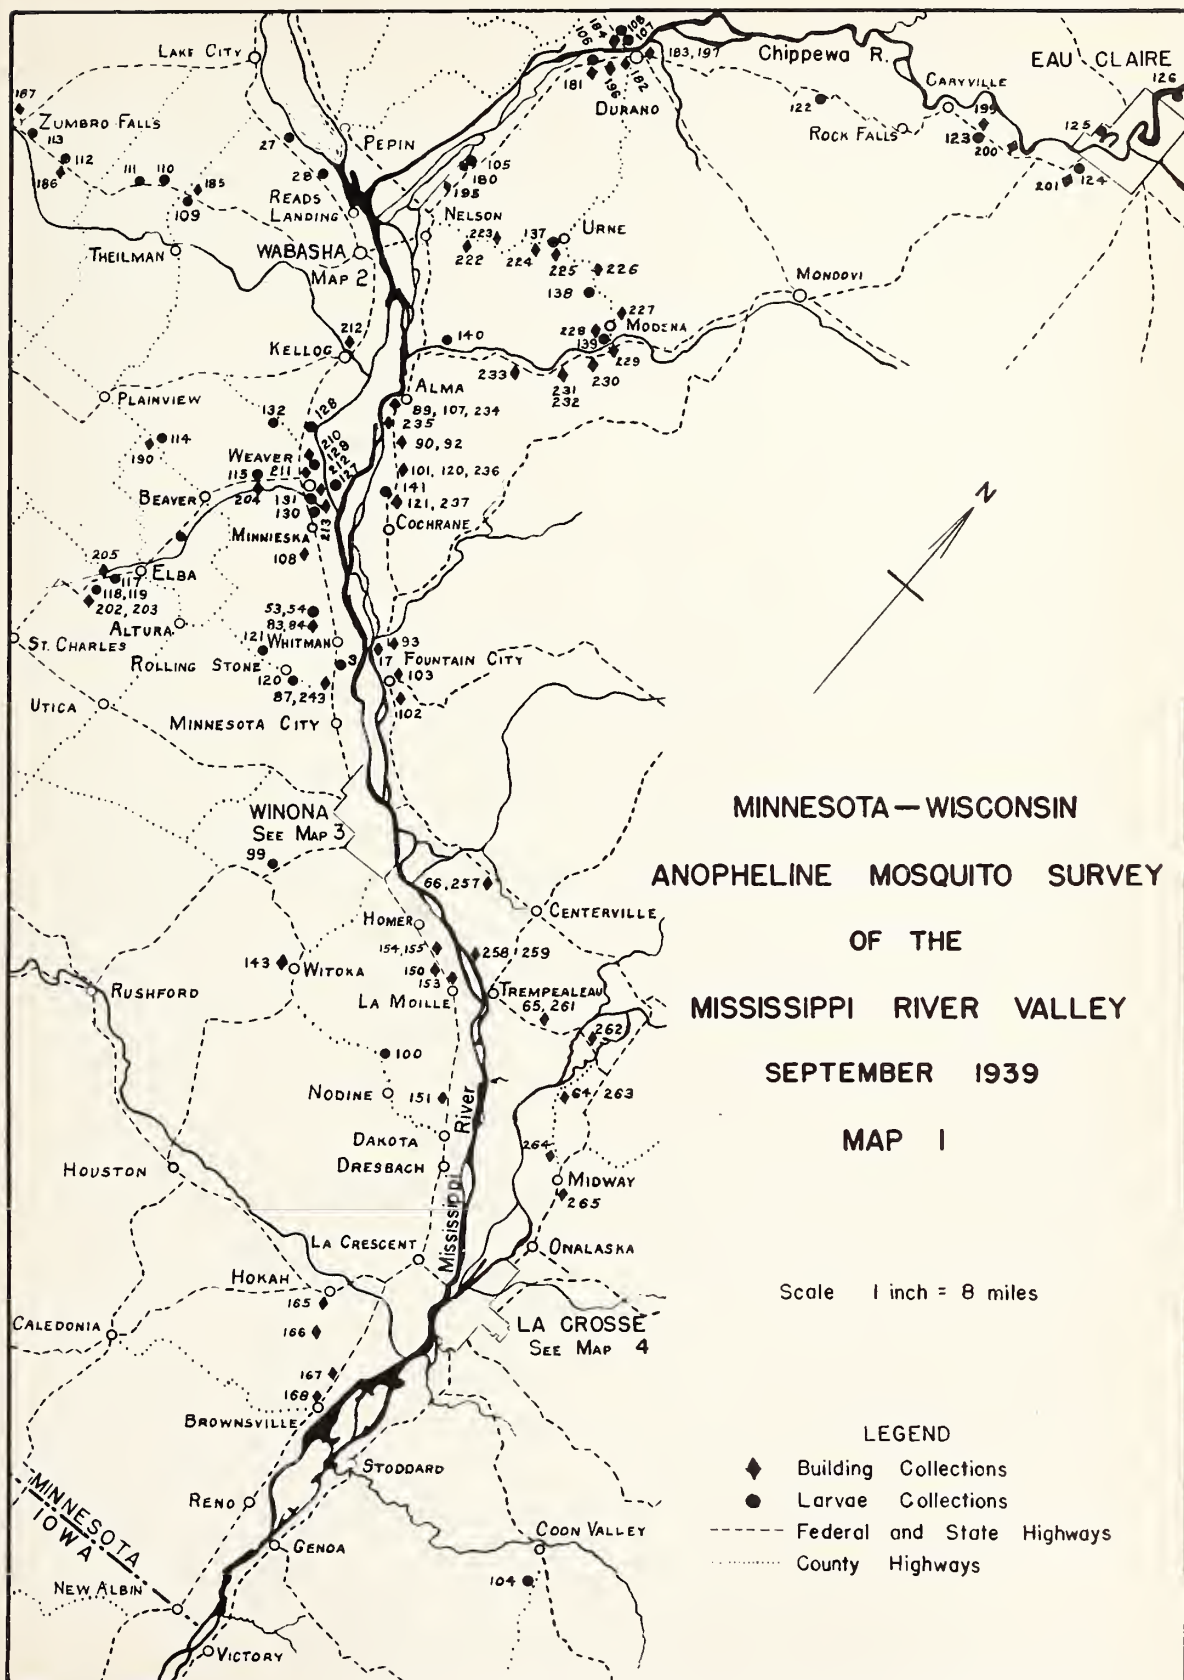

Saint Paul, Minnesota

DESPITE common belief that malaria does not occur in Minnesota and Wisconsin, it is well known to those in touch with the situation that locally acquired cases occasionally present themselves. There is current an impression that such cases are on the increase since the installation of the dams for improvement of navigation along the Mississippi River. The increasing

number of cases of the disease reported to the Minnesota and Wisconsin State Health Departments would seem to afford some evidence in support of this view.

In Minnesota there were reported for the three seasons 1935-1937, inclusive, a total of nineteen cases, of which seven were clearly indigenous and two others presumably so. In 1938 there were eight reported cases, of which three were indigenous. In 1939 there were recorded twenty-

*This paper embodies partial results of a coöperative study made with the aid of the U. S. Public Health Service, by the Minnesota and Wisconsin State Health Departments, covering the period August 25 to September 26, 1939.

two cases. Parallel conditions prevailed in Wisconsin where there was reported for the three seasons 1935-1937 a total of twenty cases, of which twelve were indigenous. In 1938 there were seven reported, of which five, occurring in cities bordering the Mississippi River, were indigenous. In 1939 the number of reported cases reached twenty-eight.

Associated in the work were Harold Peters, H. Laurence Burdick and Robert Dicke, without whose efficient aid the scope of the work would have been greatly restricted. Acknowledgements are also due Mr. Theodore Olson, Biologist of the Minnesota State Department of Health, who kept in close touch with the studies and who, as did Mr. Peters, made numerous photographs illustrating typical breeding places.

Four species of anophelines, each a potential malaria carrier, occur in Minnesota. These are *Anopheles maculipennis*, *A. punctipennis*, *A. quadrimaculatus*, and *A. walkeri*. Data regarding their incidence and distribution are few, as compared with those relating to other insects of economic importance. In view of the awakened interest in malaria, Dr. A. J. Chesley, Secretary and Executive Officer of the Minnesota State Board of Health, in August, 1939, suggested to Dr. C. A. Harper, State Health Officer of Wisconsin, that an intensive survey be made of the anopheline fauna along the Mississippi River, on both sides, from Wabasha, Minnesota, to La Crosse, Wisconsin. Late as the season was, it was evident that important data relative to the incidence and breeding habits of the various species might still be obtained.

The project and the necessary expenditures of federal funds were promptly approved and equipment assembled. On August 26 a general survey of the area under consideration (see map) was made to determine the most favorable location for the field laboratory. Ready access to a bridge, to boats, and to typical flooded areas on both sides of the Mississippi led to the selection of Wabasha, Minnesota, as headquarters for both the Minnesota and the Wisconsin field workers. A cabin adjacent to a considerable swampy area was available and intensive work was begun on August 27.

Methods of Work

In so far as the limited time permitted, four main lines of work, as follows, were carried out:

1. *Building collections* were made over as

many scattered localities in the area as was feasible. Regardless of species, mosquitoes resting in sheds, outdoor privies, bath houses, basements, and similar shelters, were collected by the use of an aspirator. Search was also made beneath bridges and culverts. The total collections were counted and the anophelines identified.

2. Collection of anophelines attacking the workers was carried out to only a limited degree.

3. *Light trap catches*, utilizing the available two and, for a part of the time, three of the well-known New Jersey electrically controlled mosquito traps, were made during the entire period of the survey.

4. *Larval collections* were particularly emphasized, with a view to determining the extent of favorable breeding places. To insure correct identifications the specimens were usually bred out.

The survey was most fortunate in securing, through the courtesy of the District Engineer, U. S. War Department, a set of the maps prepared in connection with the river improvement project. These consisted of key maps to the various regions in the valley as well as a number of detailed maps showing areas of marsh, open water, flood plain forest, streams, et cetera, on a large scale. Although various changes have occurred in the course of completion of the dams, the maps were invaluable aids for the field studies.

Records of temperature and other weather conditions were kept throughout the work. These and other details will be filed for future reference and additions.

September weather in Minnesota is very undependable and the group was fortunate in having a full month, August 27 to September 27, of practically uninterrupted field work. According to the Weather Bureau monthly summary the mean temperature for September was 69.1° F., a departure of +6.6°.

Collections from Buildings and Other Shelters

In the course of the work, mosquitoes were taken from many kinds of diurnal resting places. These included privies, basements, sheds, bath houses, bridges, culverts, cattle underpasses and other shelters. All resting mosquitoes, including the non-anophelines, were collected from as many different localities in the area, as time per-

mitted. Of the 12,321 specimens thus secured, 11,798, or 95.7 per cent, were anophelines.

As illustrative of the conditions in buildings, exclusive of other shelters, we may consider the results at Wabasha, where collections were made daily in the basement of the field laboratory and in each of three outdoor privies near the laboratory.

For the period August 27 to September 26, 1939, there were 4,853 mosquitoes collected from these four stations. Of the total, only 79, or 1.6 per cent, were non-anophelines.

There were 4,774 anophelines, or 98.4 per cent, of the total catch. These were distributed as follows:

<i>Anopheles quadrimaculatus</i>	4,500	94.4%
<i>A. punctipennis</i>	262	5.4%
<i>A. walkeri</i>	12	0.2%
<i>A. maculipennis</i>

The enormous preponderance of *A. quadrimaculatus* in building collections was clearly indicated from the outset but was quite at variance with such distribution records as were available in the entomological collections of the University of Minnesota. Such records indicated a probable greater incidence of *A. punctipennis* in southeastern Minnesota. As we shall see, this was due to the fact that most of the previous collections had been made at points not on the Mississippi.

Examination of the detailed report of collections shows that there was a daily influx of anophelines and particularly of *quadrimaculatus* into these buildings. Even though removed daily, large numbers were always present the following morning. Thus, on the morning of September 3, 243 specimens were captured in the basement, although it had been cleared carefully the day before. On September 16, 231 specimens of *quadrimaculatus* were collected from one of the privies.

The picture is essentially the same when the total collections of 11,191 mosquitoes from buildings and other resting places throughout the river valley area are considered. The anophelines constituted 95.9 per cent of the catch and of these *quadrimaculatus* represented 91.7 per cent.

A significant contrast is afforded by the collections made in the surrounding hills and valleys, outside of the river valley proper. In these localities, referred to in subsequent discussion as "inland," there were taken 1,130 adult specimens from resting places comparable to those searched

in the river valley. Again the anophelines were dominant, being represented by 1,070 specimens, or 94.7 per cent. The distribution of species was strikingly different from that found in the river valley. *Punctipennis* led with 917 specimens, or 85.7 per cent, while *quadrimaculatus* was represented by only 151, or 14.1 per cent, as compared with the total of 94.7 per cent found in the river valley collections from similar shelters. *A. walkeri* and *A. maculipennis* were represented by a single specimen each.

These findings agree with previous records indicating that *punctipennis* is the most common widely distributed anopheline in southern Minnesota. It breeds by preference in spring-fed streams and pools among the hills of this region, a fact which is in agreement with the known habits of the species.

While there is ample evidence to support the view that *quadrimaculatus* is the chief carrier of malaria in the southern United States, there should be further investigation before it is concluded that it plays an equally important rôle in Minnesota. As bearing on this question it should be noted that most of the dwelling houses in the area are well screened and that *walkeri*, also an efficient carrier, readily attacks man in the open, even in mid-day, in bright sunlight.

Anophelines Caught While Attacking

Throughout the survey specimens of anophelines feeding on man in the open were collected. Unfortunately time did not permit extensive collecting of this type and the following data represent occasional catches during the course of other work. On three occasions a definite attempt was made to obtain feeding records.

Of the total catch of 134 mosquitoes *quadrimaculatus* supplied sixteen, or 11.9 per cent. *A. walkeri* was represented by 114, or 85.1 per cent, *punctipennis* by four, or 3 per cent, and no specimens of *maculipennis* were so taken.

Of the 114 *walkeri*, fifty-five were collected when a definite effort was made to obtain feeding records. These collections were made on three successive days.

Obviously the data on feeding habits are so meager as to be merely suggestive. However, the preponderance of *walkeri* was also noted in similar catches of feeding mosquitoes made by William Chalgren, in 1938, in the Minneapolis-St. Paul area. Of 4,166 specimens, representing

ANOPHELINE MOSQUITO—DAGGY, MUEGGE AND RILEY

TABLE I. SUMMARY OF LIGHT TRAP CATCHES AT WABASHA, MINNESOTA

August 26-September 25, 1939

	LIGHT TRAP A		LIGHT TRAP C		LIGHT TRAPS A AND C	
<i>Anopheles quadrimaculatus</i>	632	18.2%	1,061	74.4%	1,693	34.5%
<i>Anopheles punctipennis</i>	493	14.1%	130	9.1%	623	12.7%
<i>Anopheles walkeri</i>	2,357	67.7%	234	16.4%	2,591	52.8%
<i>Anopheles maculipennis</i>	1	..	1	..
Total Anophelines	3,482	100.0%	1,426	100.0%	4,908	100.0%
Total Anophelines	3,482	22.0%	1,426	21.3%	4,908	28.1%
Total Non-Anophelines	12,322	78.0%	5,272	78.7%	17,594	71.9%
	15,804	100.0%	6,698	100.0%	22,502	100.0%

twenty-one species, *walkeri* was the only anopheline, and of it forty-seven specimens were taken. The relative frequency with which it occurred in trap catches also indicates that it may be more important than ordinarily has been considered.

Light Trap Catches

Three electrically controlled mosquito traps of the New Jersey type, which has become standard for mosquito survey work, were available and two of them were in use for the entire period, at Wabasha. The third was operated for a five-day period at La Crosse, Wisconsin.

Of those in use at Wabasha, trap "A" was suspended in an apple tree close to the laboratory, on a ridge overlooking an extensive mosquito-breeding swamp (Fig. 1). Trap "C" was located in a back yard in the residential district known as West Wabasha.

From trap "A" 15,804 mosquitoes were taken during the period August 26 to September 24 (Table I). Of these 3,482, or 22 per cent, were anophelines, the percentage in the daily catches ranging from four on August 29, to a high of 51.4 on September 18.

The total daily catch as well as the percentage of anophelines varied. On two occasions, no mosquitoes were collected. This occurred on September 23 and again on September 25, when the light trap studies were concluded because of cold weather.

The largest single catch occurred on the night of September 15 when 2,264 mosquitoes were collected. Of these, 740, or 30.6 per cent, were anophelines. This record catch was made at the hottest period of the survey, a situation noted by other workers using light traps in sampling mosquito populations in other regions. Examination of the humidity records did not show any definite effects due to variations in this factor.

When one considers the distribution of the species captured by trap "A," he is immediately struck by the preponderance of *walkeri*, which is generally referred to in literature as an uncommon species. In the course of the month during which this trap was operated, 2,357 specimens of *walkeri*, or 67.7 per cent of the total anophelines, were taken as contrasted with 632, or 18.2 per cent of *quadrimaculatus*. It is the more striking in view of the fact that the trap was hung in the location where such large collections of *quadrimaculatus* were made in buildings. That it was not due to failure of the traps to attract the latter is evident when it is noted that the condition was almost completely reversed with trap "C," where 74.4 per cent were *quadrimaculatus* and only 16.4 per cent were *walkeri*. When the catches of the two traps are combined it is seen that a little over half of the anophelines were *walkeri*, around one-third *quadrimaculatus* and an eighth *punctipennis*.

Trap "C," instead of hanging in the open, near the edge of an extensive breeding place, as was trap "A," was in a yard with crowded shrubbery, in a residential district. The total number of mosquitoes caught here during the season was 6,698 compared with 15,804 at "A." It is interesting to find that the percentages of anophelines were almost identical—22 for trap "A" and 21.3 for "C."

In the absence of more complete data it is difficult to explain these differences in the catches from the two traps, located only two miles apart. They were identical in construction and light bulbs of the same intensity were used. Breeding conditions for anophelines were more favorable in the surroundings of trap "A," but also existed more remotely within range of "C." That *quadrimaculatus* was present in abundance in the former locality is shown by the fact that 4,500 speci-

mens were collected from the basement and the three outbuildings routinely inspected. Unfortunately only meager indoor collections were made in the region of "C" and hence comparisons between the two areas in this respect are not possible.

The discrepancies in the performance of the two traps serve to emphasize a fact well-known to workers accustomed to their use—it is not safe to rely on one or two traps to give a true picture of the mosquito fauna of a region. Care must be taken to select different significant locations or carefully to select comparable areas if information concerning their relative breeding is sought.

While more extensive collections from buildings might have cleared up the discrepancies in the data relative to catches of *quadrifasciatus*, there remains the more puzzling question as to the reason for the great numbers of *walkeri* taken with trap "A" as compared with those from "C." Earlier studies had convinced us that the species is common in Minnesota and that it feeds readily in the open, at any time of day.

That *walkeri* is not a household mosquito is indicated by the fact that only twelve specimens were included in the routine collections from buildings at Wabasha. It seems probable that it does not penetrate into residential districts as readily as does *quadrifasciatus* or is more restricted in its flight from breeding places. However, the fact that *walkeri* may overwinter in the egg stage (Matheson and Hurlbut, 1937; Hurlbut, 1938) might account for its being less attracted to houses during the period covered by this survey.

Light trap collections in the Minneapolis-St. Paul area as well as our experience with trap "A" suggest that *walkeri* may more readily be attracted to lights than are the other anophelines in this region. Johnson (1936) found that from 15 to 50 per cent of the anophelines caught by a light trap at Reelfoot Lake, Tennessee, were of this species, although it was very scarce in collections from buildings and in the larval surveys.

It is evident that further studies of the biology, distribution, and incidence of *A. walkeri* are highly desirable, particularly since it is known to be capable of transmitting both *Plasmodium vivax* (experiments of Matheson, Boyd and Stratman-Thomas, 1933) and *Plasmodium falciparum* (experiments of Kitchen and Bradley, 1936). Recently Bang, Quinley and Simpson,

1940, reported finding a wild-caught specimen harboring malarial parasites. The salivary glands were heavily infected and six oöcysts were found on the stomach.

Fig. 1. (above) Trap "A" and a portion of the extensive swampy area below the laboratory at Wabasha, Minnesota. Photo by Harold Peters.

Fig. 2. (below) Backwater area with algal mats in which anophelines were breeding in numbers, near the field laboratory. Photo by Harold Peters.

The above-discussed light trap data relate to conditions at Wabasha, Minnesota, where the two traps were run throughout the entire period, August 26 to September 25. A third trap of the same type was operated at La Crosse, Wisconsin, for the five-day period September 12 to 16, during which larval surveys and building collections were being made in the vicinity. The trap was located on the edge of the main channel of the Mississippi river, on La Plume Island. A total of 1,751 mosquitoes was collected here—less than that of either of the Wabasha traps for the same period. Of this total, *walkeri* was by far the most abundant anopheline, constituting 84.7 per cent of the 483 taken, while *quadrifasciatus* made up 15.1 per cent. A single specimen of *punctipennis* was included in the catch.

For purposes of comparison the catches of the La Crosse and the two Wabasha traps for the same five-day period are given in Table II. Since the La Crosse trap was in a position somewhat similar to that of trap "A" at Wabasha, the

TABLE II. A COMPARISON OF THE LIGHT TRAP CATCHES AT LA CROSSE AND AT WABASHA FOR THE FIVE-DAY PERIOD SEPTEMBER 12-16, 1939

	LA CROSSE		LIGHT TRAP A		LIGHT TRAP C	
			(Wabasha)		(Wabasha)	
<i>Anopheles quadrimaculatus</i>	73	15.1%	290	16.6%	478	75.8%
<i>Anopheles punctipennis</i>	1	.2%	249	14.3%	43	6.8%
<i>Anopheles walkeri</i>	409	84.7%	1,206	69.1%	110	17.4%
<i>Anopheles maculipennis</i>
Total Anophelines	483	100.0%	1,745	100.0%	631	100.0%
Total Anophelines	483	27.6%	1,745	35.4%	631	26.6%
Total Non-Anophelines	1,268	72.4%	3,191	64.6%	1,740	73.4%
	1,751	100.0%	4,936	100.0%	2,371	100.0%

catches of the two might be expected to be very comparable. The percentages of *quadrimaculatus* were almost identical. *Punctipennis*, with its single representative, was practically lacking in the La Crosse catch, while *walkeri* was even more predominant than at Wabasha, Trap "A."

In view of this close agreement it is apparent that the anopheline populations at the two extremes of the surveyed area are very much alike. It is believed from these and supplementary studies that the entire valley between these points would yield similar results if the mosquito populations were similarly sampled.

Larval Survey

Most of the actual time for the month of the survey was spent in the field locating important anopheline breeding places. The surveys were more or less centered at Wabasha, Reads Landing, Winona, and La Crosse, which, as seen by the map, afforded typical conditions for the river valley. Some collections were made at additional points of interest and two days were devoted to inland surveys, away from the valley proper.

A total of 102 collections of anopheline larvæ were made in the river valley, the larvæ being taken to the laboratory and usually reared. No mosquitoes were reared from thirteen of the collections, in most of which the anophelines were not abundant and such as were present were in early instars. For the other eighty-nine collections, adults in numbers were recovered. Detailed records were kept as to the stations studied, the typical vegetation, the amount of shade or exposure, presence of fish and other significant data. These and the field notes are on file and will serve as a basis for more extended work in the future.

The anopheline larvæ were generally found in clean, quiet waters with abundant vegetation.

Sloughs, sluggish streams, impounded waters behind wing dams and similar situations all through the surveyed area were favored breeding places. Dense tangled thickets of submerged *Ceratophyllum*, *Myriophyllum* and occasionally of *Potamogeton* with algal mats of *Spirogyra* and, more often, of *Hydrodictyon* (Fig. 2) were particularly favored by *quadrimaculatus* and *punctipennis*. Scattered over these areas there were often the duckweeds *Lemna* and *Wolffia*, but when they were present to the extent of thick, almost solid, layers, the larvæ were not present in numbers. As was to be expected, situations where vegetation was not abundant, and the water was deeper, and accessible to fish, yielded few anopheline larvæ.

All four species were obtained in these larval collections. Of a total of 948 reared, 544, or 57.4 per cent were *quadrimaculatus*. Second was *punctipennis* with a total of 366 reared adults, or 38.6 per cent. *Walkeri* was represented by only thirty-seven reared adults, or 3.9 per cent and *maculipennis* by a single one.

From these data, obviously very meager and based on restricted seasonal collecting, it would appear that *quadrimaculatus* and *punctipennis* are the most common two anophelines breeding in the sloughs and impounded waters in the valley. Of the eighty-nine larval collections, thirty-four yielded adults of both species, while twenty yielded only *punctipennis* and twenty-two *quadrimaculatus*. It should be pointed out that only one or two adults were reared from many of these latter samples.

How this condition compares with what existed before the installation of the dams cannot accurately be determined. The whole area was swampy and subject to overflow, affording many favorable breeding places for breeding of *quadrimaculatus* especially. However, much of the

swamp was covered by trees which were removed in the course of the river improvement program and this exposure to light rendered it more attractive to the anophelines. It is highly probable that there is greatly increased breeding by *quadrimaculatus* in the river valley.

Relative to *walkeri* there are a number of puzzling questions which can be answered only by further detailed studies. As we have seen, it was by a very wide margin the dominant species taken in light trap "A" and at La Crosse, both of which were located near marshy breeding areas and not in residential districts as was trap "C." It was also the species most frequently taken while attacking man. Why was it represented only to the extent of 3.9 per cent in the larval collections?

The most obvious answer to this question would appear to be that the particular breeding places favored by *walkeri* were overlooked in the larval survey. This may be the case although the larval survey was most intense in the Wabasha area and particularly in the area from which trap "A" attracted mosquitoes. It seems improbable that any important concentrated breeding area of *walkeri* would be overlooked, especially when all types were being examined here from the beginning of the survey. Another possibility is that the favorable breeding period for *walkeri* had passed before the survey began. Of this we have no evidence, beyond indications, that the species overwinters in the egg stage in the North, in which case the summer broods would have already completed their development and no larvæ would be hatching.

Such limited data as are at present available suggest that *walkeri* favors flooded grassy areas in shallow water for breeding. These areas were on some occasions cut grass, but probably included sedges and rushes as well. In most cases these stations were rated as poor because larvæ were not abundant. However, these grassy areas do cover large extents of bottom land and even though *walkeri* larvæ are sparsely scattered over them, the total emergence might be very great.

If this proves to be the breeding habit of *walkeri*, it affords one explanation of the species being obtained so infrequently in the larval survey. With the time strictly limited, the area to be examined very extensive, and the possibility of weather conditions limiting the survey, each collecting stop was brief and if no larvæ, or a very few, were found, the collectors moved on to an-

other station. This resulted in emphasis on areas where larvæ were concentrated. Thus, if *walkeri* does not breed in concentrated areas as do *quadrimaculatus* and *punctipennis*, it would very likely be missed.

This may also account for difficulties others have experienced in locating the breeding places of the species. Bradley and McNeel (1935) in Florida and Johnson (1936) in Tennessee, found *walkeri* readily attracted to light traps but also had great difficulty in locating breeding places. Johnson reared only one adult from all nearby breeding places, while Bradley collected only eight larvæ.

In order to learn how extensively the four species of anophelines occurred elsewhere in the general region, two days were spent in a survey away from the river valley. The topography of these areas of southeastern Minnesota and corresponding sections of Wisconsin is rough and hilly. Much of it is unglaciated and hence drainage is well developed, with no ponds, lakes, or marshes to serve as mosquito breeding places. The only favorable places are springs, spring pools, seepage pools and small clear streams. In all of these locations larvæ were found in numbers.

By far the dominant species in the whole range of differing habitats was *A. punctipennis*, which constituted 98.8 per cent of all the anophelines reared from these inland collections. The remaining 1.2 per cent consisted of thirteen *quadrimaculatus*. The latter were all reared from static water while *punctipennis* alone was found in all the streams and springs examined. The streams were usually rather small, clean, with sand bottoms and a marginal fringe of green filamentous algæ. In this fringe *punctipennis* larvæ were always found, in numbers. Many were observed on the very edge of the algal margins, moving back and forth in the currents. On many occasions the larvæ were so numerous that they could easily be collected in a teaspoon. In a number of places, twelve to fifteen could be obtained in a single teaspoonful.

Summary

In considering the results of this preliminary survey, it should again be emphasized that it covered a period of only one month, beginning the 26th of August, 1939. The weather conditions were unusually favorable, the mean temperature for the month being 69.1, which was 6.6° F.

above the average. It did not fall below the freezing point during the month—a very unusual circumstance.

Under these conditions it is probable that the anopheline populations were at their peak. The situation is complicated, too, by the fact that the hibernation periods for the various species were approaching. No data were available regarding the early mid-season conditions.

The findings for the period of the survey, August 26 to September 25, may be summarized as follows:

1. Anopheline mosquitoes were found to be much more abundant in the Mississippi river valley, from Wabasha, Minnesota, to La Crosse, Wisconsin, than had previously been supposed.

2. Four species of anophelines already reported for Minnesota were found: *quadrimaculatus*, *walkeri*, *punctipennis*, and *maculipennis*. *Maculipennis*, which occurs commonly in northern Minnesota, was so rare as to indicate that it is of no significance in the survey area.

3. On the basis of building collections alone, where it constituted 91.7 per cent of the anopheline catch, *quadrimaculatus* would appear to be the most common species in the valley proper, while *punctipennis* with its 85.7 per cent was the most abundant inland. *Walker*i was almost absent in these collections, although there is reason to believe that it may be the most common of the four.

4. In light trap collections in the residential district of Wabasha *quadrimaculatus* was present to the extent of 74.4 per cent while in the catches by traps located near extensive swamp areas at both Wabasha and La Crosse *walkeri* made up 67.7 per cent and 84.7 per cent, respectively, of the total anophelines.

5. In the small collection of anophelines attacking man in the open, *walkeri* was the dominant species. This is in agreement with observa-

tions elsewhere in Minnesota, and emphasizes the need for detailed studies on the biology of the species.

6. Anophelines were breeding abundantly throughout the valley in the extensive sloughs and backwaters. Larval collections yielded 57.4 per cent *quadrimaculatus* and 38.6 per cent *punctipennis* in these situations. Such evidence as is available indicates that *walkeri* oviposition is less concentrated but that it occurs in submerged grassy areas which are extensive in the region. An alternative is that the favorable season for larval development of the species had passed.

7. Data from collections from buildings, from light traps, hand catches, and larval collections revealed a surprisingly high incidence of anophelines, with *quadrimaculatus* and *walkeri* the dominant species. While there are no data relative to the abundance of these species prior to installation of the flood control dams, there is evidence that there has been a marked increase in favorable breeding places in the river valley for *quadrimaculatus* and apparently for *walkeri*, as well.

8. In the inland, in contrast to conditions in the river valley proper, *punctipennis* was the only anopheline found breeding in numbers. It constituted 98.8 per cent of the specimens reared from the inland collections.

SCHIZOPHRENIA IN CHILDHOOD*

ROYAL C. GRAY, M.D., Ph.D.

Minneapolis, Minnesota

IN 1863 Kahlbaum isolated the mental disorder hebephrenia and in 1869 catatonia. Kraepelin, in 1896, united these two and the paranoid types into his concept dementia præcox and differentiated it from manic-depressive psychosis. As the disease does not always progress to dementia or appear precociously, at or soon after puberty, in 1911 Bleuler proposed the more accurately descriptive name schizophrenia. He considered a splitting and dissociation of the personality to be the fundamental symptom of the disease. Freud postulated that schizophrenia represents a fixation at the auto-erotic stage of development and is a narcissistic regression psychosis. Meyer regards schizophrenia as the reaction of a maladapted individual whose principal fault is a persistent misapplication of his instincts. Campbell² has defined the disorder as follows: "The schizophrenic type of reaction seems to be characterized by diminished interest in, and adaptation to, the work-a-day world, increased interest in subjective creations or phantasies which are emancipated from the control of ordinary logical or scientific thought, the frequent occurrence of hallucinations, odd and fragmentary behavior and utterances of little adaptive value in relation to the present situation."

The nervous system in the child is physiologically immature. His intellectual development and life experiences are comparatively limited. Therefore, Potter⁹ states, children are essentially beings of feeling and behavior. Their language is restricted and hence they cannot fully verbalize their feelings. Consequently their psychopathology is expressed largely through distorted affective responses and altered behavior reactions.

All normal children live in their phantasies to a greater or lesser degree and the schizophrenic reaction is often likened particularly to the child at play. But according to Creak⁴ these phantasies and vivid imaginations, ritualistic play, emotional instability, and other similar immature thought and conduct may be distin-

guished from a psychosis in the making by the early age of the patient, the temporary nature of the activity, and the fact that it may be understood. Manic-depressive psychosis in children is very rare indeed, arises only close to the time of puberty, and in the long run generally proves to be a schizophrenic reaction.

Cleland³ maintains that the different types of schizophrenia have characteristic conduct disorders in childhood. Listless, lazy, tired-out attitude toward life presages the simple or hebephrenic type. Incoherent conduct and much activity without accomplishing anything foretells the catatonic type. But both prototypes may be characterized by irritability, periods of excitement and depression, mannerisms, and conduct peculiarities. Lutz⁸ describes two types of schizophrenia in children, one slowly progressive without marked remissions and the other type often with catatonia, of rather sudden onset, and with definite exacerbations. However, any of these symptoms may be found in a normal child and differentiation of the various types of schizophrenia in children is practically impossible.

The schizophrenic is the odd, queer, or different child in the family and one is unable to really contact him. Richmond¹⁰ says that in comparison the psychopathic child has some semblance of rapport and, furthermore, is cunning and possesses self-defensive instincts. He impresses one as capable if he would only apply himself whereas the schizophrenic impresses one as dull or defective. However, apparent dullness in a psychotic child is probably inattention due to his preoccupation rather than lack of comprehension.

The schizophrenic child may be differentiated from the mental defective by the fact that in the defective walking, and especially talking, motor coördination, and all learned reactions are greatly delayed. Consequently the psychotic child is likely to show some initiative even in devising varieties of his abnormal behavior. Finally, an intelligence test may provide a differential diagnosis between schizophrenia and mental deficiency. Lay⁶ summarizes the differences as fol-

*From the Division of Nervous and Mental Diseases, University of Minnesota Medical School.

lows. In schizophrenia the patient shows scattering of responses through several age levels, does better on verbal than performance tests, does not react to urging or praise, improves on retest, and his intelligence quotient will not be noticeably low. In mental deficiency all these points are the reverse.

Schizophrenia is a psychosis of psychogenic origin without clearly defined tangible cause or structural change. Schilder¹¹ aptly emphasizes that pictures which resemble schizophrenia in childhood are very often schizoid reactions to organic processes or defects of the brain. Dementia precocissima and dementia infantilis, referred to in the foreign literature as forms of schizophrenia, really are not schizophrenia at all but primarily organic processes. Similarly, propf-schizophrenia is not a functional entity but rather is a schizoid reaction appearing in and incident to an oligophrenia.

The principal definite etiological factors in 151 cases of schizophrenia studied by Bowman and Kasanin¹ were environmental stress in 81 per cent and heredity in 64 per cent. It would seem that heredity does not predispose to any one type of psychosis but rather to an early mental breakdown. A primary psychic factor, a predisposition, may be the basis for mental disease; Jung termed an individual so conditioned to developing schizophrenia an introvert.

Schizophrenia constitutes about 25 per cent of all the psychoses. The number reported in childhood before the physical appearance of puberty is very small. The ages of those cases reported range from 3 to 16 years. Bleuler took 15 years as the dividing line and said 4 per cent of his cases had symptoms of schizophrenia before that age. Kraepelin, in 1913, reported a series of 1,054 dementia præcox patients of whom 3.5 per cent developed symptoms before ten years of age.

In about 6,000 admissions to the Boston Psychopathic Hospital from 1923 to 1925, Kasanin and Kaufman⁵ reported that sixty-five under sixteen years of age were psychotics, of whom six were typically schizophrenic. Lurie et al⁷ studied 1,000 children, ages eight to sixteen years, at the Cincinnati Child Guidance Home. These children were sent to the Home not because they appeared insane but because of failure to adjust either in their home, school, or community. Nineteen of these 1,000 children

had a definite functional psychosis; thirteen of the nineteen were schizophrenic.

In 1,265 admissions of children under sixteen years of age to Maudsley Hospital, London, from 1935 to 1937, Creak⁴ diagnosed thirty-five as functional psychosis. The author felt that practically without exception such a psychosis in childhood is schizophrenia and therefore did not subdivide these thirty-five cases.

In 5,000 consecutive admissions to the Pennsylvania Hospital Strecker¹³ found eighteen functional psychotics under fifteen years of age. Of these, four were diagnosed schizophrenia, four doubtful, and ten manic-depressive psychosis.

In 32,443 hospital admissions in Munich from 1904 to 1922 Seelig¹² found 753 psychotics under fifteen years of age of whom forty-seven had been diagnosed schizophrenia. He questioned this incidence of schizophrenia and compiled the data in 23,935 admissions in Munich from 1922 to 1931 wherein he determined there were 480 psychotics under fifteen years of age of whom only four were schizophrenic. He also noted that during the same years of 27,377 admissions in Cologne 1,497 were psychotics under fifteen years of age but only three of these were schizophrenic.

During the ten year period from 1929 to 1939 there were 18,976 patients admitted to the three largest State Hospitals for the insane in Minnesota. Thirty-eight of these patients were under fifteen years of age and of this number eleven were diagnosed schizophrenia. The remainder had psychoses with mental deficiency, with epilepsy, with psychopathic personality, or with chronic encephalitis. Table I is a recapitulation of the incidence of childhood schizophrenia reported by various authors.

The prognosis in childhood schizophrenia is definitely unfavorable although not altogether hopeless. Kasanin and Kaufman⁵ reported three of their six childhood schizophrenic patients continued in the hospital. In Creak's⁴ series of thirty-five psychotic children, presumably all schizophrenic, twenty-six were traced, of whom fourteen improved and twelve remained ill. Potter⁹ studied six schizophrenics, four to twelve years of age, all of whom showed symptoms before the age of ten. No one of the six had any improvement after periods of hospitalization of three to eighteen months.

All of the eleven schizophrenic children ad-

mitted to the Minnesota State Hospitals from 1929 to 1939 were traced. Four of these patients remain hospitalized after periods ranging from three to seven years. Table II is a recapitulation of the prognosis of childhood schizophrenia reported by various authors. It indicates that recovery is very rare and that over 50 per cent of these patients remain unimproved.

Table III has further data concerning these eleven Minnesota State Hospital patients. In this series the ratio of childhood schizophrenia in boys and girls is about 1 to 2, which agrees with previous observations. The types of the psychosis were distributed as follows: hebephrenic seven, catatonic two, and paranoid two. The only patient who recovered was one with the hebephrenic type. Of the remaining six hebephrenic patients, three improved and two are unimproved. One of this group (Case 6) was unimproved at the time of her death from bulbar palsy and progressive muscular atrophy. This organic neurologic disorder, which is most unusual in childhood, appeared about one year after her commitment to the state hospital. It indicates a marked abiotrophy of the nervous system and suggests that schizophrenia and other functional psychoses perhaps in the final analysis may be structural in nature. Of the catatonic and paranoid patients one improved and one remains unimproved in each of these two types. One patient, a catatonic (Case 8), had two hospital

admissions, each of three months, with improvement in each instance. The other four patients who improved and the one who recovered were discharged from the hospital and have continued acceptably adjusted or well after periods ranging from two to seven years.

Schizophrenia in childhood is a rare and interesting mental disorder. Therefore the following report is presented concerning a patient affected with schizophrenia from nine years of age to his present age of twenty-four years.

Case Report

In September, 1930, M. M., a fourteen-year-old boy, was admitted to the University Hospital at the request of his paternal grandfather. His mother was residing in Colorado, and the whereabouts of his father was unknown. The history which the grandfather was able to furnish was very sketchy. The principal informant was the boarding mother, a trained nurse, with whom the patient had been living much of the preceding five years.

The father's age was forty years, the mother's thirty-two. Her health was good. The patient was an only child. His parents were divorced when he was about six years of age. Thereafter for two years he was in an orphanage, for one year with his mother, and then, in 1925, was placed in the informant's home.

The boarding mother said when the patient first came to live with her he would sneak about and appeared to be afraid. He was a peculiar and imaginative child. He would have frequent temper tantrums. He had piano lessons for three years and made very good progress. He was honest and trustworthy in all respects. He was always neat and polite. He was a member of a local Boy Scout troop, but never seemed to get into the spirit of the organization. He was

unduly sensitive and did not want to play with his schoolmates because they teased him for being timid.

After school hours he would stay in the house reading or writing poems, the subject matter of which frequently was in reference to religion or to a boy without a home. It was difficult to draw him into conversation, and one practically had to ask him a question in order to get him to say anything. In answering he would never talk directly to one but would turn away and look out of the window or he would stare into space for a while before replying.

A year previous to his hospital admission he spent one week with his father. He ran away from his father, returned to the informant's home, and said he had been mistreated. For three months previous to his hospital admission he had been living with his grandfather, who, according to the informant, was an overly religious individual.

The boy had completed the seventh grade in public school. His sixth grade teacher said he was peculiar in many ways and subject to a violent temper. Once when she reprimanded him he became very angry and shouted for a gun to shoot her. He was a superior student, especially in arithmetic and reading. In written work he was somewhat slow but very thorough. His seventh grade teacher said he did passing work in all his subjects, but was inclined to be a dreamer. He never seemed interested in playing with the other children unless he was in the right mood. He was slow in working with his hands. He excelled in writing original stories as he had an unusual imagination. The following poems, taken from his composition book, clearly show his trend of thought.

My Mother

I walk upon the rocky shore
Her strength is in the ocean's roar
I glance into the shaded pool
Her mind is there so calm and cool.
I hear sweet rippling of the sea
Naught but her laughter 'tis to me.
I gaze into the starry skies
And there I see her wondrous eyes.
I look into my inmost mind
And here her inspiration find.
In all I am and hear and see
My precious mother is with me.

Sweet Death

When at last your tired eyes close
No more to witness earthly woes
No more your struggle against cruel life
Which is only filled with tears and strife.

As far as could be learned the family and personal histories were negative. The boy said for six weeks he had been disturbed about his past evil acts and his present bad thoughts. He said he had heterosexual experiences when he was nine or ten years of age, his nerves were now hurting him, and he had funny ideas. He complained of weakness, headache, indistinct vision, heartburn, generalized gastric discomfort after eating, and tingling in his hands and feet. He said he had trouble in breathing, that he breathed too much with his stomach and not enough with his chest. He could not sleep well and was disturbed by distressing dreams.

The general physical and neurologic examinations and the routine laboratory tests all were negative.

His attitude and general behavior were variable.

Some days he was quiet and well mannered and helped with various chores around the wards. Often he had outbursts of unusual activity such as violently rocking forth and back in his chair or pacing excitably about the room pushing chairs from place to place. He would shout about God and the devil and talk disconnectedly frequently about snakes. At times he would strike the wall and beat himself. He would throw whatever might be at hand and mechanical restraints were sometimes necessary.

Other days he appeared depressed, cried considerably, and remained in bed. He said he did not want morning to come because it would be just another day. Sometimes he walked with a peculiar limp. He had spells wherein he seemed to have considerable difficulty in breathing.

He talked much about religion, the end of the world, and politics, and lectured to fellow patients on these subjects. Sometimes he went from patient to patient telling them they only imagined they were sick.

Most of the time he was uncommunicative, stared fixedly and without expression at some object, and appeared to be out of contact with his surroundings. There was commonly a long pause before he had any answer; whatever reply he made was disconnected and contained pronouns without antecedents. Sometimes he read in a loud voice from a book, usually starting at the back of the book. He said that no one understood him and everyone was talking about him. Then he would say he was disgusted with the Bible—"It's no good, I'd sooner play cards." He would mutter under his breath, repeat words and phrases several times, slam doors, and say he was going to kill himself by taking poison or jumping out of the window.

Some days he carried an apparently useless article, such as a roll of newspaper, around with him. He would snatch at space and say he saw little white things. He developed periods of silly laughter. He was suspicious of black-haired persons and said their purposes could not be defeated. He would put his bathrobe on backwards, did not understand how to put on his bedroom slippers, and stumbled awkwardly as he walked. He continually heard people say he was not a real boy. He often spoke of the sound of rain falling out of doors.

As time passed he became disoriented, his memory for remote and recent events poor, and his retention and recall lost. His grasp of general information became progressively more inaccurate. His insight and judgment failed.

He became very noisy, incontinent, and would not eat. He finally became so difficult to manage that he was transferred to the State Hospital in December, 1930.

The symptomatology in this case of autistic thinking, preoccupation, negativism with no basic mood disturbance, episodes of excitement, bizarre behavior, and mental regression warranted a diagnosis of schizophrenia, hebephrenic type.

The patient was unsuccessfully paroled from the State Hospital to his grandfather from May to August, 1931. In August, 1932, he was again paroled, this time

to his mother. He ran away from her home, was apprehended in Pennsylvania, and returned to the hospital in January, 1933. He eloped from the hospital in April, 1935, and was subsequently paroled to his mother in June, 1935. During a part of the next two years he was employed and rather interested in his work. However, disabling symptoms of the psychosis reappeared and in September, 1937, he was returned to the Hospital, where he has since remained.

His present mental status is as follows: At times he becomes very disturbed and peculiarly manneristic. He is careless about his personal appearance and generally is preoccupied. He appears apathetic, indifferent, and somewhat depressed. He does not initiate any conversation and answers only fragmentarily. He has aural and visual hallucinations and persecutory delusions. He is oriented for person and place but not for time. His remote memory is fairly good; recent memory is poor. His calculations are slow but accurate. His grasp of general information is moderately deficient. His insight and judgment are severely impaired.

Summary

The incidence of schizophrenia at whatever age obviously varies somewhat with the diagnostic criteria employed. Approximately one in 400 cases of schizophrenia manifests itself in childhood. The prognosis of childhood schizophrenia appears poor; recovery is an exception and improvement occurs only in about one-half the cases.

The fourteen-year-old boy here reported was diagnosed as schizophrenia, hebephrenic type. The symptoms of the psychosis were evident from the age of nine years. He remains unimproved at age of twenty-four. His pre-psychotic personality was that of an introvert. There is no known hereditary or constitutional factor involved in this case. The patient's conduct and writings indicate that environmental stress incident to the broken home was likely the precipitating factor in his psychosis.

ERYTHROBLASTOSIS (ICTERUS GRAVIS) IN THE NEWBORN

Report of a Family of Three Children

JOHN M. ADAMS, M.D., and RAY F. COCHRANE, M.D.
Minneapolis, Minnesota

ALTHOUGH confusion prevails as to the existence of erythroblastosis fetalis as a definite clinical entity, severe icterus and edema of the newborn occur not uncommonly and require immediate treatment if life is to be preserved. We are calling attention to a family of three children: the first child died two hours after birth; the second child developed a typical picture of erythroblastosis and lived following treatment; the third child is perfectly normal, the mother having been treated during pregnancy with liver extract.

The highly familial tendency in this disease is well recognized. The possibility that many still-births or premature deaths are cases of

erythroblastosis, unrecognized, is a point which needs a great deal of emphasis. Javert³ and Macklin⁴ have both emphasized this fact. Bleeding or evidence of hemorrhage at necropsy following a difficult delivery may often be listed as the cause of death. This was the situation in the first case here reported. Only by the more careful and frequent examination of the viscera at necropsy in these babies will the true incidence and cause of death be revealed.

The prognosis of erythroblastosis heretofore has been very unfavorable. In the presence of universal edema of the newborn, death always results.⁶ When icterus is associated with edema, there have been a few recoveries. Three such

cases have been reported by Diamond, Blackfan and Baty in the literature.¹ Pehu⁵ believes the disease occurs more frequently than previously recorded and reports several families in which eight to nine pregnancies are recorded with but a single living child. He states that the disease can occur without the presence of numerous nucleated red cells being present in the peripheral blood, the only positive diagnostic evidence being found in the bone marrow and visceral organs. Pehu further states that in cases of previous evidence of erythroblastosis in the family, it is the duty of the physician to treat the mother during pregnancy with liver extract and transfuse the baby immediately following birth.

The early diagnosis of this condition is vitally important. The presence of an edematous placenta as well as a deep yellow amniotic fluid and vernix caseosa will greatly facilitate diagnosis. Jaundice usually appears in twelve to twenty-four hours following delivery. Pallor or anemia is an important feature but may be masked by the deep yellow color of the skin. The spleen and liver are enlarged. The blood picture usually shows a large number of erythroblasts and immature forms of both the red and white blood-cell series, the nucleated red cells averaging 20,000 to 100,000 per cubic millimeter. Anemia is striking and the hemolytic feature is outstanding, as manifested by increasing jaundice and anemia in spite of frequent transfusions. The van den Bergh is invariably indirect.

The differential diagnosis involves the following: congenital syphilis, sepsis of the newborn, congenital biliary obstruction, icterus neonatorum, acholuric jaundice and erythroblastosis fetalis,⁷ which includes icterus gravis, erythroblastosis, leukoblastosis and edema associated with icterus. Because of the bleeding tendency in some cases, hemorrhagic disease of the newborn should be included in the differential diagnosis.⁸

Pathologically the disease is one of diffuse erythropoiesis. The liver shows large numbers of hematopoietic areas scattered throughout the parenchyma. There is hyperplasia of the spleen, kidneys, heart, pancreas and bone marrow.

The following family is reported to emphasize the importance: (1) of the familial nature of this disease; (2) complete diagnosis in stillbirths and deaths attributed to difficult delivery; (3) the importance of early diagnosis and im-

mediate treatment by multiple transfusions; (4) the importance of the possibility of preventing the disease by treating the mother throughout pregnancy with parenteral liver extract. This suggestion was first made by Pehu,⁵ in the French literature. The third pregnancy reported here was treated throughout with parenteral liver extract. The baby is perfectly normal. This is offered merely as a suggestion worthy of further trial in families where the disease is known or even suspected to exist.

Case 1.—The mother is a twenty-one-year old primipara. The last menstrual period was July 5, 1936. She had no toxic symptoms during her pregnancy and had received regular prenatal care. Labor commenced May 1, 1936, and after five and a half hours a male infant was delivered, footling presentation. There was some difficulty in extracting the after-coming head.

The condition of the baby was poor and he died two hours after birth, all of the usual methods of treatment having been employed. The findings of significance at necropsy were as follows: Birth weight 9 lbs. 11 oz.—4400 grams, liver weight 130 grams (normal 70-88 grams). No gross edema was noted. There was a cephalhematoma in the left temporo-parietal region about the size of a hen's egg. There was hemorrhage over both cerebral hemispheres and blood at the base of the brain.

Diagnoses: (1) Cerebral hemorrhage; (2) Cephalhematoma.

Microscopic examination of the liver and spleen revealed a normal appearing tissue containing several blood islands, but appeared to the pathologists to be within normal limits for a newborn. The spleen showed hyperplasia. Bone marrow study was not done.

Clinically this patient might conceivably be classed as a case of erythroblastosis, the weight of the baby being in excess of the average newborn and over 2 pounds heavier than her subsequent children at birth. The liver weight of 130 grams was about two times the average weight of the liver of the newborn. The cephalhematoma and cerebral bleeding indicated an abnormal bleeding tendency, occasionally seen as a clinical feature of erythroblastosis.

Case 2.—The second pregnancy was normal throughout and resulted in a female child born following a normal delivery on August 4, 1937. The birth weight was 7 pounds 5.5 oz. (3300 grams). The baby appeared slightly pale and sallow at birth, but otherwise normal on examination.

About twelve hours following delivery, definite jaundice was noted and physical examination at that time revealed an enlarged spleen, palpable 3 cm. below the costal margin. The liver was not felt at that time.

The stools were dark brown in color and gave a positive test for bile. The urine was also dark in color with a positive test for bile pigments. The hemoglobin was 80 per cent or 13.6 grams (Sahli) (normal 110), white blood cell count 31,000, Kline test for syphilis negative.

The report of the hematologist on August 6 was as follows: "The blood smear shows the following morphological features: Anisocytosis of considerable degree, numerous macrocytes, polychromasia and many nucleated red blood cells. Most of these appear to be macro-normoblasts, and a few cells have many fea-

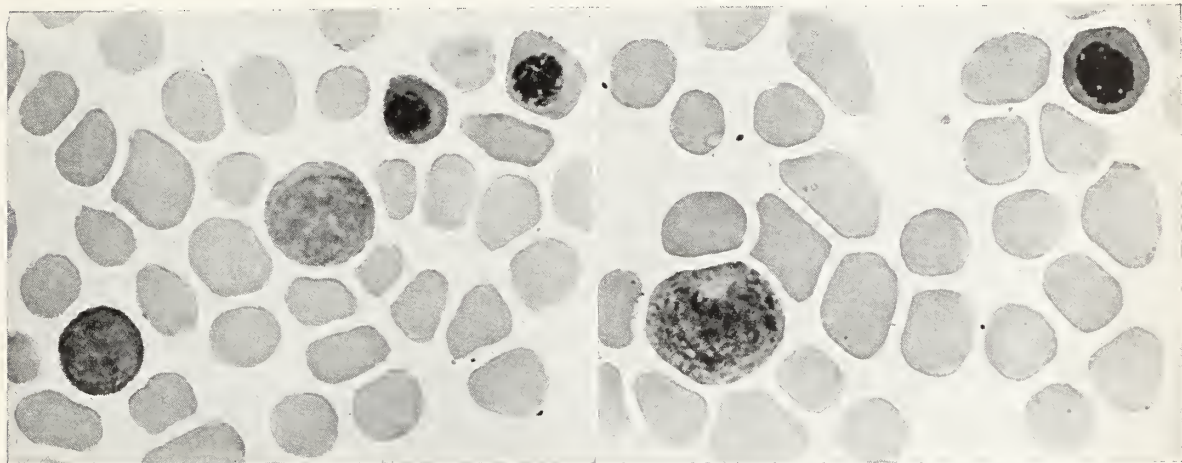

Fig. 1. Stained blood smears, Case 2, showing microcytosis and macrocytosis, immature red blood cells, normoblasts and macro-normoblasts, and immature white blood cells (oil immersion).

Blood smears taken on August 5 revealed a large number of immature red blood cell forms of the normoblast series, over 50 per cent of the nucleated cells being of this series. The differential white blood count revealed myelocytes 9 per cent; metamyelocytes 7 per cent; polymorphonuclears (I) 2 per cent; polymorphonuclears (II) 23 per cent; polymorphonuclears (III) 36 per cent; lymphocytes 22 per cent; monocytes 1 per cent.

Except for a temperature elevation to 100° F. (rectal) on the second day of life (August 5) the course was entirely afebrile.

On August 6 a transfusion of 80 c.c. of citrated blood from the father was given. The hemoglobin following this procedure was 89 per cent or 14.8 grams (Sahli). Cevitamic acid was started, 50 mg. daily being given orally throughout the hospital stay. Progress was favorable although evidence of hemolysis continued. The jaundice became intense and the spleen remained readily palpable, 3 cm. below the costal margin.

On August 9 the hemoglobin was 76 per cent or 12.8 grams (Sahli), and a second transfusion of 90 c.c. of citrated blood was given.

On August 12 the hemoglobin was 34 per cent or 5.6 grams (Sahli), and a third transfusion of 80 c.c. of citrated blood was given. Following this procedure, on August 13 the hemoglobin was recorded at 69 per cent or 11.6 grams (Sahli). The red blood cell count was 3,460,000.

On August 14, 1 c.c. of concentrated liver extract was given intramuscularly.

On August 15 the spleen was definitely smaller, being barely palpable, and the patient was sent home on iron medication only.

tures consistent with megaloblasts. There is a shift to the left in the myeloid line all the way to stem cells which may be found with relative ease. I do not believe this may be said to constitute a leukemia on the bases of the present findings, but rather a leukemoid reaction."

On September 3, 1937, four weeks after birth, the hemoglobin was 50 per cent or 8.4 grams (Sahli), reticulocytes 10.1 per cent. In spite of the evidence of active hematopoiesis, the hemoglobin was 52 per cent or 8.6 grams (Sahli) on October 2, 1937. One month later, on November 2, the hemoglobin had risen to 68 per cent or 11.6 grams (Sahli). The tip of the spleen could still be felt. On January 4, 1938, the hemoglobin was 92 per cent or 15.6 grams (Sahli). The spleen was no longer palpable. On March 1, 1939, the hemoglobin was 85 per cent or 14.4 grams (Sahli) and on May 9, 1938, it was 91 per cent or 15.4 grams.

One year following birth the physical examination was negative. The hemoglobin at this time was 82 per cent or 13.8 grams (Sahli). The child's development is normal, physically and mentally. At two years of age the patient is perfectly normal.

The above case seems to be rather typical of erythroblastosis fetalis, the striking features being pallor at birth, jaundice twelve hours later, increasing in severity for several days. The spleen was markedly palpable. The blood picture contained all of the characteristic features, large numbers of erythroblastic as well as leukoblastic cells.⁶ The response to multiple intra-

venous transfusions was very favorable. The importance of giving whole blood early cannot be overemphasized. Blood grouping and cross matching should always be done regardless of the patient's age or the use of parental donors.

Case 3.—The third pregnancy was normal throughout. The mother was given concentrated liver extract intramuscularly the last seven months of pregnancy at monthly intervals. X-ray examination of the mother was made in accordance with the technic outlined by Hellman and Irving,⁸ and failed to reveal any thickening or increased density of the soft parts of the fetus, indicative of edema. On September 14, 1939, a normal baby was born, weight 8 pounds 6 ounces. Examination revealed a normal newborn baby infant. The blood picture was as follows: hemoglobin 120 per cent, red blood cells 5,000,000, white blood cells 27,600, polymorphonuclears 64 per cent, lymphocytes 32 per cent, eosinophiles 4 per cent, bleeding time 3 minutes 30 seconds, clotting time 4 minutes. The smear showed no abnormality. At the age of six months this patient is quite normal.

Conclusions

1. The importance of complete and accurate diagnosis in all cases of still-births is again emphasized.

2. Treatment by multiple intravenous transfusions offers the greatest hope of cure in cases of erythroblastosis. Ascorbic acid and liver extract was also used in Case 2.

3. The possibility of preventing this disease by the administration of parenteral liver extract to the mother during pregnancy is merely suggested. The result of the third pregnancy in this family following liver therapy was normal.

THE SULFAMIDO COMPOUNDS: THEIR PRACTICAL APPLICATIONS IN CLINICAL MEDICINE*

ALEX E. BROWN, M.D.

Rochester, Minnesota

THE present importance of sulfamido therapy as well as the rapidity with which this field has developed suggests the advisability of reviewing certain practical phases of this subject. It is true that our knowledge is still incomplete in many respects but it is also true that experience has taught us certain factors which serve to distinguish between adequate and inadequate therapy. I wish to discuss what I believe to constitute some of these factors.

Fundamentally, we have available only four sulfamido drugs of proved clinical value, namely neoprontosil, sulfanilamide, sulfapyridine and the sodium salt of sulfapyridine.

With this number of compounds to choose from it is necessary to use care in selecting the one most suited for the infection to be treated. There are several factors of importance which enter this decision. 1. Marked variability in ab-

sorption and acetylation of sulfapyridine. It is possible because of this factor to give a large amount of sulfapyridine without obtaining a satisfactory concentration of the free drug in the blood. On the other hand, with the use of sulfanilamide it is usual to obtain a concentration of that drug in the blood which is fairly closely related to the amount given. 2. Sulfapyridine appears to be a more toxic preparation than sulfanilamide. It produces all of the toxic effects of sulfanilamide and in addition shows an increased tendency to produce nausea and vomiting. It also may give rise to renal complications. 3. Neoprontosil while less toxic than sulfanilamide, is also proportionately less effective therapeutically. Neoprontosil thus lends itself for use particularly in instances in which sulfanilamide is not well tolerated and in which prolonged or intermittent treatment is indicated. It is also of value in circumstances in which it is not possible to keep the patient under close observation dur-

*From the Division of Medicine, The Mayo Clinic, Rochester, Minnesota. Read before the annual meeting of the Minnesota State Medical Association, Rochester, Minnesota, April 22, 1940.

ing treatment. 4. The individual drugs vary in their therapeutic effect on specific types of organisms.

Sulfanilamide to date, because of the foregoing reasons, is the drug of choice for infections produced by the beta hemolytic streptococcus. This is true of localized lesions and of more widespread infections such as septicemia and meningitis. In cases of hemolytic streptococcus septicemia, Herrell and I have found in a recent unpublished review that the mortality rate at The Mayo Clinic has dropped from 70 per cent to less than a half of that figure since the use of sulfanilamide was instituted. Sulfanilamide is probably also the drug of choice for infections produced by gonococci, although the controversy in regard to its merits and those of sulfapyridine for this condition is as yet unsettled. For infections involving the urinary tract, I should feel that, in general, sulfanilamide is also the drug of choice. Finally, infections produced by meningococci and by *Clostridium welchii* are members of the group of conditions preferably treated with sulfanilamide.

Sulfapyridine is definitely the best sulfamido drug for infections produced by pneumococci. The question as to the respective merits of sulfamido versus serum therapy for pneumonia is as yet unsettled and time will permit us only to touch briefly on this subject. It is necessary to bear in mind that the fundamental approaches of each of these methods of treatment are essentially different from one another. Serum acts by throwing an increased number of specific antibodies into circulation which neutralize capsular substance and thus permit phagocytosis and lysis of the organisms. Sulfapyridine reduces the multiplication of organisms and diminishes their invasive power and thus permits a normal number of antibodies to overcome weakened organisms which are diminished in numbers. It can be seen that for these reasons there is a basis for a synergistic action of serum and sulfapyridine such as has been described by Branham and Rosenthal and by MacLeod among others. Because of this the combined use of these two methods of treatment is justified for the severely ill patient when specific serum is available. In considering the problem it is necessary to take into consideration the cost of serum, plus the necessity for typing with its delays, as well as the availability of specific serum. Experience

has shown that the results of sulfapyridine therapy compare very favorably with the results of serum therapy. With all of this in mind it seems reasonable to start immediate treatment with sulfapyridine in cases of pneumonia and to carry out typing simultaneously. The sodium salt of sulfapyridine should be given intravenously, initially, for the acutely ill patient or may be given within a period of twenty-four hours if satisfactory improvement does not occur or if a satisfactory concentration of the drug in the blood is not obtained.

Sulfapyridine is the preferable drug for infections produced by the *Staphylococcus aureus*, Friedlander's bacillus and the *Streptococcus viridans*. Because of the effect of this drug on the beta hemolytic streptococcus it is also the drug of choice for infections of unknown etiology.

There is a second group of conditions aside from the foregoing in which the results from sulfamido therapy are not entirely satisfactory but appear to be of some benefit. Included in this category are such conditions as trachoma, lymphogranuloma inguinale, chancroid, undulant fever, and chronic ulcerative colitis.

Acute rheumatic fever, chronic infectious arthritis, subacute bacterial endocarditis, tularemia and the virus infections constitute a third class of conditions which definitely have failed to respond to sulfamido therapy.

The question of proper dosage is next in importance to that of selection of the most suitable drug, for failure to give a sufficient amount of the drug ranks equally with overdosage as a serious error of judgment. Good therapy requires the presence of an adequate concentration of the drug in the blood as soon after treatment is started as is possible. In using sulfanilamide for infections of moderate severity, concentrations of 5 to 8 mg. of the drug per 100 c.c. of blood are usually sufficient and ordinarily can be obtained in adults by giving 60 to 90 grains (4 to 6 gm.) of sulfanilamide daily. For mild infections and infections of the urinary tract concentrations of 3 to 5 mg. of the drug per 100 c.c. of blood will usually give satisfactory results and can be obtained in adults by giving 40 to 60 grains (2.7 to 4 gm.) of sulfanilamide daily. In the foregoing two groups of infections, there exists a frequent tendency to give more drug than is necessary. This, of course,

often results in symptoms of toxicity which disturb the patient and at times make it necessary to discontinue treatment before recovery has taken place. In using sulfapyridine for such infections as pneumonia, it is best to have a concentration of 4 to 6 mg. of the drug per 100 c.c. of blood. Usually an initial dose of 60 grains (4 gm.) and a daily maintenance dose of 90 grains (6 gm.) will result in such a concentration in adults.

The grave error of insufficient dosage usually is made in dealing with serious infections such as bacteremia and meningitis. For these conditions, there is a frequent tendency to give too little drug initially. The tendency is then to increase gradually the amount of the drug given as the situation grows more serious until in the terminal stages of the disease the patient as a last resort receives amounts of the drug approaching those which should have been given initially. Lockwood aptly expressed the effect of sulfamido therapy when he stated that the best results were obtained in the presence of maximal invasion of tissue and minimal destruction of tissue. He also produced experimental evidence to show that increased destruction of tissue causes increased formation of peptone which in turn seems to inhibit bacteriostasis. For these reasons, it is essential in cases of bacteremia and meningitis to obtain high concentrations of sulfamido drugs in the blood as soon as is possible in order to combat the infection before it can be well established in scattered regions and produce increased destruction of tissue. Experience has shown that treatment of this type will definitely lower pre-existing mortality rates. It has also shown that any tendency to lower these high concentrations of the drug before recovery is complete will definitely result in prolonged periods of morbidity. In using sulfanilamide for these conditions it is advisable to obtain a concentration of 12 to 16 mg. of the drug per 100 c.c. of blood. In using sulfapyridine for bacteremia associated with pneumonia, the concentration of the drug in the blood should be 10 to 12 mg. per 100 c.c. In cases of *Staphylococcus aureus* septicemia, the concentration of sulfapyridine in the blood should be 16 to 18 mg. per 100 c.c.

In using the sulfamido compounds it is essential that these high concentrations be established by the initial dose and that subsequent doses be

directed at maintaining the concentrations thus obtained. In using sulfanilamide, this type of result can usually be obtained by giving an initial dose of 50 to 80 grains (3.3 to 5.3 gm.) of the drug to adults, depending on the patients' weight.

In order to obtain the desired high concentration of sulfapyridine in the blood, it is frequently necessary to supplement oral administration with the intravenous use of the sodium salt of sulfapyridine. As a rule, we have given 0.06 gm. of the sodium salt of sulfapyridine per kilogram of body weight as originally suggested by Marshall and Long. At times we have given amounts greater than this but in no instance have we given more than 5 gm. of the sodium salt of sulfapyridine in a single dose. We have dissolved this material to make up a 5 per cent solution in distilled water. As this solution is highly alkaline it must be given directly into the vein and must be given slowly. The dosage suggested will usually serve to increase the concentration of the drug in the blood by 5 to 8 mg. per 100 c.c., and the dose may be repeated in six hours if desired. It is to be emphasized that this form of intravenous medication is to be used essentially as an adjunct to oral therapy and in instances in which oral therapy will not produce the desired concentration of the drug in the blood or where it is desired rapidly to produce this desired concentration. We have used it only in rare instances as the sole measure of treatment. It is well to remember that if the patient is unable to swallow, sulfapyridine may be given as a suspension in milk or water through a Rehfuß tube. The sodium salt of sulfapyridine in a 5 per cent solution should never be given intramuscularly or subcutaneously and sulfapyridine should never be given intravenously.

In conjunction with treatment I would like to emphasize that it is possible to commit a serious error in the treatment of some conditions by discontinuing the use of the drug too soon. Recurrences of disease are particularly likely to occur if infections are produced by staphylococci or pneumococci, or in cases in which the lesion involves the ear, bone, meninges or blood stream. In the presence of infections of this type, it is well to continue with some administration of drug for six to ten days after recovery has apparently taken place.

CASE REPORT

The toxic effects which result from the use of these compounds are too generally well known to bear a systematic review at this time. There are, however, certain points connected with these toxic effects which are of sufficient importance to be briefly emphasized. Among these are such facts as: 1. Cyanosis is probably the most prevalent and impressive of toxic symptoms but is of least importance as an indicator of danger. 2. Acute hemolytic anemia tends to occur in the first week of treatment and a mild progressive anemia may occur later. 3. Leukopenia and agranulocytopenia tend to occur after the first week of treatment. 4. Cutaneous eruptions and fever tend to occur particularly in the seven to eleven days of treatment. 5. Persistent mild symptoms of toxicity may offer a warning of more serious impending complications and should be carefully heeded. 6. When high con-

centrations of drug are present in the blood it is necessary to observe carefully for possible renal complications or cerebral manifestations of toxicity.

It has been our experience to learn that increasing observance of the foregoing principles has resulted in a definite improvement in the results which we have obtained with infections treated with sulfamido compounds.

CASE REPORT

THREE VARIANTS OF SOLITARY RENAL CYSTS*

ARNOLD SCHWYZER, M.D.

Saint Paul, Minnesota

THREE cases of solitary renal cysts are herewith reported which illustrate variations in their site and relation to the kidney and pelvis and also as to their pathogenesis.

Case 1.—Mrs. T. St., a woman fifty-five years old, had had seven children, but no serious previous illnesses. For about a year she had often suffered from nausea and intestinal pain. Some months before coming to us she had had repeated vomiting but never any severe attacks of pain. She had lost some weight. She was referred to us on account of a large mass in the left hypochondrium, which was sensitive and extended from the kidney lodge to below the navel and almost to the midline. Bilateral retrograde pyelograms were made. The right side appeared normal. The left kidney shadow was found markedly enlarged, the inferior pole extending down almost to the iliac crest. Evidence of considerable pressure on the inferior portion of the left renal pelvis was noticed and also on the inferior calix which was markedly dilated and had lost the terminal markings. The left ureter was displaced mesially. The appearance indicated a large mass in this region which could be either a large tumor or a cyst. The absence of invasion of the inferior calix made the roentgenologist decide, though not definitely, in favor of a cyst.

At operation a cyst as shown in the sketch (Fig. 1) was found. It was the size of a very large grapefruit (11 cm. in diameter). After freeing the cyst, a sling, made of gauze, was placed around it and with this help

the mass which was almost too large for the wound could be brought to the surface. The upper pole of the kidney was left undisturbed. The lower pole of the kidney from which this cyst originated, was then resected and sutured step by step. The report of the operation reads that less than a teaspoonful of blood was lost in resecting the kidney. Recovery was uneventful. There is nothing particularly noteworthy about this case except that the cyst is the largest of this kind I happen to have seen.

Case 2.—Mrs. St. Gl., on February 16, 1937, came to our office where the following notes were made: Age thirty-five, had three children living and well. Had thyroidectomy in 1926 and tonsillectomy six weeks later.

For four days pain had been frequent in the right iliac fossa. Eating caused cramps and no appetite was present. Bowels have been regular.

Examination of the decidedly nervous person yielded no evidence of disease of the head, neck or chest. The upper abdomen was normal, the cecum bulky and was the seat of the pain. The right kidney was very loose; it could readily be brought far over to the midline and downward to rest with its midportion over the innominate line. The pain was, however, not located in the kidney. A bulky hump could be felt on the kidney and two sketches were made which showed that we were uncertain whether the rounded prominence rose from the midportion (Fig. 2) or the upper pole. The x-ray showed a distorted middle calix and no filling of the lower one. The urine was normal. After a transfusion on account of marked anemia, we first removed the long and thickened appendix through a small grid-iron incision. Before closing the wound we had the

*Demonstrated before the Saint Paul Surgical Society, March 7, 1940.

patient draw a deep breath which brought the kidney down where we could hold it over the innominate line. We then saw on the kidney a bluish round bulging, the size of a tangerine, distinctly a cyst. A lumbar incision of 4 or 5 inches, half of which was over the lumbar muscles, was made and through the anterior half

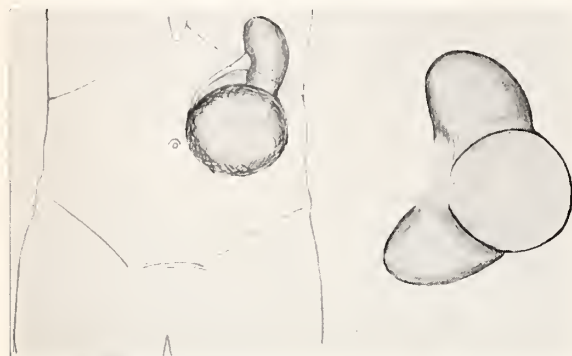

Fig. 1 (left) Case 1. Large cyst of lower pole.
Fig. 2. (right) Case 2. Cyst over posterior aspect of midportion of kidney.

of it the flat abdominal muscles were simply split. We did not feel we needed much of an opening. However the costo-vertebral ligament was cut. Through this restricted incision the kidney could not be brought out of the wound but with the help of a rubber tube looped around it, was brought sufficiently into the wound to excise the cyst which proved to be sitting on the midportion of the posterior surface. Considerable urine escaped from the pelvis of the kidney. However, the cyst was not opened. It was cut away with a very thin layer of kidney parenchyma. A continuous catgut suture controlled the bleeding. The hemostasis was assisted by Sistosan. The ptosis was counteracted by the insertion of four rubber drains. It is now nearly three years and there are no complaints referable to the kidney though the patient is of a highly neurotic type. The cyst, which you see here, has a diameter of about six centimeters.

The patient had herself felt the floating kidney and had been worrying about it. What symptoms there may have been, were due rather to the pulling on the renal pedicle than to the harmless looking cyst.

Case 3.—A para-and intercalicular cyst of kidney. The patient, Dr. A. W., a woman of sixty-five years, had spent twenty-three years as a missionary physician in upper India. She had been of robust physique but went through most strenuous years being the only scientifically trained doctor in an area 150 miles long and 50 miles wide, doing all kinds of medical and surgical work, neglected appendices, gallbladders, goiters, hysterectomies, cesarean sections, bone operations and what not, with several hundred cataract operations thrown in for good measure. In the course of years she had undergone an appendectomy, hysteromyomectomy, but always afterwards resumed her work. However, about five years ago she was forced to give up when she was taken with a severe hemorrhage at the base of the brain. In 1938 a profuse hemorrhage from a duodenal ulcer occurred and in addition to all this she was suffering from a moderate diabetes and high blood pressure (210/102).

She came to me primarily on account of a severe and constant pain in her right hand where the index finger had been removed on account of a septic infection thirteen years before. Excision November 15, 1939, of a neuroma of a branch of the median nerve and resection of a tendon to which the neuroma was fixed gave such prompt relief that she had the courage a few days later to tell me of a constant great pain in the left kidney region. Palpation of the kidney area

was very painful. The kidney itself appeared somewhat enlarged. The sugar in the urine had cleared up after a few days of strict diet. Blood urea 42 and 24 mg. on two occasions. Phenol-sulphone-phthalein test yielded for the first hour 30 per cent and for the second 15 per cent.

X-ray study before and after the intravenous injection of Diotrast showed an enlargement of the upper pole of the left kidney (Fig. 3). A rounded pressure defect on the upper part of the pelvis was seen which also caused an elongation of the lower calices. In addition the roentgenologist (Dr. Medelman) saw evidence of marked pressure on the upper calices. The right side appeared normal.

On November 20 we exposed the left kidney under spinal anesthesia. A most severe perinephritis was encountered, the kidney being firmly adherent to the hardened cicatricial fat. Caution forced us to deliver the kidney only partially into the wound on account of the cicatricial fixation of the pedicle. The sketch demonstrates the appearance of a cyst resting broadly against the posterior aspect of the renal pelvis. It was very thin walled, bluish, and if it had not been for the great thinness and transparency of its wall, could have been taken for a distended pelvis on account of its relation to the kidney. It then ruptured and was widely opened, which allowed us to recognize its peculiar relation with the pelvis, the bulk of which ran freely through the center of the cystic cavity and was considerably elongated. The calix leading to the upper pole was greatly drawn out. It ran freely through the lumen of the cyst cavity and could be hooked over the finger. It was hardly bigger in its midportion than a parlor match, (2.5 to 3 mm.). The portion lying free in the cavity was 3 to 3.5 cm. in length. It was seen emerging from the main portion of the pelvis which was also for the greatest part of its circumference in the cavity of the cyst.

We had the impression that a thin-walled cyst had developed in or very near the space between the upper main calix and the main portion of the pelvis, perhaps near the surface of the columna Bertini, corresponding to this interspace. The cyst would then have separated the parts, grown in where the resistance was least, encircled the upper calix completely and almost completely the remainder of the pelvis. The cyst walls where they touched each other after surrounding the upper calix, must have disappeared, an occurrence one sees quite commonly for instance in multilocular ovarian cysts where parietal remnants of such septa tell the tale.

It did not appear proper to stretch the parts too much for further investigation for fear of incurring damage. The free parts of the cyst wall were resected and the remainder swabbed with absolute alcohol. Collapsible rubber drains were put in place and the wound closed, after a pea-sized cyst on the surface of the cortex had been punctured. The patient left the hospital on the eighteenth day. The wound then slowly closed. In a letter dated January 15th, the patient reports that the old pain was gone. How much of the distress had been due to the cyst and how much to the severe perinephritis remains questionable. A later report announced again much pain in that area.

The microscopic examination of the cyst wall showed only thin strands of connective tissue. No lining, neither epithelium nor endothelium, was seen.

To sum up:

The first case was a solitary cyst of the type most frequently seen but unusually large.

The second one was located in the midportion of the kidney and had an intimate connection with the renal pelvis.

The third case appears to be quite unusual on ac-

CASE REPORT

count of its extending in between the calices and also by the absence of any epithelium which otherwise lines these cysts. A parasitic cyst, like an echinococcus, could definitely be excluded, though exposure to tropi-

These three cysts were distinctly outside the renal parenchyma and appeared to have had no connection with it. In the second case there was, however, an intimate connection with the renal pelvis. Though

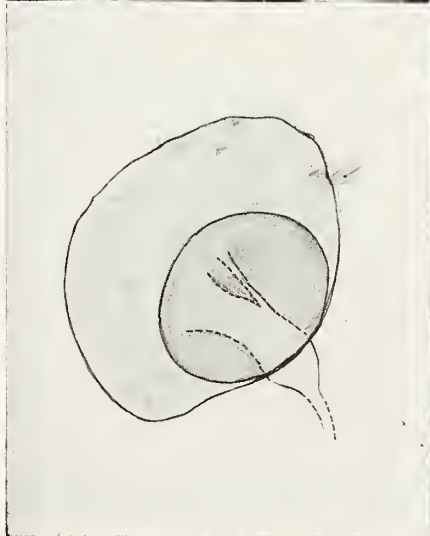

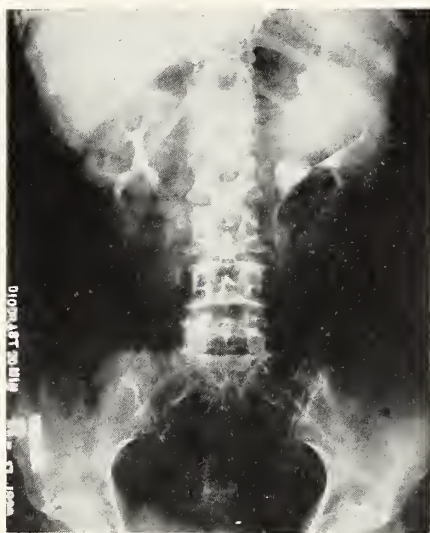

Fig. 3 (upper left) Case 3. Retrograde pyelogram. Evidence of pressure on the left renal pelvis. Note drawn out lower calices and absence of connection between lower part of pelvis and the peripapillary distal portion of upper calices.

Fig. 4 (upper right) Case 3. Outline of kidney and vertebrae traced through the x-ray film. Size and position of cyst shown by dotted line.

Fig. 5 (lower left) Case 3. Appearance of renal pelvis after opening the cyst. Note severe perinephritis, drawn out thin upper calix running entirely free through the cystic cavity. The main portion of the pelvis was almost completely free in the cyst cavity.

Fig. 6 (lower right) Case 3. Retrograde pyelogram taken twelve days after operation.

cal filth and poverty leads the thoughts in such a direction. There remains the possibility of lymphatic origin or of some infective process leading in the late end to a local hydropic condition. This latter view would be supported by the very outspoken perinephritis. However, the distinct cyst wall, though paper-thin with loose connective tissue on it, speaks against it. Perhaps we have to fall back on the alibi of some congenital malformation.

the dissection of the cyst was done most carefully and without breaking it, the renal pelvis was opened. The opening itself was not seen, but much urine escaped from the renal pelvis into the wound.

All three patients were women, thirty-five, fifty-five, and sixty-five years of age. This corresponds with the general experience that most of such cysts are found in grown people, often in later years and more frequently in women.

HISTORY OF MEDICINE IN MINNESOTA

HISTORY OF MEDICINE IN WINONA COUNTY

(Continued from July issue)

Biographies

Samuel D. Miller was born in Union County, Indiana, about 1824. He served during the Mexican War, and came to Winona County in the fall of 1869. First he settled at Homer. He moved to Centerville in 1874, and four years later moved to Witoka. He was a member of the Legislature during the sessions of 1878-1879. He engaged in the drug business during his stay at Witoka. In 1882, he moved to the city of Winona, and died there from a dose of morphine in the year 1883. He was a member of the Masonic Order and of the Temple of Honor.

C. C. Moore, M.D., homeopathist and surgeon, came to Winona in 1856, giving many references on his card, three judges in Iowa, Wisconsin, and New York, a Wisconsin bank president, and Rev. H. S. Hamilton of Winona. The year following his establishment in Winona, he engaged in the jewelry business and continued in it for several years. During this time he probably continued to practice medicine.

William S. Morrison came to Winona County in the 1860's. In 1868 he moved from Lewiston to Fremont. There he continued to practice his profession for many years. In 1884 he opened an office at Lewiston, probably retaining his Fremont practice at the same time.

Edwin S. Muir came to Winona in 1898 from Plainview where he had practiced for four years following his graduation from the University of Minnesota in 1894. He was associated with Dr. W. T. English when he first came to Winona and succeeded Dr. English when the latter died. Dr. Muir was highly esteemed both by his professional confreres and the people of Winona. He served as Mayor of Winona for two terms. Dr. Muir remained in Winona until the time of his death July 14, 1919.

L. H. Munger graduated from the Missouri Medical College in 1879. He came to Saint Charles to practice in 1881. He may have moved to Stearns County for a time, but later he returned and became a member of the Winona County Medical Society.

William Netter, a doctor from Rochester, moved to Winona about April of the year 1882. William Netter was engaged in the drug business in Winona with Dr. Wedel during the sixties.

William J. Newberry, M.R.C.S., a practicing physician at Minnesota City, came in 1882 from London, England, and bought the residence and office of Dr. Walrath. Dr. Newberry was a licentiate of the Society of Apothecaries,

London. After coming to Winona County, he became a member of the Winona County Medical Society.

John C. Norton, A.M., M.D., settled at Homer in 1855. In that year he ran for the office of assessor. In January, 1857, the following card was published in the Winona paper:

J. C. NORTON, A.M., M.D.
Physician and Surgeon
Justice of the Peace
Land Surveyor, & Coroner
Homer, M.T.

Dr. Norton wrote a series of articles on the botany of Winona County which were published in the Winona paper in 1858. He was also a very popular lecturer.

Jean O'Hara, a homeopathic physician and surgeon, came to Winona about 1873. He was a druggist and physician between 1878-1885. Dr. O'Hara was a man of unruly disposition, and got into several small disputes during his stay in Winona. In 1884, he shot a barkeeper in the leg while drunk. At another time he had a man arrested and fined for shoving him off the sidewalk.

Dr. Palmer owned a farm in Winona County about 1882.

W. Thorton Parker graduated from the Royal University of Munich. He was surgeon of the White Earth Reservation before coming to Winona, and had been for a time a resident of Boston, Massachusetts. He located in Winona in May, 1881.

J. S. Pashley, M.D., physician and surgeon, settled in Winona with a view to permanent residence in July, 1865, and solicited a share of public patronage by his card in the newspaper.

D. C. Patterson, M.D., came to Winona in May, 1856, at which time the following card was published:

D. C. PATTERSON, M.D.
Late of Cleveland, Ohio
Will give his attention exclusively to the practice of
Medicine & Surgery

In 1859 Dr. Patterson took Dr. C. B. Dayton as a partner. Three years later, Dr. Patterson had left Winona, probably going directly to Washington, D. C., where he resided in 1879 and later.

E. H. Patterson was a Winona physician about 1860. Possibly confused with Dr. D. C. Patterson.

Dr. Peake practiced in Winona County about 1863.

J. L. Peregrine practiced in Winona about 1883.

Thomas A. Pierce, M.D., came to Winona from Galena in November 1863. At that time he published the following card:

THOMAS A. PIERCE, M.D.
Homeopathic Physician and Surgeon
Office over Wickersham's drug store
Second Street
References: W. W. Huntington, P. M.; E. A. Small, J. A. Packard, Galena, Ill.; A. E. Small, M.D., D. S. Smith, M.D., Chicago.

Dr. Pierce graduated in 1850 from the Homeopathic Medical College of Pennsylvania. Not long after coming to Winona to practice he took Dr. William A. Whippy as a partner. Dr. Pierce was much interested in politics and in educational matters. He served on the Board of Education in 1874 and in 1879. He was a director of the Board in 1880 and again in 1882. Dr. Pierce was known as the leading homeopathic practitioner of Winona for many years.

Charles H. Prague (or Pague), **M.D.**, was a graduate of the Bellevue Hospital Medical College of New York City, and a member of the Oneida Medical Society there. He came to Winona to practice in September, 1866, and remained there for a decade or more.

J. E. Putnam was listed as a Winona County physician in 1865.

August Putsch graduated from the Homeopathic Medical College of Missouri in 1869. In 1872 he practiced as a physician and surgeon in Winona. During 1872-1873 and possibly later, he had a jewelry store in Saint Charles. He still practiced in Winona in 1885.

Dr. Reddington was listed as a Winona County physician in 1864.

L. Redmon opened an office and started practice in Winona in May, 1882. Dr. Redmon was an early settler of Preston and was well liked there, both personally and as a physician.

Dr. Reinholz was a physician at Lewiston in 1883.

A. D. Reynolds was a Winona County physician about 1863.

Edson Rhodes, M.D., graduated from the Rush Medical College in 1883. He came to Winona the following year and became the partner of Dr. D. H. Stewart. Before his arrival, Dr. Rhodes had held the position of resident physician of the Cook County Infirmary, Chicago. He became a member of the Minnesota State Medical Society in 1885, and was also a member of the Winona County Medical Society.

William H. H. Richardson, M.D., came to the United States in 1854. In 1856 he took out citizenship papers in Fillmore County, Vermont. He practiced for many years at Montpelier, Vermont, until his coming to Winona in the spring of 1867. Upon arriving, he formed a partnership in the practice of medicine and surgery with Dr. Franklin Staples. Dr. Richardson is recorded as a graduate from the Bellevue College, New York. He was a charter member of the Winona County Medical Society, and became a member of the State Medical Society in 1870. Dr. Richardson died of apoplexy on June 10, 1874, in Winona. He was known as a thoroughly educated and skilled physician.

S. D. Richardson was a physician in Winona County about 1863-1865.

W. H. Robbins was a practicing physician at Saint Charles about 1879. He was medical examiner for the Royal Arcanum Council of Saint Charles and a charter member.

T. W. Roberts graduated from the Homeopathic Medical College of Chicago in 1884. He had practiced in Winona County for many years previous to that date, having come as early as 1866.

Carl H. Roemer came to Winona to practice in 1876, or before. He departed in 1877 on the pretext of seeing a patient in La Crosse. He had married a widow with tempting property a few months previously, and made his disappearance after drawing \$4,000 from the banks. He returned later, but after another attempt to abscond in 1878, was caught and brought back by the sheriff.

F. H. Rollins, M.D., practiced in Winona County about 1880. In 1930 he was still practicing at Saint Charles.

Augusta L. Rosenthal, M.D., located in Winona for the practice of medicine and surgery in July, 1884. In her card she offered special attention to diseases of women. In 1885 she was proposed for membership in the Winona County Medical Society, but was not accepted because of her sex. However, she became a member of the Minnesota State Medical Society later the same year.

R. N. Sackett, physician and surgeon, practiced in Winona County about 1869-1870.

J. W. Scott graduated from the medical department of the University of Wooster in 1880. In February, 1882, he came to Saint Charles from Ohio, and started practice. He became a member of the Winona County Medical Society in the year of his arrival. In 1885, he served on the local Board of Health, and the same year he attended the conference of state and local boards of health and sanitary councils for southeastern Minnesota.

J. B. Seaman was a Winona County physician who came before the close of 1856. He practiced medicine to some extent but later advertised himself as a "surgeon-dentist."

Samuel B. Sheardown was born in Catlin, Chemung County, New York, on October 7, 1826. He commenced his practice in the office of Dr. Winton of Watkins, New York. He married Dr. Winton's daughter, Mary, and brought her to Winona in 1856. His card, published in January of that year, read as follows:

DR. S. B. SHEARDOWN
Physician and Surgeon

Having had long and extensive experience in both the above professions, offers his services to the citizens of Winona and the public at large. He will be found at any time, when not engaged, during the day and night, at his office in the Drug Store, opposite the Post Office.

In May of the same year, Drs. Sheardown and Cole formed a partnership. During the Civil War, Dr. Sheardown served as surgeon of the 10th regiment and was stationed for some weeks in hospital service at St. Louis, Missouri. He practiced in Winona, then at Stockton for several years before his departure, and was again at Stockton after the war. There he opened a drug store, and at the same time continued his medical practice. He was very much interested in the development of the village and in its

religious and educational growth. He owned a half interest in a very productive flour mill and also part interest in a creamery.

At the same time the political affairs of the country claimed his interest. He was an active Republican and was elected to the lower House of the Legislature in 1862 and to the Senate in 1869, and again to the House in 1881.

He went to the aid of the New Ulm people during the Indian outbreak in 1862-1863, and was present at the hanging of the thirty-eight Indians at Mankato, and acted as one of the examining surgeons, pronouncing life extinct.

Dr. Sheardown was one of the charter members of the Winona County Medical Society organized in 1869, and was its first president. He served again in that capacity in 1870, in 1877, and in 1889. He was also a member of the State Medical Society and held the office of treasurer from 1869 until the time of his death. In 1875-1876 he taught in the Winona Preparatory Medical School.

At several times Dr. Sheardown had an office in Winona and made the first attempt at establishing a hospital there. His practice at Stockton was large, however, and required most of his attention. In the year 1882, Dr. Sheardown was postmaster at Stockton.

In the year 1884 Dr. Sheardown and his son, Dr. T. W. Sheardown, opened an office in Winona and both remained there for a time. Dr. Samuel Sheardown died August 1, 1889.

Thomas W. Sheardown, M.D., was the son of Dr. S. B. Sheardown. He was born in 1856, the year of his father's arrival in Winona. In March, 1879, he graduated from the Jefferson Medical College in Philadelphia, after a two years' course, with high standing in his class. First he took up his practice at Lake Benton. In the year he started practice he became a member of the Minnesota State Medical Society. The following year, there was a note published in the Winona newspaper to the effect that Drs. Andrews and Groesbeck of Lake Benton complimented Dr. Thomas Sheardown on a successful amputation.

In 1881, Dr. Sheardown practiced in Stillwater, but in December of that year he moved to Minneapolis, where he opened a drug store. In November, 1883, he moved to Knoxville, Tennessee, to practice. It was the following year that he and his father opened an office in Winona. Some time later, he went to Chicago, where he did not practice medicine but was employed by the McIntosh Battery and Optical Company as manager of the stereopticon department. He remained with this company until his death in 1896.

Charles S. Sheldon came to Winona to practice in September, 1868. His card stated that he was a late resident physician of the Buffalo General Hospital. He had graduated from the New York College of Physicians and Surgeons in 1868. Dr. Sheldon was a charter member of the Winona County Medical Society and became a member of the Minnesota State Medical Society in 1871. While in Winona he was assistant superintendent of the Congregational Sunday School, and upon his departure from the city in December, 1871, he was presented with a watch chain and cross by that organization. He moved to Greenville, Michigan, after leaving Winona.

George Sieler was a practicing physician at Alma during the eighties or before. He became a member of the Winona County Medical Society.

Thomas M. Sime, physician and surgeon, came to Winona to practice in 1866. He was an oculist and aurist. During his stay in Winona he was involved in two court cases. In February, 1873, he brought suit against E. L. Frary to recover \$40 for medical services in treating a sore eye. The case resulted in his being allowed \$10 by the court. In 1874 a case was brought against him and he introduced Drs. D. A. Stewart and J. B. McGaughey, both men of high reputation, for the defense. In November of that year he sold out his interests in Winona and moved to Menomonie, Wisconsin.

A. O. Slade was a druggist and physician in Winona. He came about 1879 and lived there during the eighties. He was "Surgeon-at-Arms" for the Winona Archery Club.

Columbus G. Slagle was a physician and surgeon of Saint Charles. He was a charter member of the Winona County Medical Society, organized in 1869. During that year and the next he was the partner of Dr. Sudduth. After leaving Saint Charles he practiced in Minneapolis for many years.

M. K. Smart was listed as a Winona County physician about 1864.

J. G. Smith came to Winona and started practice in May, 1879. He had been the house surgeon and physician at Bellevue and Blackwell's Island Hospitals, New York City.

(To be continued in the September issue)

President's Letter

WITH all Europe a battleground, Japan trying to conquer China and threatening to involve most of Asia, and Italy fighting the British in North Africa, it is time the United States started better defense measures and embarked on a program for enlarging her army and navy. During the World War about 63,000 physicians volunteered and served as medical officers. At the June meeting of the American Medical Association in New York a resolution was passed by the House of Delegates offering the full services of the American Medical Association and of the physicians of our country as needed. Dr. George C. Dunham of the United States Army presented a plan for the procurement of professional personnel for the Medical Corp of the Army in the event of a national emergency. This will be worked out through the office of the American Medical Association.

Our State Medical Association has had a Committee on Military Affairs for many years and the procurement plan in our state will be worked out with the aid of this committee working in conjunction with the Council of our State Medical Association. A questionnaire has been sent to every physician inquiring whether he wishes to enlist for active service or home service, age, family obligations, and special qualifications, training, and experience. Each physician is expected to fill out the questionnaire and return it so a complete list of the physicians and their qualifications and answers will be on file in Chicago. Should there be a call of physicians the quota for each state will be determined and our State Committee on Military Affairs will designate the men needed to fill the quota in the State.

Selections will be based on many considerations with special attention to the responsibilities of the individual to family and community. When the questionnaire arrives, each physician is requested to fill it out and return as promptly as possible. While we all realize that a war would be a calamity and earnestly hope it will be averted, should it come, we as a body of physicians have a patriotic duty to fulfill. The same loyalty and self-sacrificing devotion which the physicians have shown in every emergency in our country's history is expected, and will, undoubtedly be shown again should the necessity arise.

B. S. ADAMS, President
Minnesota State Medical Association

MALARIA THREAT IN MINNESOTA

THE report of a survey by Daggy and others
which appears in this issue of *MINNESOTA
MEDICINE* shows a marked predominance of the
anopheles mosquitoes in the valley of the Mis-
sissippi River in Minnesota. In view of the lim-
ited number of anopheles found in previous more
limited surveys in Minnesota, it seems this consti-
tutes a change in the species of mosquitoes in this
territory.

Malaria has never been a serious problem, or
any problem at all, in Minnesota. Two or three
indigenous cases have been reported each year
until 1939, when the number suddenly jumped
to seventeen definite indigenous cases, and pos-
sibly four more of the total twenty-three cases

reported in the state. Wisconsin has had a simi-
lar experience.

The situation has caused some concern in pub-
lic health quarters. Attempts have been made to
explain the apparent influx of malaria-carrying
mosquitoes. The question has been raised wheth-
er damming of the Mississippi has provided more
quiet and clean waters which this particular spe-
cies prefers.

With an apparent abundance of malaria-
spreading mosquitoes in the state all that is need-
ed is a few accessible malaria patients for the
disease to spread.

The influx into Minnesota of thousands of sol-
diers from the South for military maneuvers,
which has already begun, will doubtless provide
cases of smouldering malaria for the anopheles
to work on. The anopheles exist in the regions
where some forty or fifty thousand recruits will
be encamped. It is safe to assume that the mos-
quitoes will have considerable access to the re-
cruits.

The report calls attention to the increase in
malaria in Minnesota last year and suggests the
likelihood of a further increase this year. The
profession should be malaria minded.

RUDOLPH MATAS: NESTOR OF AMERICAN SURGERY

IN LEGENDARY lore Nestor, King of Phyllos
in Ancient Greece, was the oldest and most
experienced warrior who took part in the siege
of Troy. His name has therefore come to be
used as a title of honor and respect for those of
advanced years who have reached leadership in
any field of human endeavor. Very fittingly can
it be applied to the case of Rudolph Matas, whose
eightieth birthday occurs on September 12, 1940.
His career as a surgeon, coupled with his work
as a teacher and writer, entitles him to the highest
degree of recognition and an enduring place in
the topmost ranks of his fellows.

Matas received his medical degree in 1880 at
the age of twenty, after the customary short
novitiate of that period when medical knowledge
was scanty. Supplementary training like fellow-
ships was unknown and even internships were

rare and primitive, never obligatory. But Matas was quick to grasp opportunity and soon secured a demonstratorship of anatomy which he held for ten years and today regards it among the most profitable and happy experiences of his life. At thirty-four he became professor of surgery at Tulane and thereafter his record is one of steady progress and accomplishment.

While best known for his original and extensive work in blood vessel surgery, which revolutionized all the old ideas, Matas was a pioneer in many other fields of general surgery and made enduring contributions. His bibliography includes over four hundred titles covering practically the whole field of surgery. He devised many original procedures, especially for the relief of postoperative complications, which have later been rediscovered and publicized by others. For further details of these and other similar matters attention is invited to the current issue of the *Bulletin of the American College of Surgeons* which contains the addresses delivered at the testimonial dinner tendered to Dr. Matas in New Orleans earlier in the year, on the occasion of his completion of sixty years' practice.

To study the record of a life of achievement like that of Rudolph Matas is a refreshing interlude at a time like this when the world is filled with the echoes of the forces of destruction and the finer things of life are in the shadows.

—GILBERT COTTAM, M.D.

QUARTERLY JOURNAL OF STUDIES ON ALCOHOL

THE appearance in June of the first number of the *Quarterly Journal of Studies in Alcohol* questions why such a journal was not published in this country before. With the discontinuance of the *British Journal of Inebriety*, this new journal is the only one devoted to problems of alcohol published in English.

There is need for such a journal. The subject of alcohol is an important one and a journal devoted to it makes available authoritative and unbiased information on the subject. Information put out by the liquor interests or by the temperance league is questionable because of its source.

That this new journal will be scientific and reliable is assured by the personnel of the editorial board and the editor, Howard W. Haggard. The Research Council on Problems of Alcohol re-

cently formed by the American Association for the Advancement of Science has chosen the journal as its official organ.

If the quality of the articles which appear in the first number of the journal is maintained in future issues the new publication will make a contribution to the problem of alcohol. Our best wishes for a long and useful mission are extended to the *Quarterly Journal of Studies on Alcohol*.

The journal is published at 4 Hillhouse Avenue, New Haven, Connecticut. Subscription price \$3.00.

MINNESOTA EMPLOYMENT SERVICE

Every doctor knows the difficulties he faces when he finds it necessary to hire a new office girl, typist, stenographer, a laboratory technician or a registered nurse. Most of the trouble and annoyance usually encountered at such times can be avoided if the assistance of the employment service of the Division of Employment and Security is requested.

This governmental activity in Minnesota is under the direction of Victor Christgau. In pointing out that the service is free and is available to both employers and workers, Mr. Christgau says, significantly: "It's paid for. It should be used more!"

Under Mr. Christgau's administration, the service is being developed into an agency that serves the small employer in very much the same way as does the personnel department that all large business organizations find it so necessary to maintain.

The Minnesota Employment Service is a state-wide clearing house for workers and jobs—an organization that brings qualified people who seek employment to employers who have positions they want filled. Neither profit nor charity enters into its operations. It maintains the largest reservoir of employables in the state. Its records constitute a great pool of employee possibilities, a detailed examination of the more than 150,000 in approximately 3,000 different occupational classifications reveals.

When a doctor, for example, needs a new employee, all he has to do is to telephone detailed specifications to the nearest office of the state agency. There, trained placement officers search their files for workers who can meet these requirements. These placement officers are expert interviewers, men and women who have been specially trained and who know the qualifications that a given job requires. From their files they will refer one, two, three—or as many persons as the employer may desire to interview personally. From these referrals, the employer makes his own selection. In this way, he acquires a trained worker and loses no time interviewing a crowd of applicants. His time is not taken up by misfits.

The service of the Division of Employment and Security is state-wide and all its thirty-seven full time local offices can be reached by telephone.

MEDICAL ECONOMICS

Edited by the Committee on Medical Economics
of the

Minnesota State Medical Association

W. F. Braasch, M.D., Chairman

PREPARATION FOR MEDICAL DEFENSE

The first line of defense in modern warfare is medical defense and, unless this is adequately organized, success is impossible. The Council on National Defense is well aware of this and, as a first step in preparedness, requested that medical organization proceed at once. Although certain federal authorities, coöperating with politicians and a group of welfare workers, have made every effort in recent years to belittle the medical profession and besmirch organized medicine, with the threat of national danger they have been silenced and now hasten to acknowledge the profession's importance to public welfare. It should be stated, however, that the attitude of the Army and Navy has always been friendly and coöperative with the medical profession.

Important Issue

The most important issue before the medical profession today in any case is preparation for the national defense.

Physicians of America have never waited to be drafted for a national emergency. They have been ready and waiting whenever the need arose.

Today it is not a question of rushing out to enlist with the fighting forces. It is not a question of repairing the injuries of war. Instead, it is a question of organizing for a vital part in the preparedness effort of a nation.

Never again in America, it is to be hoped, will an actual declaration of war find a feeble fighting force bereft of equipment, and without the organized services of physicians ready at hand to judge the physical fitness of troops and workers, to rehabilitate the unfit and to care adequately for civilian needs at the same time that the overwhelming needs of the war injured are cared for.

To Provide Machinery

It is to provide the information and machinery for preparedness, not for war, that the new mobilization plan for physicians is now getting underway. The questionnaire sent out in July by the National Medical Preparedness Committee appointed by the American Medical Association in New York is the first step in that mobilization.

The National Research Council is also organizing representatives of the various fields of medicine so as to have available the most modern developments in medical progress. Plans are being made to set up schools of instruction in various fields, in order that those who are engaged in medical defense may be adequately instructed. Publication of a bulletin is being considered which will make information concerning recent developments immediately available.

This time the doctors of America are setting up their own organization for national defense as scientifically as they habitually set up their service for the care of the sick and the injured.

No Hit-and-Miss Enlistment

There is to be definite and detailed information about every physician on file in Chicago. Those who are likely to volunteer for war service, in case a war is declared, will be sent as they are needed to the places they are best qualified to fill. Those who will not for many reasons be assigned to fighting units will be marshalled at home according to the equally important need for proper selection of soldiers, for repair of correctible defects, for medical supervision of industrial workers and for uninterrupted service to the civilian population at home.

This time there will be no hit-and-miss enlistment of medical aid for the nation's defense forces and the questionnaire is the absolute essential guarantee of the new order.

Minnesota physicians have now received their questionnaires. Most of them have already sent them back carefully filled out to Chicago headquarters.

Reminder

A few still remain to be filed, however, and it is for the sake of the laggards, principally, that the post card plea of Dr. F. L. Smith of Rochester, State Chairman for the Committee on Medical Preparedness, went out to all members of the Minnesota State Medical Association this week.

The post card asked each member who had completed and mailed his questionnaire to notify the State Office on an attached card.

Thus all would be reminded of their duty, and also the state chairman would have in his possession a list of the doctors of Minnesota who had filled in the questionnaire to aid him in coöperating with the national committee.

Many a physician whose loyalty and willingness to serve in any capacity is beyond question, still finds it easy to postpone small chores like the filling and mailing of this questionnaire.

It is to these men that the state chairman and officers of the Association address a special plea.

This, for the present, constitutes the full military duty of the average practicing physician and delay in complying will cast an undeserved reflection upon the patriotism and loyalty of the profession in Minnesota.

FOR NATIONAL COORDINATION

A ringing call for coördination of medical and public health services under a coördinator of medical and health preparedness for national defense was sounded in New York recently by Surgeon General Thomas Parran.

The need for such a coördinator in times of peace as well as in times of stress such as these, has long been clear to the doctors of the country. The considerations which have kept the health agencies of the Children's Bureau separate and independent of those under the Surgeon General of the Public Health Service and have tried to bestow upon still another quarter federal efforts to aid industrial health, have been compounded of politics, personalities and precedents inherited from an earlier and simpler time. This is the time to strike hard for unified cohesive

federal health services under competent medical control.

At the same time, it is a time for watching closely that no standards of freedom, independence and scientific quality, be sacrificed in a frenzy to convert the medical services of the nation over night into a strong arm of national defense.

Dr. Parran's address as printed in the *Journal of the American Medical Association* should be read by every physician for its provocative review of the immediate problems to be faced by physicians in bringing America to an adequate state of preparedness. His remarks on the subject of coördination are reprinted here for especial emphasis on this problem of coördination and leadership in the United States.

Health, Military Problems Inseparable

Said Dr. Parran:

"In time of stress, the health problems of the military and civilian population are inseparable. At present they are the responsibility of many unrelated Federal agencies having the happiest personal good will toward one another, but with no more official authority or compulsion toward coördinated action than did an airplane factory and an automobile plant two months ago. Each of these agencies legally can perform only certain functions set up by law. None of them has a close, working integration with the organized medical and public health professions. The State Health Departments are as diverse as the forty-eight states. None of the official agencies have the benefits of a full working relationship with the great voluntary associations for health and welfare, in which doctors, dentists, nurses, engineers, in their technical capacity, work side by side with citizens to caulk up the leaks in the hull of our national manpower. None of the official agencies has the full aid and service which the public spirited foundations set up to promote health and welfare are able to give. . . .

"I Propose a Coördinator"

"Our defense plans, for the immediate emergency, are still young. There is much in the way of organization and coördination yet to come. But as a first step in meeting the vital needs of manpower preparedness, I propose that a coördinator of medical and health preparedness for national defense be appointed under the National Defense Council. There is much for him to do. He would work with and through the Surgeons General of the U. S. Army, the U. S. Navy, and the U. S. Public Health Service, other Federal agencies, and the national voluntary organizations concerned with the prevention, diagnosis, and treatment of disease.

"A first task is the need for listing and classifying professional and technical personnel in the country;

for planning and aiding, if and when necessary, the recruitment and mobilization of medical and health personnel. . . .

"If or when war comes, every 1,000,000 men mobilized need 7,500 doctors drawn from civil practice. Dentists, nurses, sanitary engineers are needed too. In the mobilization of four million during the last war, more than a fourth of the effective medical men of the country were called to the colors. Whole counties were depleted of doctors. Many medical schools were almost put out of business, because the best men left for military duty. We should not repeat these mistakes. Today we should investigate who should go, who should stay to practice, to teach, to operate an essential civilian service. We have no machinery now to do this. A Coördinator of medical and health preparedness should create the machinery, working with the public health agencies, the schools, and the medical profession itself.

Malnutrition Cited

"If our workers are malnourished, they cannot be efficient in producing what we need for defense. Yet every survey of nutrition, by whatever method conducted, shows that malnutrition in this country is widespread and serious. For example, studies by the Department of Agriculture show that forty per cent of the people are not getting a diet adequate to maintain good health and vigor. Eight out of every ten in this category do not have an income sufficient to purchase, at market prices, a diet adequate in amount and kind; this in spite of the fact that the foods of which the Nation has an apparent surplus are those in which the dietary of so many is deficient—milk and milk products, citrus fruits, green vegetables, and meat.

"Not through any pity for their working people, but because their scientists proved to them it was an essential to national power, the Germans began several years ago to provide for the working masses a diet better than ours have now. We have made a beginning in this direction through the foodstamp plan. What we need is an intensive national drive, with rigid scientific controls, to use the food we have to improve the fitness of our manpower.

"There is no time for dogged adherence to outworn patterns, nor for a major change in proved forms of medical practice. Medical science grows, expands, opens up new possibilities for saving life and building strength. In the application of its basic sciences, medical practice must expand also to meet the new demands of the Nation for self-preservation."

"THREE YEARS COULD BE SAVED"

It is interesting at this time to recall that many efforts were made to modify or lower standards of licensure and medical graduation after the United States entered World War I.

The matter was discussed according to the *July Bulletin of the Federation of State Medical*

Boards of the United States, at Federation meetings in February, 1917, and again at the annual session in 1918.

One board member declared that it was the obligation of the medical boards to protect and help humanity rather than look entirely to the preferment of doctors and that medical boards should be "reasonable and considerate to meet the needs of the times."

It was proposed that three years could be saved in preparatory education and another year could be eliminated from the medical course if men were taught only the things which are really essential to the making of a good general practitioner. The author further urged that "this great medical protectorate of federated medical boards assume the responsibility of establishing a new order of things" and create a committee forthwith with power to act.

"When it is made reasonably easy for men to become real doctors," the author declared in a quotation that should be of particular interest to medical educators today, "they will cease being cultists, and if we, as medical boards, are really trying to help humanity, this will aid us in the accomplishment of our duty."

Standards to Be Upheld

Fortunately, these proposals were vigorously opposed by other members of the federation.

In the event of another national emergency, the *Bulletin* declares, the Federation will again take a firm stand in upholding the highest standards of medical training required for efficiency in civil and military medical practice.

"PUBLIC LIABILITY INSURANCE"

(Monthly Editorial Prepared by the Medical Advisory Committee)

Recently, two cases brought to the attention of your medical Advisory Committee have made the discussion of the relationship between Physicians' and Surgeons' Liability (Malpractice) Insurance and Owners', Landlords' and Tenants' Public Liability Insurance pertinent.

In both cases injury followed closely on surgical treatment and loose interpretation of the points involved may place the defense within the wording of either or both of the policies carried.

The usual Malpractice Policy provides defense

for the Insured in event of legal procedure and indemnity for loss or expense resulting from claims for damages on account of malpractice, error or mistake committed or alleged to have been committed by the Insured in the practice of his profession, while the Owners', Landlords' and Tenants' liability policy indemnifies the insured against loss resulting from legal liability due to accidental injuries suffered by persons other than employees in the insured premises due to "ownership, care, maintenance or use" of the office quarters, including accidents involved in making ordinary repairs. This insurance would cover loss not included in the Physicians' Liability policy which provides only for losses due to the practice of his profession.

It is the thought of your Committee that it might be well for members of our Association to carry both. The cost would be little additional. The security and peace of mind warrants the small outlay. The defense, of course, would have fewer complications and would be facilitated generally if both policies were carried in the same indemnifying company.

—B.J.B.

MINNESOTA STATE BOARD OF MEDICAL EXAMINERS

Julian F. Dubois, M.D., Secretary

Supreme Court of Minnesota Upholds Mower County District Court in Denying Austin Physician and Fraternal Order of Eagles an Injunction against the Minnesota State Board of Medical Examiners

Re: Fisch, et al. vs. Sivertsen, et al.

On June 21, 1940, the Supreme Court of Minnesota in a unanimous opinion, sustained the District Court of Mower County in dismissing the lawsuit instituted by Dr. Herbert Matthew Fisch, a physician and surgeon of Austin, Minnesota, and Lookout Aerie No. 703, Fraternal Order of Eagles, against the Minnesota State Board of Medical Examiners.

The Honorable Norman E. Peterson, Judge of the District Court for Mower County, had made an order on October 21, 1939, dismissing the plaintiffs' lawsuit, and on December 21, 1939, Judge Peterson made a further order denying the plaintiffs a new trial; it was from this order that the plaintiffs appealed to the Supreme Court of Minnesota.

The plaintiffs instituted the lawsuit in July, 1939, following an informal hearing held by the Minnesota State Board of Medical Examiners, and after a ruling by the Honorable J. A. A. Burnquist, Attorney General of the State of Minnesota, and Mr. John A. Weeks, Assistant Attorney General, that the Fraternal Order of Eagles and Dr. Fisch were violating the laws of the State of Minnesota, and particularly those relating to the practice of healing and the practice of medicine. The Attorney General also ruled that any physician who was

a party to the operation of such a plan, subjected himself to the possible loss of his license as a physician. The legal objection to the operation of such a plan is that the Fraternal Order of Eagles, a corporate entity, acts in the capacity of an intermediary in the practice of medicine contrary to law and usurps the privilege and franchise of the practice of medicine, in violation of law. The plaintiffs attempted, in their lawsuit, to enjoin the Minnesota State Board of Medical Examiners from interfering with the plan and also from taking any action to suspend or revoke Dr. Fisch's license as a physician. As originally instituted, the lawsuit was also brought against the members of the Mower County Medical Society, but the plaintiffs voluntarily dismissed their case against those defendants when the case was called in Court.

As operated, the Fraternal Order of Eagles at Austin, charged its members \$12.50 per year dues, and out of this amount the sum of \$4.00 per year per member was allocated for medical care, the money being divided equally between Dr. Fisch, a physician and surgeon, and Dr. Nicholsen, an osteopath.

Following the Supreme Court's decision and under date of July 15, 1940, Dr. Fisch notified the Minnesota State Board of Medical Examiners that he had resigned as Aerie Physician at Austin.

License of Hastings Physician Suspended for Three Years in the Matter of the Revocation of the License of Norbert J. Kulzer, M.D.

On July 12, 1940, the Minnesota State Board of Medical Examiners, following a hearing, suspended for three years the license to practice medicine held by Norbert J. Kulzer, M.D., of Hastings, Minnesota. The Medical Board found Dr. Kulzer guilty of immoral, dishonorable and unprofessional conduct as defined by law. The complaint against Dr. Kulzer grew out of Dr. Kulzer's alleged misconduct with a woman patient. Dr. Kulzer frankly admitted his guilt, but pleaded extenuating circumstances, and begged for leniency.

Dr. Kulzer was born at Melrose, Minnesota, in 1905, and graduated from the Medical School of the University of Minnesota in 1933. He was licensed in Minnesota by examination in 1934.

STATE LABORATORY FACILITIES

The Division of Preventable Diseases of the Minnesota Department of Health is open Saturday mornings for routine examinations. Specimens considered to be emergencies by the physicians submitting them will be examined Saturdays or Sundays on special request. Due to a misunderstanding, physicians have been under the impression that these laboratories operate on a five-day week. This is not true, since the laboratories are open 365 days in the year.

To serve physicians who occasionally must have specimens examined immediately, service is available in the morning on Saturdays, Sundays and holidays, and a twenty-four-hour service is maintained for pneumococcus typing. Although the Division of Preventable Diseases requests that emergency work be kept at a minimum, its facilities are available seven days each week.

MINNESOTA DEPARTMENT OF HEALTH

A. J. Chesley, M.D.

Secretary and Executive Officer

MINNESOTA MEDICINE

OF GENERAL INTEREST

A practice has been established in Badger by Dr. Herman J. Holte, formerly of Seattle, Washington.

* * *

Dr. E. L. Baker of Minneapolis rounded out thirty years of practice in Minneapolis, July 15.

* * *

A new hospital building was recently opened in Tracy under the guidance of Dr. W. H. Valentine.

* * *

Dr. and Mrs. Walter H. Ude of Minneapolis spent a month's vacation in Alaska and the Canadian Rockies. They left Minneapolis, June 22.

* * *

Dr. Meyer Z. Goldner has opened offices at 1129 Medical Arts Building, Minneapolis, for the practice of orthopedic surgery.

* * *

Dr. Milo H. Larson, of Norwood and Cologne, has returned to Nicollet, repurchasing his practice and the Nicollet Hospital.

* * *

Drs. John A. C. Leland, Jr., and Frederic F. Wipperman have been commissioned Lieutenants (junior grade) in the Medical Corps, U. S. Naval Reserve.

* * *

Dr. N. F. Musachio, who has been associated in practice with Dr. Clarence Henry of Milaca for the past year, will locate soon in Foley, it is announced.

* * *

Dr. A. E. Osterberg of Rochester attended a meeting of the Committee on Chemical Service to Medicine of the American Chemical Society in Ithaca, New York, June 28.

* * *

Reclassification of employees of the Minnesota State Department of Health under the new civil service act is under way, and adjustments are now being made in the department.

* * *

Dr. and Mrs. W. B. Dublin of Rochester have gone to Fort Steilacoom, Washington, near Tacoma, where Dr. Dublin has become associated with the Western State Hospital as pathologist.

* * *

To become associated with the Lemley Clinic at Rapid City, South Dakota, Dr. R. S. Ahrens has resigned as assistant superintendent of the Fergus Falls State Hospital.

* * *

After practicing medicine in Nicollet village since April, 1939, Dr. C. F. Wohlrabe has moved to North Mankato where he has opened an office at 300½ Belgrade Avenue.

* * *

Dr. R. K. Dixon of Denver, formerly of Rochester and St. Charles, flew to Minnesota to participate in dedicatory exercises of Crystal Springs trout ponds near St. Charles, June 29.

Dr. William A. O'Brien of Minneapolis will give the banquet address at the meeting of the American Hospital Association in Boston, September 19. His topic will be "An Education Program for Hospital Administrators."

* * *

Dr. C. L. Warren of Chicago, a former Minnesota physician, passed away June 25 in Chicago. His wife and four children, Eugene, Clark, Florence and Chester, survive. Dr. Warren practiced at LeRoy and at Brewster.

* * *

Dr. Robert S. Hunt, a graduate of Northwestern University Medical School, has located at Fairmont where he is associated with Dr. R. C. Hunt in the Hunt Hospital. He interned at St. Mary's hospital in Minneapolis and at the Cook County Hospital, Chicago.

* * *

Dr. Hugh R. Butt of Rochester addressed a meeting of the American Association for the Advancement of Science, research conference on the subject of vitamins, at Gibson Island, Baltimore, July 19. His subject was "Clinical Studies of Vitamin K Deficiencies."

* * *

Winners of Hospital Day awards, as announced by the Council on Public Education are: large hospital class, the Nopeming Sanatorium of which Dr. A. T. Laird is the director; small hospital field, the Glenwood Hospital, of which Dina Bremness is the superintendent.

* * *

Dr. S. Marx White of Minneapolis has been elected to the Hennepin County Sanitarium commission. He succeeds Dr. F. E. Harrington. Dr. White previously served on the commission for eighteen years, from 1919 to 1937.

* * *

Dr. J. A. O'Hanlon has opened an office in Norwood, Minnesota. A graduate of the Marquette University Medical School at Milwaukee, he has been associated with the Webber Clinic in Duluth for the past four years.

* * *

New Diplomates of the American Board of Obstetrics and Gynecology through qualifying in the June examination held in Atlantic City are Drs. Charles Hugh McKenzie, Owen Francis Robbins and William Paul Sadler of Minneapolis.

* * *

Dr. Rollin E. Cutts, until recently of Minneapolis, is associated with the department of child hygiene in the Illinois State Department of Health at Springfield, Illinois. While practicing in Minneapolis, he was on the staff of the University of Minnesota Medical School, pediatrics department.

* * *

Dr. Morris Fishbein of Chicago, editor of the *Journal of the American Medical Association*, addressed members of the Mayo Clinic staff and Fellows of the Mayo Foundation, July 26, at the Mayo Foundation

House in Rochester. His topic was "Problems Involving Medical Preparedness."

* * *

Dr. L. C. Barr and Dr. D. L. Donovan have become associated in practice in Albert Lea, establishing offices at 306 Freeborn County National Bank Building on South Broadway. Drs. Barr and Donovan practiced with the late Dr. H. D. Burns of the past five years, though recently Dr. Barr had offices of his own.

* * *

Dr. John E. Low of Saint Paul has become associated in practice with Dr. J. J. Ederer at the Mahnomen Hospital in Malmomen. Dr. Low, who received his M.D. degree from the University of Minnesota Medical School this year, interned at Ancker Hospital in Saint Paul.

* * *

Dr. H. M. Keith of Rochester was renamed president of the Minnesota Mental Hygiene Society at a meeting of the board in June. Other officers are Mrs. Stella Ames of Saint Paul, vice president; Miss Elizabeth Glynn of Minneapolis, secretarp; Stanley Hedstrom of Saint Paul, treasurer.

* * *

Dr. Theodore F. Hammermeister has resumed his practice of general medicine and surgery in New Ulm after a prolonged leave of absence. He is president of the Union Hospital Medical Surgical Staff and vice president of the Loretto Hospital Medical and Surgical Staff.

* * *

Three papers were presented by Dr. John S. Lundy of Rochester at a meeting of the Pacific Northwest Medical Association in Spokane, Washington, in July. The papers were: "Intravenous Anesthesia with Pentothal Sodium," "Choice of Anesthetic" and "Regional Anesthesia; Its Place in Present-day Anesthesia."

* * *

A new appointment to the University of Minnesota Medical School faculty is that of Dr. Lemen Jonathon Wells, who has been named associate professor of medicine. Dr. Wells held the posts of instructor of anatomy at the University of Missouri from 1935-37, and of assistant professor of anatomy since 1938.

* * *

The Minnesota State Department of Health has set up division headquarters at Little Falls to supervise sanitary engineering and public health aspects, as 50,000 men mobilize during July and August in the largest troop mobilization ever to be conducted in the state. Directing operations are Dr. Ralph R. Sullivan and Harold A. Whittaker.

* * *

Dr. and Mrs. Robert N. Bowers, who were married March 9, are making their home in Mazeppa, where Dr. Bowers began practice on August 1, 1940. A graduate of the University of Minnesota Medical School, Dr. Bowers recently completed an internship at Grand Hospital in Columbus, Ohio. Mrs. Bowers is the former Miss Lenna Guthrie of Columbus.

* * *

Dr. Ole Heiberg, a graduate of the University of Minnesota Medical School in 1935, has opened a prac-

tice in Montevideo. His offices are in the Security Bank Building. After graduating from the University, Dr. Heiberg was resident physician in the Minneapolis General Hospital for three years. For the past two years, he has been a member of a clinic in Manhattan, Kansas.

* * *

Dr. Carl W. Anderson, national champion of hurdlers in 1923-24 and now assistant medical director of the Northwest National Life Insurance Company of Minneapolis, was an official at the National inter-collegiate track meet staked at the University of Minnesota in June. He acted in the capacity of Judge of the finish. Dr. Anderson was the United States hurdler representative in the Olympic games in 1924.

* * *

Two Virginia, Minnesota, clinics will occupy offices on the second floor of a new building now being erected at Second Street South and Third Avenue in that city. The Malmstrom & Sarff Clinic, and the Morsman Eye, Ear, Nose and Throat Clinic expect to move into the building about September 1. About thirty rooms are being provided for offices and laboratories on the second floor.

* * *

Worthless checks have been passed recently in two Minnesota towns by a man who represented himself as a "Dr. Daly," looking for a location to open a practice. The checks were drawn on a Montevideo bank and came back marked "Unknown." Investigation reveals no person of that name in Montevideo. Physicians should be warned against similar attempts in other towns.

* * *

Dr. A. G. Sanderson has been elected president of the Riverside Sanatorium in Granite Falls. He fills the vacancy created by the death of Timothy O'Connor of Renville. Dr. G. H. Mesker of Olivia was chosen vice president. Members of the purchasing committee are Dr. H. A. Roust of Montevideo, B. A. Deterling of Granite Falls and Dr. Sanderson. Dr. L. S. Jordan is superintendent and medical director.

* * *

The practice of the late Dr. H. D. Burns of Albert Lea has been purchased by Dr. D. S. Branham, his former associate for ten years, and Dr. S. A. Whitson of Alden. They have taken over Dr. Burns' office in Albert Lea, and will also continue the Alden practice of Dr. Whitson who was located in that city for twelve years. Dr. Branham and Dr. Whitson have been associated in the practice of surgery for the last four years.

* * *

Dr. Harold S. Diehl, dean of medical sciences at the University of Minnesota, heads an all-university committee appointed to coördinate the university's efforts to coöperate in national defense efforts.

The defense efforts include: pushing two medical school research projects, one of which is concentrated on medical surgery and the other on human fatigue; organization of the United States General Hospital No. 26, comprising about forty medical officers; training men in the naval R.O.T.C.; participating in the civil aeronautics authority flight program; and the loaning of Dr. Elvin B. Stakman, internationally known plant

pathologist, to a federal expedition to South America to study possibility of expanding rubber production.

The university is one of four selected to assist in studies of the impact of the preparedness and defense program on business.

* * *

Equipped with the most modern facilities, two new neuro-surgical operating rooms have been opened at St. Mary's hospital in Rochester. They were built at a cost of more than \$50,000. A feature of both rooms is a glass screen which separates the operating surgeon from surgeons and nurses who may be observing. Communication is possible by means of a sliding panel in the glass. An x-ray cabinet on the wall allows the operating surgeon to study x-rays of the patient while he is working. For the benefit of spectator surgeons, a moving picture of similar operations may be exhibited in the room as an operation is being performed.

* * *

Dr. J. C. Litzenberg, professor emeritus of the Department of Obstetrics and Gynecology at the University of Minnesota Medical School, was elected president of the American Gynecological Society at the organization's meeting in Quebec, June 17-19. Dr. Litzenberg was also re-elected to the American Board of Examiners of Obstetrics and Gynecology for a five-year term.

Dr. M. J. Shapiro of Minneapolis has been named a member of the American Heart Association committee for the study of rheumatic diseases, which will devote its time to setting up standards for the care of children with rheumatic fever. The committee will publish a pamphlet on this subject early next year under the editorship of a special committee, composed of Dr. Shapiro, Dr. Edward F. Bland of Boston and Dr. Helen Brooke Taussig of Johns Hopkins Hospital in Baltimore.

Dr. Shapiro presented a paper before the American Heart Association at its meeting in New York City in June.

* * *

Among the new names in the 1940-1941 edition of "Who's Who in America," are those of sixteen Minnesota physicians. In all, there were seventy-five Minnesotans included in the volume for the first time.

New from Minneapolis are the names of Drs. George Edmeston Fahr, Arthur Douglass Hirschfelder, John Leyland McKelvey and John Charnley McKinley.

Dr. Everett K. Geer is new in the Saint Paul list.

New on the Rochester list are the names of Drs. Arlie R. Barnes, David M. Berkman, Albert C. Broders, Fred W. Gaarde, Herbert Z. Giffin, Howard K. Gray, Norman M. Keith, Frank H. Krusen, Charles W. Mayo, Robert D. Mussey and Gordon B. New, all of the Mayo Clinic staff.

Among the most outstanding members of the "Who's Who" family who have died during the biennium and consequently are no longer recorded in the volume are Dr. Charles H. Mayo and Dr. William J. Mayo. Of the sketches in the previous edition, that of Dr. Charles H. Mayo was the longest. The new edition has 31,752 names, as compared with 8,600 in the initial volume published in 1899.

The University of Minnesota medical class of 1920 has taken over the first annual membership campaign for the Minnesota Medical Foundation, it is announced by Dr. Erling S. Platou, president.

The campaign will wind up with a scientific program and reunion to be held in connection with Homecoming on the University campus next fall. Meetings will be held in the new Minnesota Union.

Membership in the Foundation is increasing rapidly and is far beyond the expectations of those first interested in this foundation of medicine, which is for all alumni and friends of the University Medical School. The Foundation prints a bulletin containing scientific articles, which is sent to all members.

A great deal of interest in the Minnesota Medical Foundation was evidenced at the reunion of the Minnesota medical alumni held at the Madison Hotel in New York City during the meeting of the American Medical Association. Approximately fifty persons, including many residing in the East, attended the reunion, at which short informal talks were given by Dr. H. S. Diehl, Dr. Platou and Dr. Harold G. Benjamin, president of the Minnesota Alumni Association.

* * *

July 14 was "Ridgway Day" in Annandale, residents honoring Dr. Alfred M. Ridgway, who noted his fiftieth anniversary as a physician in that city.

Beginning practice in the "horse and buggy days," Dr. Ridgway has been the family friend, neighbor and dependable confidant of hundreds and hundreds of Annandale people in his fifty years of medical service in that community.

Regarding Annandale as a temporary location when he came there in 1890, Dr. Ridgway stayed on as his practice kept increasing each year. As "country doctor," Dr. Ridgway first used a two-wheel cart pulled by a single horse on his visits to patients through the countryside. Later, he had six horses (eight in the winter). His first motorized vehicle was a one-cylinder chain-drive Cleveland, which gave him wonderful mechanical experience.

For the past forty years, Dr. Ridgway has been a physician for the Soo Line railroad, being given that appointment following a train wreck near Maple Lake at which he gave passengers medical aid. He belongs to the Soo Surgical Society and the Interstate National Railroad Surgeons, as well as the Minnesota State and American Medical Associations. Dr. Ridgway helped to organize the Wright County Medical Society nearly fifty years ago.

Before studying medicine, Dr. Ridgway was a registered pharmacist in Minneapolis. To obtain funds to study medicine, he opened a real estate office in Minneapolis in January, 1886. Business was so good that in September he had enough money to enroll in the University of Minnesota Medical School. He interned at the Minneapolis General Hospital.

Since 1930, Dr. Ridgway has been assisted in his practice at Annandale by Dr. Lester H. Bendix, a graduate of the University of Minnesota Medical School in the class of 1930.

In Memoriam

Hiram D. Burns

Dr. Hiram D. Burns, for nearly twenty-five years one of the leading physicians of Albert Lea, died very suddenly June 19 while visiting his farm near his home.

Dr. Burns was born at Litchfield, Minnesota, March 20, 1889. He spent his boyhood in Minneapolis and at Omaha where he graduated from high school in 1908. He received his medical degree from the University of Nebraska Medical School in 1914. At medical school he was a member of the Phi Rho Sigma medical fraternity. His internship was served at the Clarkson Memorial Hospital of Omaha.

In 1915, Dr. Burns married Corinne Searle of Omaha and came to Albert Lea to practice.

Dr. Burns has shown an interest in community activities having been past-president of the Chamber of Commerce and the Rotary Club, a member of the Y.M.C.A. Board of Directors and the school board and a devoted worker in the First Presbyterian Church. He was a man of good judgment and of deep personal convictions in matters of civic affairs. He was not deterred by any type of opposition from giving able expression by word and action to his convictions. He was successful in his profession, a loyal friend—and will be greatly missed by this community, its hospital and entire staff. He was also a 32nd Degree Mason.

He was associated at first with the late Dr. R. G. Stevenson and later with Dr. Leo Donovan. He was a member of the Freeborn County Medical Society, the Minnesota State and American Medical Associations. At one time he served as president of his local medical society.

Dr. Burns' avocation was farming and he has built up some of the finest dairy herds in the country.

He is survived by his widow; a son, Robert Burns, and three daughters, Catherine, Alice and Marjorie. His mother, Mrs. Alice Burns, and a brother, Dr. Douglas Burns of Omaha, also survive.

—A. GULIXSON, M.D.

Malvin M. Hauge

Dr. Malvin M. Hauge of Clarkfield, Minnesota, died at his home on January 31, 1940, of myasthenia gravis, aged sixty-three.

Dr. Hauge was born in Bremangerpollen, Norway, February 6, 1876. Left fatherless at the age of one year, he spent the early years of his life as a clerk and sailor, traveling in foreign waters extensively, until shortly before he came to this country in 1897. He came directly to Minneapolis where he started as a student

at Augsburg Seminary. Dr. Hauge received his Master of Arts degree from Augsburg Seminary in 1902, and his Doctor of Medicine degree from Hamline University School of Medicine in 1907. In 1914, he took a postgraduate course in the postgraduate school of Medicine, University of Vienna, Vienna, Austria. In 1936, he became a member of the American College of Surgeons.

Dr. Hauge was married in Minneapolis, April 4, 1903, to Anna Schjelderup. He is survived by his wife and six children, Malvin, Cecelia, Waldemar, Erling, Bergliot, and Dagmar.

He began the practice of medicine in Clarkfield in 1907, continuing there until a few months before his death. In addition to carrying a large practice, Dr. Hauge was a leader in both civic and musical circles. He was a member of the Camp Release District Medical Society, the Minnesota State Medical Association, and the American College of Surgeons.

William D. Kelly

Dr. William D. Kelly was born in Saint Paul in 1864. He was the eldest son of Daniel and Mary Kelly, pioneer settlers of Saint Paul. He attended the parochial and public schools in Saint Paul, where he received his preliminary education. Later he entered the Philadelphia College of Pharmacy and after graduating from that institution he matriculated at Jefferson Medical College in Philadelphia, from which he received a degree in 1887.

Returning to Saint Paul he began the practice of medicine and was active in his profession until shortly before his death, which occurred in St. Joseph's Hospital, April 7, 1940. During the course of his medical career, Dr. Kelly served on the staff of both the Ancker and St. Joseph's Hospitals. He spent two years in the late nineties visiting the various surgical centers in continental Europe, and also visited clinics in Edinburgh and London.

He was a one time member of the American Medical Association, the Minnesota State Medical and the Ramsey County Medical Society. He was also an honorary member of the University of Minnesota chapter of Alpha Kappa Kappa fraternity. Dr. Kelly served for several years, beginning in 1904 with the rank of Major, in the hospital service of the Third Infantry of the State of Minnesota. For more than twenty years he was the medical representative of the Milwaukee Railroad in Saint Paul and also served as medical officer to the Federal Court of this district for many years. Dr. Kelly was an active member of the Junior Pioneers and the Knights of Columbus and a former member of the Benevolent Order of Elks.

REPORTS and ANNOUNCEMENTS

MEDICAL BROADCAST FOR AUGUST

The Minnesota State Medical Association broadcasts weekly at 11:00 o'clock every Saturday morning over Station WCCO, Minneapolis, Station WLB, University of Minnesota, and KDAL, Duluth.

Speaker: William A. O'Brien, M.D., Professor of Preventive Medicine and Public Health, Medical School, University of Minnesota.

The program for the month will be as follows:

- August 3—Leg Cramps
- August 10—Hyperchlorhydria
- August 17—Embolism
- August 24—Sacro-iliac Disease
- August 31—New Dentures

AMERICAN BOARD OF OPHTHALMOLOGY EXAMINATIONS

The Board will hold only one written examination in 1941 and this will be in March in various cities throughout the country. Applications should be made before December 1, 1940.

Oral examinations will be held in May and October and a special one on the Pacific Coast if candidates warrant.

Address American Board of Ophthalmology, 6830 Waterman Avenue, Saint Louis.

AMERICAN CONGRESS OF PHYSICAL THERAPY

The nineteenth annual scientific and clinical session of the American Congress of Physical Therapy will be held September 2 to 6, inclusive, at Hotel Statler, Cleveland, Ohio. This year there will be a departure from the usual arrangements in that the mornings will be devoted to an instructional seminar with the scientific program presented afternoons and evenings. This enables physicians to economize on time by attending both the instruction course and the annual convention during the same week.

Registrants may pursue only the individual courses they desire. The complete course consists of twelve lectures from a diversified list of forty-eight. The scientific program itself consists of papers, demonstrations and motion pictures covering every branch of physical therapy. There will be a separate scientific program covering eye, ear, nose and throat subjects. Write for schedule, fees, et cetera, to the American Congress of Physical Therapy, 30 North Michigan Avenue, Chicago, Illinois.

AMERICAN NEUROLOGICAL ASSOCIATION RESOLUTION

The American Neurological Association, in its Executive Session at the Westchester Country Club, Rye,

New York, on June 7, 1940, unanimously passed the following resolution and directed its Secretary to send copies of this resolution to the Secretary of each State Board of Medical Examiners and to the editors of the *Journal of the A.M.A.* and of each State Medical Journal:

WHEREAS official statistics indicate that the immigration of refugee physicians is numerically small, representing in its totality less than 0.6 per cent of the practising physicians of this country;

AND WHEREAS such an influx of physicians from abroad cannot adversely affect the economic welfare of American physicians if the émigrés are distributed widely to those sections of the land in which they are needed;

AND WHEREAS information gathered from governmental and private investigations indicates that there are at least 2,000 communities in this land in need of immediate medical staffing which in large part cannot be supplied by the graduates of our own medical schools;

AND WHEREAS many of the demands for physicians come from states in which it has become impossible, either by reason of legal enactments or because of regulations of the State Boards, for the refugee physician to take his medical license examinations;

AND WHEREAS there now exists in New York a competent agency for diverting the unfit among the refugee physicians into non-medical fields thus making it possible only for those who are fit in training and in personality to be considered for examinations;

NOW THEREFORE BE IT RESOLVED that the State Boards of Medical Examiners in the United States shall create a uniform policy with regard to refugee physicians so as to make possible the wide distribution of these physicians to those places where they are needed throughout the land;

AND FURTHER that these uniform changes in the regulations of our State Boards shall be in the direction of the recommendations made by Dr. David L. Edsall in his article on "The Émigré Physician in American Medicine" (*Journal of the A.M.A.*, March 23, 1940, Volume 114, pages 1068-1073);

AND FINALLY that the Committee for Resettlement of Foreign Physicians of the National Refugee Service, Inc., 165 West 46th Street, New York City, shall be utilized as a clearing house for information in regard to available émigré physicians for specific placements.

—HENRY ALSOP RILEY, M.D., *Secretary.*

MISSISSIPPI VALLEY MEDICAL SOCIETY

The Sixth Annual Meeting of the Mississippi Valley Medical Society, "The Mid-West's Greatest Intensive Post-Graduate Assembly for General Practitioners," will be held at the Hotel Fort Armstrong, Rock Island, Illinois, September 25, 26, and 27, 1940. The program will be given by thirty-two clinician-teachers who will give over sixty lectures, demonstrations, round table discussions, et cetera. Further information may be secured from the Secretary, Harold Swanberg, M.D., W.C.U. Building, Quincy, Illinois.

PROCEEDINGS of the MINNESOTA ACADEMY OF MEDICINE

Meeting of May 8, 1940

The regular monthly meeting of the Minnesota Academy of Medicine was held at the Town and Country Club on Wednesday evening, May 8, 1940. Dinner was served at 7 o'clock and the meeting was called to order at 8:10 p. m. by the president, Dr. James Johnson.

There were thirty-eight members and two guests present.

Minutes of the April meeting were read and approved.

The scientific program followed.

EOSINOPHILIC LEUKEMIA OR MYELOGENOUS LEUKEMIA WITH EOSINOPHILIC HYPERLEUKOCYTOSIS.

Case Report with Discussion of the Medical Literature

J. A. LEPACK, M.D.

Saint Paul, Minnesota

Eosinophilic leukemia is a rare and much disputed disease. Only a few reports are found in the medical literature and some of those do not remain unchallenged. No doubt additional cases have been observed and studied but not recorded, because the very definition, description, and designation of what constitutes this condition varies so widely among scholars of hematology as to preclude a satisfactory discussion. The following case, typical or atypical as it may be, in accordance with the views expressed by the different hematologists, is, therefore, presented more to stimulate further discussion of the medical nature of this condition, rather than to add something new about it to our scientific knowledge.

Case Report

A man, single, aged forty-one, seeking relief for a backache, fever, abdominal distress, loss of weight, and severe pains in the hips and lower extremities, was admitted to St. Joseph's Hospital on December 1, 1939.

The past history revealed that in October, 1929, he had received treatment for a week in the hospital for chronic alcoholism, acute bronchitis, and nervous exhaustion. A month later a tonsillectomy had been per-

formed. In 1930 he received treatment again for chronic alcoholism in the hospital for two weeks. During these hospital stays, however, he had no blood examinations. On November 30, 1937, he entered the hospital on Dr. E. K. Geer's service and remained there until March 21, 1938. Positive tubercle bacilli were found in the sputum and it became necessary to collapse the left lung. He also developed an ulcerative tuberculous infection involving the proximal half of the ascending colon, the cecum, and terminal ileum. Stool examinations showed no parasites. Sedimentation rates on two occasions were 8 and 12 mm. for one hour, respectively. During this hospitalization several blood examinations were made and revealed a persistent eosinophilia.

The air in the left chest was then replenished about once a month and he remained quite well until September 1, 1939, when he was attacked by an upper respiratory infection. Gradually he grew worse and on November 15, 1939, he was tired, listless, feverish, pale and complained of severe backache, enlargement of the abdomen, abdominal distress, severe pains in the hips and excruciating aches in the lower extremities. The examination now revealed, in addition to the previous findings an enlarged liver, a large tender spleen, and a fever of 100 degrees. A myelogenous leukemia existing concomitantly with the tuberculous processes was suspected and hospitalization was advised, but delayed until December 1, 1939, when the night sweats became severe, cough marked, fever 101 degrees, dyspnea pronounced, pain more severe in the left side of the abdomen and the patient semiconscious. On admission urinalysis showed a faint trace of albumin and many hyaline and granular casts. Blood examination showed: hemoglobin 82, red blood count 4,180,000, white blood count 40,300; polymorphonuclear 45 per cent, eosinophils 30 per cent, basophils 4 per cent, small lymphocytes 11 per cent, large lymphocytes 5 per cent, monocytes 5 per cent, metamyelocytes 1 per cent, myeloblasts, 4 per cent, myelocytes 6 per cent, band cells 6, non-S-shaped 7, multilobed 21, and the laboratory commented: "Summary of findings indicates a marked myeloid reaction, which probably represents a myelogenous leukemia, although the picture seems to be atypical. The eosinophilia and toxic changes have been seen in previous examinations and the above picture seems to be superimposed upon these findings." An X-ray picture of the abdomen confirmed the presence of a large spleen extending down to the level of the iliac crest. In spite of the usual supportive measures, on the second hospital day the patient became comatose and the temperature rose to 102.4 degrees, on the third day to 105 degrees, and on the fourth, just before death, to 106.8 degrees.

Due to the peculiar temperament of the family, it is to be regretted, no punctures nor special studies were

BLOOD EXAMINATIONS

Date	12-1-37	12-22-37	2-2-38	2-5-38	3-12-38	9-15-39	12-1-39
Hemoglobin	102		94	94	94	86	82
Red Blood Cells	5,470,000		4,920,000	4,820,000	4,820,000	4,460,000	4,180,000
White Blood Cells	9,450	12,250	11,800	11,550	15,550	12,100	40,300

permissible, either before or after death, of the bone marrow and spleen and hence the scientific data of the case remain incomplete and inconclusive and thus invite justifiable argument and conjecture regarding their nature.

Comment

The most striking feature of this case is the marked eosinophilia. According to Downey⁶ eosinophilia frequently accompanies a great many diseases or disorders, some of which are: (1) parasitic infestations, like malaria, hookworm, trichinosis; (2) infectious diseases, as asthma, endocarditis, scarlet fever, rheumatic fever, intestinal tuberculosis, chronic colitis, Hodgkin's and Addison's diseases, leprosy, purpura, pyelitis and pneumonia; (3) dermatoses, like dermatitis herpetiformis, pemphigus, bulbous dermatitis, scabies, mycosis, fungoides and urticaria; (4) constitutional disturbances, such as, treated pernicious anemia, post-splenectomy, vagotonia, osteomalacia, polycythemia, gout; (5) malignant tumors; (6) drugs, like camphor, coal tars, gold, and toxic conditions due to foreign proteins.

It is reasonably certain that all the above conditions can be excluded in this case except the tuberculous colitis. That a tuberculous process of the intestines could become so severe and fulminating as to produce in the terminal three weeks of life an enlarged liver, an enormous spleen, and so active a myeloid reaction seems unlikely. Familial eosinophilia occurring not infrequently, as one notes from the excellent review of the literature and the report of eosinophilia in four families by Stewart,¹⁶ was also eliminated. To maintain, again, that this was just an individual constitutional eosinophilia appears both groundless and defenseless.

Since hematologists today recognize the ability of a leukemia to develop from the primitive myeloid cell stems or elements that eventually appear either as the polymorphonuclear neutrophil, basophil, or eosinophil, the classification and determination of each kind of leukemia would be definite and indisputable if the basophilic and eosinophilic leukemias behaved like the neutrophilic type. Unfortunately the basophilic as well as the eosinophilic types of leukemia resemble, as Groat, Wyatt, Zimmers and Field⁹ have shown, each other by keeping "toward the mature"—instead of the immature cell in the circulating blood "regardless of the company they keep." This is also true of the case under discussion. Nearly all of the eosinophils are mature. Most hematologists detest making a diagnosis of leukemia on predominantly or nearly exclusively mature cells, yet many admit the possibility that an eosinophil or basophil might well behave in such a manner and appear in the mature form in basophilic or eosinophilic leukemia. Some, therefore, are accepting reluctantly the diagnosis of eosinophilic leukemia, while awaiting a definite solution. Others again, prefer to designate such a condition as a myelogenous leukemia with eosinophilic hyperleukocytes or eosinophilic hyperleukocytosis with splenomegaly. The trend of medical writers, however, leans toward the retention of the designation of eosinophilic leukemia, at least, until there is a better understanding of this condition.

Brief Review of the Literature

Hays and Evans¹¹ in a masterly review of the subject of eosinophilic leukemia attributed the first report to Stillman¹⁷ in 1912, under the title "Myeloid Leukemia with Preponderance of Eosinophil Cells." The subject was a man, aged 27, who showed an enlarged liver, spleen and cervical, inguinal and epitrochlear glands. The blood Wassermann was positive and the urine contained a trace of albumin and some casts. The white cells varied from 118,000 to 165,000 per c. mm. of which number 85 to 91 per cent were eosinophils (polymorphonuclear 69.8—metamyelocytes 19.4—myelocytes 1.8). It is stated that the eosinophils were larger than normal, but the granules somewhat smaller. What happened later to the patient is unknown. Giffin⁸ studying a man, aged thirty-one, who complained of dyspnea and pain in the chest, found in addition to marked evidences of cardiac decompensation, a large liver, spleen, and axillary glands. The white count was 15,400, of which 66 per cent were eosinophils but myelocytes were very rare. After the removal of the spleen, which weighed 2,100 grams, the white count reached 208,000 in ten months and the eosinophils accounted for 79 to 90 per cent. After six years death ensued. The necropsy revealed a broncho-pneumonia, chronic pleurisy, obliterative pericarditis, fibrous perihepatitis, cirrhosis of the liver and a hyperplastic bone marrow. He concluded thus: "I am inclined to regard the case as an instance of eosinophilic hyperleukocytosis, the blood picture of which was remarkably altered by splenectomy." Shapiro¹⁴ reported a man, aged forty-nine at death, with a five year illness, who had a large spleen and liver and palpably enlarged inguinal and epitrochlear lymph nodes. The Wassermann was strongly positive and the white count read 19,800 with 70 per cent eosinophils. In less than a year it reached 236,000 with 79 per cent eosinophils, most of which were of the adult type. Autopsy showed a large liver, and spleen, and cellular marrow with numerous eosinophils, both myelocytic and polymorphonuclear, also numerous myeloblasts. He, therefore, came to the conclusion that this was a case of leukemia arising in the eosinophil system of cells. Again in 1922 McDonald and Shaw¹³ reported a man, aged forty-six, with digestive disturbances for several years' duration, who had a large spleen and white cell count of 34,000 with 71 per cent eosinophils. The removed spleen weighed 1,276 grams. Some fourteen months after the splenectomy, the white cell count had risen to 138,000 with 84 per cent eosinophils, of which around 98 per cent were the adult type and 2 to 8 per cent myelocytes. Sometimes basophilic granulations were mixed with the eosinophilic ones. The patient died within two years. No autopsy was done. The authors are inclined to view the case as more allied to leukemia than any other condition. Alexander¹ studying a man, aged forty-seven, five years after a splenectomy, noted marked asthenia, pronounced anemia and dyspnea. The spleen weighed 2,200 grams and had been removed for the anemia. While the blood count before the splenectomy was only 9,400 it was now 150,000 of which 24 per cent were eosinophils. Later the red blood count too

fluctuated between 1,200,000 and 4,300,000; the white count, between 19,000 and 70,000; and the eosinophils constantly averaged about 30 per cent. Necropsy showed a large liver and cellular bone marrow with many eosinophils. This case was considered to be an atypical form of myelogenous leukemia.

In 1925 Bass³ reported an unusual eosinophilia with splenomegaly in a child aged six. Clinically she had rickets, but in addition the spleen, liver and cervical glands were enlarged. The blood showed: hemoglobin 80, red blood count 4,300,000, white blood count 25,000 of which 64 per cent were eosinophils. Death followed from a broncho-pneumonia in two months, but no autopsy was obtained. Evans and Hays¹¹ described in 1928 a case of acute eosinophilic leukemia in a man, aged forty-one, which the course of the disease ran to a fatal termination in less than three weeks. The eosinophils constituted over 83 per cent of the total white blood count of 72,187. A study of the eosinophilic cell showed 75.5 per cent polymorphonuclear, 3.8 per cent myelocytes, and 4.4 per cent metamyelocytes. Furthermore, they varied considerably in size and seemed to be larger than normal. The granules, too, varied in size. Sometimes they appeared larger than normal but at times they were very fine or almost totally absent in certain areas of the cytoplasm. At autopsy the bone marrow was found to be very cellular and the spleen markedly infiltrated with eosinophils as well as the lymph nodes and liver. They state, "It is curious that in this as in other reported cases, the eosinophils were mainly of the adult type, considering the acute nature of the disease (three weeks) this case seems unique in medical literature."

Harrison,¹⁰ in 1930, reporting the case of a man, aged 33, who died of eosinophilic leukemia, called attention to the increased metabolic rate. The case showed a basal metabolism of plus 35 per cent and at autopsy in addition to the usual eosinophilic infiltration in all the organs contained multiple small hemorrhages in the lungs resembling tuberculosis. The white blood count averaged 13,000 to 16,000 of which 55 to 60 per cent were mature and one per cent immature eosinophils. Bass,⁴ reporting a second case in a boy, aged eight, in 1931, found also an increased basal metabolism, namely, plus 31 to 48 per cent. The white blood cells in this case were also predominantly mature, ranging from 32 to 76 per cent in eosinophils in a count of 26,400 to 47,000. Bone biopsy showed myeloid hyperplasia. Stephens¹⁵ reported a girl, aged seventeen, with severe petechial hemorrhages. An acute leukemic state became superimposed on a chronic form and the patient died in less than two weeks. The white blood count reached 130,000 of which 67 per cent were mature and one per cent immature eosinophils. Forkner's⁷ case, a man, aged thirty-three, reported in 1937, developed after an extraction of an upper molar tooth, severe weakness, sore throat, listlessness, and hemorrhagic spots over the whole body. The platelets fell to 5,000 and the leukocytes ranged between 118,000 and 254,000 of which 75 to 81 per cent were eosinophils. The whole course of the disease ran less than a month. In the acute form of eosinophilic leukemia,

the author states, the length of the disease runs from twelve days to three months.

Thomsen, Stig, and Plum¹⁸ studied a boy, aged eleven, with eosinophilic leukemia which followed an acute tonsillitis. After radiation the spleen decreased in size and the white blood count fell from 65,000 to 5,000, of which 70 to 90 per cent were eosinophils. Eight months later, however, the gradual growing enlargement of the cervical glands was treated again by radiation. After a stationary four-month period myeloblasts appeared in the blood stream, mature eosinophils disappeared and the bone marrow showed no further stem cells. At autopsy a leukemic condition of the bone marrow was found. This case showed in the clinical course a transition from the typical eosinophilic leukemia to an entirely myeloblastic leukemia. The authors in discussing eosinophilic leukemia state: "Hematologically it is characterized by an enormous, absolute and relative increase in the number of eosinophilic granulocytes, but the dominating cell-form has a particular mature appearance, with a segmented nucleus and coarse granulation. On close examination these cells are found to differ considerably from the normal eosinophil granulocyte."—They are considerably larger, and the nuclei are more loose in structure than normally. The protoplasm is more abundant, and most often distinctly basophilic, the granules are abnormally large, and their number is far smaller than in normal eosinophils: and often the granules are heaped together in a single accentuated group. Histologically the bone marrow, spleen, liver, kidneys, and lymph glands show marked infiltration with eosinophilic granulocytes essentially of the same form as described above."

Broadly speaking laboratory studies and clinical observations point to wide variations not only in the course of certain white blood cells but also in the response of the blood-forming organs. One is almost forced to admit that under favorable conditions, any white cell, be it a lymphocyte, mononuclear, basophil, eosinophil, or neutrophil may decrease or even disappear from the circulation or again increase slightly, moderately or overwhelmingly either in mature, mixed, or immature forms. Thus, for example, the mononuclear cell might be leukopenic, hyperleukocytic, as in infectious mononucleosis, or leukemic as in monocytic leukemia. Whether or not the immaturity of the cell, to the total exclusion of the predominantly mature character of the cell with fatal termination of the case, should be the only guide in designating or classifying basophilic and eosinophilic leukemias remains still a debatable question. The tendency, however, seems to be to accept a case as eosinophilic leukemia, which has a white blood count very high in eosinophils, a large spleen, large liver and enlarged lymph glands with a fatal termination despite the largely or predominantly mature character of the eosinophil. Downey,⁶ however, leans toward the acceptance, as myelogenous leukemia, of all the conditions showing immaturity of the polymorphonuclear cell in the blood stream, and a very actively increased cellular bone marrow, regardless of whether they make their appear-

ance through the eosinophilic, basophilic, or neutrophilic routes or systems.

Summary and Conclusions

1. A case of pulmonary and intestinal tuberculosis with a high eosinophilia extending over a period of three years is reported, terminating in the last three weeks of life with a large spleen, enlarged liver, fever, and an atypical bone marrow reaction suggesting, according to some hematologists, an eosinophilic leukemia and according to others a myelogenous leukemia with an eosinophilic hyperleukocytosis.

2. Emphasis is placed on the fact that basophilic and eosinophilic leukemias, if such exist, do not conform to the established and time-honored scientific prerequisites of a leukemia based exclusively on the immaturity of the cellular elements, since the eosinophils or basophils are predominantly mature.

3. A review of the reported cases in medical literature favors the retention of the nomenclature of eosinophilic leukemia, at least until adequate studies of scientific clarification either confirm, alter or reject this designation.

Discussion

DR. E. K. GEER, Saint Paul: Inasmuch as I attended the patient to whom Dr. Lepak has alluded, for his tuberculosis, there are a few remarks I would like to make. In the first place, most tuberculous persons reveal no serious or marked blood changes. The most common blood finding in chronic pulmonary tuberculosis is hypochromic anemia of varying degrees, usually not marked. If it is marked, causes other than tuberculosis should be suspected. Of the serious blood dyscrasias, I have yet to see pernicious anemia in a tuberculous individual. I recall one case of chronic lymphatic leukemia which developed in a patient at Pokeg-

ama Sanatorium who was doing a good job of controlling her tuberculosis. If the case presented this evening is a true myelogenous leukemia, it is the first one I have seen coexisting with tuberculosis.

This patient made very satisfactory progress with artificial pneumothorax for his lung tuberculosis, his left upper lobe being closed thereby. The usual regime for intestinal tuberculosis controlled his enterocolitis and after leaving the hospital he remained well until an apparent throat infection in September, 1939, for which Dr. Lepak attended him. From this episode he did not make a complete comeback although he was up and around. In October, when he came to my office for his monthly pneumothorax refill he looked washed out, so I gave him a general physical examination. At the time no enlargement of his liver or spleen was apparent but a change was noted in his blood picture, premature cells being evident. He returned in a few days at my request to have this checked and then was advised to have consultation.

The next thing I knew of him was after his last admission to the hospital. The dramatic downhill course has been described by Dr. Lepak.

The eosinophilia which was noted while he was being treated in the hospital for tuberculosis was unexplained. He certainly was suffering from none of the disorders commonly associated with an increase of eosinophils in the circulating blood. When he developed symptoms suggesting a tuberculous enterocolitis and substantiating evidence was forthcoming with a barium enema, I was inclined to explain the eosinophilia on that basis, having noted it in the literature but never having seen it in patients under my care either before or since.

DR. H. Z. GIFFIN, Rochester: I think Dr. Lepak would want me to say something about the case I reported in 1919 which proved to be the second case in the American literature. The patient in that instance showed a very marked eosinophilia of from 70 to 90 per cent and developed a severe leukemoid reaction following splenectomy. At postmortem examination, an extensive chronic infectious process was found involving the pericardium and the peritoneum. Cases similar to Dr. Lepak's case and mine have been reported in the literature and I believe it is most logical to regard this particular type of case as not falling into the group of true leukemias. However, in the literature one finds three types of cases: (1) cases of chronic type in which the eosinophilia seems to be secondary to some other process; (2) cases in which the condition begins very much as it did in Dr. Lepak's case and in which, later, there develops a true picture of leukemia with many myeloblasts in the blood; and (3) a type in which the process is of very short duration and an acute myeloblastic leukemia develops. Four or five of these acute cases have now been reported and I do not see how we can regard them as entirely secondary, especially in view of the high percentage of myeloblasts present and the short history which, in some instances, is only of a few weeks' duration. For the sake of argument at least, I am willing to say that there are also two types of cases of the more chronic condition, one type which develops a leukemoid reaction and the other which is a true leukemia.

DR. JOHN F. NOBLE, Saint Paul: This case of Dr. Lepak's has been very interesting to me, particularly so because about a year previous to this case, we had a somewhat similar experience. I am not at all convinced that there is such a thing as a true eosinophilic leukemia. I say that on the authority of Dr. Downey, and the statement is supported by my own experience. Several years ago we saw a patient, a man, aged 28, who stated that he had been well until six years before his admission to the hospital when he developed asthma following an attack of bronchitis. During the first year

the asthmatic attacks were infrequent and were associated with respiratory infections. A change in climate gave the patient a year when he was free from symptoms, but after a recurrence of his asthma a similar change in climate gave him no relief. The patient had been taken care of by a number of physicians and he had received all the usual types of therapy, including vaccines, calcium gluconate, adrenalin and ephedrine. Protein sensitivity tests were negative, and clinically it was felt that the patient had asthmatic bronchitis on an infectious basis.

The eosinophilia was first noted in October, 1937, at which time there was 10.5 per cent present. A careful study of the smears at this time showed no abnormality. His complaint at the time of his admission to Ancker Hospital was severe abdominal pain of such degree that at one time a laparotomy was considered. There was a palpable mass in the left side of the abdomen which was thought to be the spleen. Our blood studies showed as high as 77 per cent eosinophils. About 6 per cent of promyelocytes were observed, but these were the most immature cells seen, though many of the eosinophils showed changes which were interpreted as slight immaturity. These changes were a lack of typical staining characteristics of the eosinophilic granules.

Clinically this patient was considered as a possible eosinophilic leukemia and even at autopsy the infiltration of his organs suggested this diagnosis. More careful study, however, showed that the picture was that of a periarteritis nodosa and not a leukemia. The palpable mass in the abdomen proved to be a massive retroperitoneal hemorrhage from an aneurysm of a small renal artery.

In reviewing the literature of periarteritis nodosa and eosinophilic leukemia, the similarity in the sex distribution, the clinical symptoms and the blood picture in the two groups of cases was striking, and I wonder how many of the cases of so-called eosinophilic leukemia may be periarteritis nodosa.

DR. MOSES BARRON, Minneapolis: This is a very interesting case that has been presented tonight and I am very glad Dr. Lepak reported it although I may disagree with his conclusions. An increased number of eosinophils is found in the blood of various conditions. In the foreign literature it is often reported that it is associated with some cases of tuberculosis. Loeffler described a syndrome of a peculiar spreading lesion in the lungs associated with an eosinophilia that ranged from 10 to 66 per cent. His cases were principally associated with tuberculous lesions and with asthma. In the case presented tonight it seems to me the blood picture did not show the presence of a sufficient number of myelocytes. Dr. Lepak stated that, although an eosinophilia had been present for several years, no promyelocytes, myelocytes or metamyelocytes were found until a month before death. One has to consider trichiniasis as a cause of eosinophilia. I do not believe that there is enough evidence in this case to consider it one of leukemia. It is difficult to state what was the actual cause of death. It is unfortunate that postmortem examination was not obtained. I would like to know how large the liver became, as well as the spleen. What was the blood picture at the time the diagnosis of leukemia was made?

DR. THOMAS J. KENYON, Saint Paul (by invitation): An eosinophilia was first noted in this patient in December, 1937, at which time it was 15 per cent. Another blood study was made in the latter part of December 1937 and revealed an eosinophilia of 20 per cent. During 1938, the eosinophilia ranged from 15 to 18 per cent. On September 15, 1939, the patient's hemoglobin was 86 per cent, the white count 12,100, red count 4,465,000, the color index 0.97. A differential count revealed the polymorphonuclears to be 32 per cent, the eosinophils 25 per cent, basophils 2 per cent,

lymphocytes 35 per cent, and the monocytes 6 per cent. Of the neutrophilic series alone, 1 per cent were myelocytes and 5 per cent of them were band cells. On December 1, 1939, the hemoglobin was 82 per cent and the white blood count was 40,300. The red count was 4,180,000 and the color index 1. The differential count revealed the polymorphonuclears to be 45 per cent, eosinophils 31 per cent, basophils 4 per cent, lymphocytes 16 per cent and monocytes 5 per cent. Of the entire granulocytic series, 4 per cent were myeloblasts, 6 per cent myelocytes, 1 per cent metamyelocytes and 6 per cent band cells.

As to the slides that were shown, slide I shows two eosinophils. Most of the eosinophils noted in this blood slide were of the mature type. Slide II shows a myeloblast with its narrow zone of cytoplasm and a few azure granules. The nucleus presents the typical sieve-like appearance with two nucleoli. There is an early nucleated red cell in this slide. Slide III is another myeloblast or stem cell. Slide IV shows a myeloblast and a leucoblast. There is also a basophil and neutrophilic metamyelocyte present. Slide V shows a promyelocyte and a neutrophilic metamyelocyte. Slide VI shows a nucleated red cell, basophil, a neutrophilic metamyelocyte and a neutrophil. Slide VII shows four eosinophils.

In studying blood slides made in September and December 1939 we thought that we were dealing with a myelogenous leukemia and did not attach any particular significance to the eosinophilia. It was also Dr. Downey's opinion, in the blood picture of these slides, that we were dealing with a myelogenous leukemia.

DR. E. K. GEER: Apropos of Dr. Barron's remarks concerning a European report which dealt with eosinophilia in tuberculous patients, may I add that we must have a different brand of the disease in this part of the United States; one that doesn't stimulate eosinophil formation. I am sure Dr. Noble will bear me out in this statement at least as far as patients on the tuberculosis service of Ancker Hospital are concerned.

DR. LEPAK, in closing: I am very grateful for the generous discussion of this unusual condition. The reported case was intended to serve that purpose. So far as I am concerned, the case remains doubtful since we did not have a postmortem examination. Every one can think, therefore, as he pleases about its exact nature.

DR. BARRON: How large was the spleen? How much do you think it might have weighed? And how large was the liver?

DR. LEPAK: The spleen extended down below the left iliac crest and might have weighed about 2,000 grams. The liver was found to extend about one inch below the umbilical line.

HOURL-GLOSS-SHAPED MENINGIOMA INVOLVING MEDULLA, FORAMEN MAGNUM AND CERVICAL REGION

GEORGE N. RUHBERG, M.D.,

Saint Paul, Minnesota

Hour-glass tumors although not rare are of sufficient infrequency that in many situations unless one has been conditioned to them by clinical experience or met them at the autopsy table their possibility is often overlooked.

They arise from the membranes, nerves, and ganglions of the spinal cord, from the sympathetic nervous system, from the ligaments in or about the verte-

bræ, from the cartilage of the auricular surfaces of the vertebrae and ribs and rarely from the epidural fat. The larger number have arisen from the membranes, nerves, and ganglions of the cord.

Their method of growth may be as follows:

1. Arising within the spine, growing outward and extending through an intervertebral foramen and enlarging again in the paravertebral structures.

2. Arising without the spine and progressing into the spinal space and enlarging.

3. Arising within the intervertebral foramina and growing in both directions.

4. According to Coenen these tumors take a passive and not an active part in determining their shape. They are present as tumors, possibly as spherical tumors, before the development of the skeleton, whose development impinges upon them and give them their shape.

The case presented tonight is that of a meningioma assuming an hour-glass-shape by springing from the medulla, passing through the foramen magnum and presenting as a mass in the posterior cervical region.

E. D. L., a colored boy of four years, was admitted to the Children's Hospital, Saint Paul, on January 1, 1940, because of stiff neck, pain in the neck on movements of the head, tilting of the head and a mass in the posterior cervical region. Present illness as stated by patient's uncle began two years ago after falling down stairs. Since that time he has carried his head turned to one side.

On physical examination, he was well developed and fairly well nourished, and in no acute distress or pain. Temperature was 100 2/5 rectally and varied from 99 to 100 degrees during hospitalization. He held his head tipped forward and rotated to the right side in a fixed position. On attempting to move his head from side to side he would turn his whole body. He cried when an attempt was made to passively turn, flex or extend the head. The cranial nerves and eye grounds were negative. There was some exudate in the nose. The throat was slightly injected. There was a large "cervical gland" on the right side behind the ear. This was hard and fixed. The lungs were clear. The heart was normal. The abdomen was essentially negative. The extremities showed normal reflexes. Movements of his head caused pain.

Laboratory studies of urine and blood were essentially negative. Wassermann and Mantoux tests were negative. Roentgenogram of the cervical spine was essentially negative. The chest showed moderate pulmonary congestion and bronchitis. The mastoids were negative. No definite diagnosis was made.

On January 27, 1940, a neurological examination by the writer revealed objective findings as follows:

1. Head held tilted forward and to the right.
2. Stiff neck and painful reactions on attempted movements of head.
3. Loss of left upper extremity and diminished biceps reflex.

4. Sustained left ankle clonus and increased reflexes of left lower extremity.

5. Spinal fluid showed a cell count of 4 and total protein of 210 mg.

6. Sensory findings were not reliable on account of lack of coöperation of the patient.

A diagnosis of a central nervous system involvement of the upper cervical region was made and a biopsy recommended of the "cervical gland." On account of the rapid decline in the patient's physical condition this was not carried out. Paralysis spread to both arms and left leg by January 30 and he died February 1, 1940.

Necropsy findings were essentially unimportant with the exception of the findings relative to the lesion involving the neck and central nervous system.

A subcutaneous tumor mass resembling an enlarged lymph node was found in the posterior portion of the right neck just behind the ear. It measured 4 x 2.5 x 2 cm., and it was firmly attached to the border of the foramen magnum on the right side. On section, this tumor consisted of pale yellowish gray cellular tissue, which was soft and friable. Examination of the cortex was grossly negative. On lifting the cerebrum there was found a well encapsulated rounded slightly lobulated tumor measuring approximately 3 cm. in diameter and arising by a pedicle from the dura over the right anterior surface of the lower posterior portion of the medulla and completely occluding the foramen magnum and in so doing, displacing the medulla to the left and posteriorly and compressing it. On the right side this tumor infiltrated through the foramen and directly connected with the tumor in the neck. It consisted of soft, yellowish gray cellular tissue similar in character to that found in the neck tumor. A diagnosis was made of:

1. Meningioma of the medulla with extension into neck and compression myelitis of the medulla.

This case is an example of so-called hour-glass-or dumb-bell-shaped tumor of intracranial and cervical involvement, exhibiting the syndrome of tilting head and signs of compression myelitis described by Elsberg and others in cases of tumors involving the foramen magnum. Appreciation for the opportunity of examining this case is acknowledged to Dr. George Hagerman, on whose service the patient was, and to Dr. Kano Ikeda, who performed the autopsy and made the microscopical diagnosis.

Discussion

DR. J. F. NOBLE, Saint Paul: I have nothing special to add to the discussion of this case. I have never seen a meningioma in a child of this age. From the lantern slides it seems to me that a diagnosis of meningioma is justified, and, since that was Dr. Bell's diagnosis, I can see no reason for doubting it.

The meeting adjourned.

A. G. SCHULZE, M.D., *Secretary.*

Stated Meeting, Thursday, December 7, 1939

President, DR. WILLARD D. WHITE, in the Chair

Secretary, DR. HARVEY NELSON

GASTROJEJUNAL ULCER FOLLOWING GASTRO-ENTEROSTOMY PERFORMED TWENTY-FOUR YEARS BEFORE FOR PYLORIC STENOSIS OF INFANCY

L. HAYNES FOWLER, M.D.

and

WILLIAM A. HANSON, M.D.

Minneapolis

This patient was a young man twenty-four years of age. He consulted us in June, 1938, on account of recurring attacks of epigastric pain accompanied by hematemesis and melena. He stated that he had had a gastro-enterostomy performed on account of pyloric stenosis when he was six weeks of age, i.e., in 1914. He grew to young manhood and had no symptoms relative to his stomach until six years ago, when he was eighteen years old. For the past six years he has had intermittent attacks of epigastric pain which were at first relieved by food, soda and an ulcer diet but which recently have become almost constant and much more severe. During these six years he has been hospitalized three times on account of severe bleeding, for which he has had several blood transfusions.

Physical examination was essentially negative. He was a well developed and well nourished young man. The abdomen was slightly tender to the left and above the umbilicus. Examination of his blood showed a moderate degree of secondary anemia.

X-ray examination of the stomach showed a large well-functioning gastro-enterostomy with a large area of ulceration on the jejunal edge of the stoma. Some of the barium could be forced through the pylorus.

A diagnosis of gastrojejunal ulcer was made and surgical treatment advised.

Operation was performed June 23, 1938, at Northwestern Hospital, under a general anesthetic. On opening the abdomen, a large opening from a posterior gastro-enterostomy was found. The pyloric outlet seemed smaller than normal, barely admitting the tip of the index finger. The stomach and duodenum were otherwise normal. The transverse mesocolon was dissected free from the posterior wall of the stomach, and the gastro-enterostomy taken down. There was a large necrotic ulcerated area on the proximal jejunal side of the stoma. This was excised, and the two large openings in the stomach and jejunum measuring four inches long were closed separately with two rows of chromic catgut reinforced with silk. A pyloroplasty was then done by making a longitudinal incision one and one-half inches long through the full thickness of the duodenum, pyloric muscle and stomach, and then suturing the same in a vertical direction, thus enlarging the outlet of the stomach. The abdomen was closed without drainage. The immediate postoperative condition was good. Continuous nasal suction was employed for four days. On removing the tube, the patient became very uncomfortable, the upper abdomen became distended and on reinserting the tube, 1500 c.c. of gastric retention was removed. After twelve days of temporizing, we felt satisfied there was complete obstruction, either at the pylorus or in the upper jejunum. The abdomen was re-opened. We found the pylorus in good condition. The loops of jejunum at and near the portion which had been detached from the stomach formed a mass of

distended, red, obstructed bowel, adherent in a rent in the transverse mesocolon. We first attempted to free these distended loops but found this impossible. We then made an entero-anastomosis between the jejunum distal to the obstruction and the duodeno-jejunal angle. On account of the limited space, this was done without clamps. A number 14 French catheter was inserted into the jejunum distal to the anastomosis for feeding. Following this second operation, he still continued to have considerable gastric retention. Fluid injected into the jejunostomy tube was recovered from the stomach and vice versa. A flat plate of the abdomen showed the catheter to have passed through the entero-anastomosis and extended into the transverse part of the duodenum. The catheter was removed. The gastric retention ceased, and the patient made a good recovery. A normal diet was gradually resumed, and on leaving the hospital on August 3, 1938, he was eating everything without discomfort.

An x-ray examination after the ingestion of a barium meal on November 11, 1938, showed a slight narrowing in the middle third of the stomach. The barium passed freely and rapidly into the jejunum, which had been obstructed, and also through the entero-anastomosis. Plates taken two and one-half hours later showed the stomach empty, the head of the column at the transverse colon and the tail in the lower ileum.

The patient has remained well and free from any gastric symptoms to date, which of course is only one and one-half years.

Comments

This case has several interesting features:

The first is that this six-weeks-old baby survived a gastro-enterostomy performed for pyloric stenosis. This operation was done in 1914 by a Saint Paul surgeon, name unknown, two years after Rammstedt first reported his well-known operation for pyloric stenosis.

Secondly, in a limited review of the literature we have been unable to find another reported case of a gastrojejunal ulcer forming in a gastro-enterostomy stoma performed for pyloric stenosis.

Third, the opening between the stomach and jejunum was unusually large (four inches long). Apparently the opening grew as the boy developed.

Fourth, as a result of the large stoma, there was very little tissue in the transverse mesocolon to close, which undoubtedly contributed to or caused, the postoperative obstruction.

Fifth, the essential surgical treatment consisted of disconnecting the gastro-enterostomy. It is well known that an ulcer of the stoma will heal if only this is done. Usually, gastrojejunal ulceration follows a surgical procedure done for the relief of a peptic ulcer. Such a situation ordinarily necessitates a partial gastrectomy in addition to taking down the gastro-enterostomy. In the case reported, we had no antecedent peptic ulcer. We therefore felt that a pyloroplasty was more indicated and performed the same. Time will tell whether or not our judgment was correct.

LEIOMYOSARCOMA OF THE ILEUM*

RALPH EMERSON WEIBLE, M.D.
Fargo, North Dakota

Mr. E. C. M., aged sixty-four, was a farmer weighing 200 pounds and had been well until his present complaint. He came to the hospital June 18, 1939, at 2 P. M., stating that he had fallen ill sixty-four hours previously with a severe chill and acute generalized abdominal pain. The pain subsided somewhat after a half hour and he did not go to bed. The persisting soreness seemed to him to be centered just below the umbilicus. He took no food. The day before admission he took a laxative and the bowels moved twice. At 8 P. M. he vomited. This was repeated at 3 A. M. Severe pain started again two hours before examination.

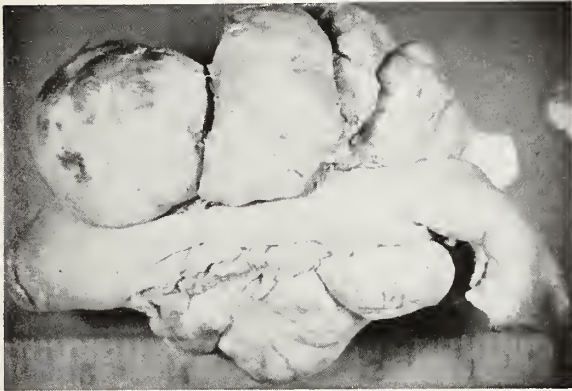

Fig. 1.

On examination the abdomen was distended and hard. No masses could be felt but it seemed he was more tender below the umbilicus. His blood pressure was 140/80, temperature 100, pulse 110. Three hundred c.c. of dark fluid were removed from his stomach. X-ray showed no free air under the diaphragm.

Under spinal anesthesia the abdomen was opened to the right of the midline. There was considerable dark, foul smelling fluid. No lesion was found in the epigastrium. A large tumor of the ileum situated below the umbilicus was brought into the wound. There was a perforated, gangrenous area in the tumor. The intestine and tumor were excised and an anastomosis of the bowel done. Fluid was aspirated and the wound closed with a drain. The patient, after a succession of complications from peritonitis, died three weeks after operation.

Leiomyosarcoma of the small intestine may be truly malignant or very mildly malignant in character. The truly malignant type are relatively small, seem to grow from the inner muscular layers, and tend to grow into the lumen of the bowel.

The mildly malignant type are large tumors projecting out from the bowel. It would seem that they grow from the outer longitudinal muscle. If operated upon before perforation occurs, the outlook is good.

A few case reports from the literature were abstracted and the subject discussed.

*From the Dakota Clinic.

CONGENITAL CYSTS AND FISTULÆ OF THE NECK

ARNOLD SCHWYZER, M.D.
Saint Paul, Minnesota

A most interesting and instructive description of branchial cleft or lateral neck cysts and fistulas and thyroglossal cysts and fistulas was given by Dr. Arnold Schwyzer of St. Paul by invitation. A very complete description of the embryology, diagnosis and treatment of these conditions was given in Dr. Schwyzer's usual thoroughness and detail. Numerous illustrative slides were presented.

Discussion

DR. MARTIN NORDLAND: It has been very pleasant and enlightening to listen to Dr. Schwyzer. He has been called upon often by Minneapolis medical societies and he always has brought something of interest and value to us. His splendid and complete presentation of this subject tonight has demonstrated how important it is to have a thorough understanding of the embryological development and the anatomy of the neck in order that one may properly diagnose and treat these lesions. Most of us have encountered cases of this nature in which the proper diagnosis was not made and as a result of this, inadequate treatment was rendered.

Dr. Schwyzer did not comment on the incidence of congenital cysts and fistulæ of the neck. In a recent article from the Lahey Clinic published in the *A.M.A. Journal*, it was reported that only .05 per cent of the total number of registrations at that clinic in a period of fifteen years from 1921 to 1936 were so classified. From the Jackson Clinic at Madison, Wisconsin, Dr. Arnold Jackson recently reported thirteen cases of lateral branchiogenic cysts encountered over a period of ten years. Cattel in a recent discussion of this subject, called attention to the infrequency of the occurrence of thyroglossal duct anomalies, by the statement that they are found to exist at a ratio of 1 to 90 as compared to thyroidectomies.

It is obvious therefore, that while the occurrence of these lesions is not rare, nevertheless, it is evident that they are encountered so seldom in the experience of the average surgeon that they are not always recognized. As a result, the proper treatment is not always administered.

It is readily seen from Dr. Schwyzer's description of these lesions that the surgical treatment must be carefully planned and executed. While it may be considered elementary, still I think it is worthy of attention that the patient should be carefully placed in good position before the operation is started. Dissection of fistulous tracts and the removal of adherent scars can then be better accomplished without accident. I was very happy to hear Dr. Schwyzer call attention to, and recommend a transverse incision. Incisions along the anterior border of the sterno-mastoid always leave ugly scars. They were abandoned years ago in the surgery of the thyroid and should never be used in any surgery of the neck. Excellent and adequate exposure for the removal of congenital cysts and fistulæ of the neck is obtained through the transverse incision.

DR. E. T. BELL: These tumors are interesting chiefly because of their rarity. This tumor is of low malignancy, barely coming into the group of sarcomas. I think the diagnosis is justified here because of the mitoses and because the tumor was steadily getting larger. The leiomyomas in the intestine as well as those

in the stomach and other situations seldom form metastases. I have only one record of a metastasizing leiomyosarcoma.

It is of interest that the myomas of the uterus which are histologically malignant, are clinically benign. We have uterine myomas with four or five mitoses per high powered field, which were cured by hysterectomy or even by myomectomy. Some of the five-year cures look very malignant histologically. In the uterus the diagnosis of leiomyosarcoma doesn't seem to carry an unfavorable prognosis with it and it doesn't demand any treatment other than what you give to a simple benign myoma.

The myomas of the stomach are of interest. I have seen two very large intraluminal myomas of the stomach. One of these had a rather interesting history. A little over ten years before the patient died, he sustained a very severe burn. Some months later he developed gastric symptoms and a diagnosis of carcinoma of the stomach was made. That diagnosis was confirmed by the best men around town; roentgenologists, as well as surgeons thought it was carcinoma of the stomach. It was maintained that the burn caused an ulcer and that the ulcer developed into a carcinoma. The man was paid compensation but he refused to die of the carcinoma—in fact, he lived for ten years. Ten years after he was awarded the compensation, he died from a perforation of the stomach. The myoma filled the stomach completely and was of enormous size. There was just a little rim of space left in the stomach around the tumor. The tumor extended the whole length of the stomach and had caused an ulceration through the wall. The pressure on the stomach caused a perforation with peritonitis.

The other case of intraluminal myoma of the stomach also ended in perforation after several years. Extraluminal tumors are quite another matter. In the stomach they produce large masses that push the stomach from the outside and one can readily recognize that there is a tumor outside the stomach.

DR. O. J. CAMPBELL: A few years ago I had an experience with such a case which indicated that it might be difficult for the pathologist to differentiate between a benign leiomyoma and a leiomyosarcoma. This patient was an elderly man, a little past middle age. He came in with an acute abdomen. He had a tender mass in the left upper quadrant. I do not recall what our diagnosis was but needless to say, we were not accurate in our diagnosis. We went in and found and resected a leiomyoma about five inches in diameter, in the very first portion of the jejunum. It had not perforated but was covered by fiber and there was a localized peritonitis around it. I found no evidence of metastases. We resected the tumor mass. The man made an uneventful convalescence. Dr. McCartney, pathologist at Abbott Hospital, studied the tumor and thought it was probably a benign tumor and diagnosed it a leiomyoma. Approximately three years later, this man returned with a large mass in his right upper quadrant. There were no inflammatory elements about it. We watched it for a while and decided the only thing we could do was to do an exploration biopsy to see if there was anything that might help. We did this and found a tumor mass about the size of the patient's head adherent to the under surface of the liver. I found no other tumor masses in the abdomen nor the liver. A section of this was taken and was found to be hemorrhagic and necrotic. Dr. McCartney studied it and made a diagnosis of sarcoma. So the tumor we had operated on and diagnosed a leiomyoma should properly have been diagnosed a leiomyosarcoma.

BOOK REVIEWS

Books listed here become the property of the Ramsey, Hennepin and St. Louis County Medical libraries when reviewed. Members, however, are urged to write reviews of any or every recent book which may be of interest to physicians.

BOOKS RECEIVED FOR REVIEW

MODERN DERMATOLOGY AND SYPHILOLOGY. S. William Becker, M.D., Associate Professor of Dermatology and Syphilology, Kuppenheimer Foundation, University of Chicago; and Maximilian E. Obermayer, M.D., Assistant Professor of Dermatology and Syphilology, Kuppenheimer Foundation. 871 pages. Illus. Price, \$12.00, cloth. Philadelphia: J. B. Lippincott Co., 1940.

CLINICAL DIABETES MELLITUS AND HYPERINSULINISM. Russel M. Wilder, M.D., Ph.D., F.A.C.P. Professor and Chief of Department of Medicine, Mayo Foundation for Medical Education and Research, University of Medicine; Head of Section on Metabolism Therapy, Mayo Clinic, Rochester. 459 pages. Illus. Price, \$6.00, cloth. Philadelphia: W. B. Saunders Co., 1940.

DIRECTORY OF MEDICAL SPECIALISTS. Certified by American Boards, 1939. Paul Titus, M.D., Directing Editor. 1573 pages. Price, \$5.00, buckram binding. New York: Columbia University Press, 1940.

THE RELATIVITY OF REALITY. René Laforge, M.D. Translated by Anne Jouard. 92 pages. Price, \$2.50, stiff board cover. New York: Nervous and Mental Disease Publishing Co., 1940.

DISEASES OF THE DIGESTIVE SYSTEM. A Text-book for Students and Practitioners. Eugene Rosenthal, M.D., Lecturer in Medical Faculty, Royal Peter Pazmany University, Budapest. Preface by R. J. V. Pulvertaft, M.D., F.R.C.P. Reader in Pathology. University of London: Director of John Burford Carhill Laboratories and Curator of Museum, Westminster Hospital School of Medicine. 394 pages. Illus. Price, \$8.50, cloth. St. Louis: C. V. Mosby Co., 1940.

THE BACTERIOLOGY OF PUBLIC HEALTH. George M. Cameron, Ph.D., Associate Professor of Bacteriology, University of Tennessee. 451 pages. Illus. Price \$3.50, cloth. St. Louis: C. V. Mosby Co., 1940.

CANCER OF THE COLON AND RECTUM, ITS DIAGNOSIS AND TREATMENT. Fred W. Rankin and A. Stephen Graham. 358 pages, 210 illustrations in 133 figures, 54 tables. Price \$5.50. Springfield, Illinois: Charles C. Thomas, 1939.

This volume is the most complete review of the subject of colonic malignancy published to date. While the whole tone of the book is authoritative, it is in the chapters dealing with "Choice of Operations and Operative Mortality and End-Results," that the authors are at their best. An operative mortality of 7.5 per cent for combined abdomino-perineal resection for cancer of the rectum and rectosigmoid is an achievement. However, it will be interesting to note if there will be any difference in the number of five-year survivals following abdomino-perineal resection and posterior excision for carcinoma of the rectum below the peritoneal reflection. For the surgeon who only occasionally operates upon such patients, colostomy followed by posterior excision is certainly the safer operation and would seem to be the procedure of choice.

Some may not agree with the statement that hernia-

tion is prone to occur after transverse colostomy (page 268); others may not believe that there is such a close correlation between histologic grading of colonic tumors and prognosis. However, the general excellence of the book overshadows any of these minor differences of opinion. The volume is strongly recommended for all interested in the subject of colonic malignancy.

—CHARLES E. REA, M.D.

THE MEDICAL CAREERS. Harry Cushing, M.D., Boston: Little, Brown and Co., 1940. An Atlantic Monthly Press publication.

In this volume is assembled a number of addresses and biographies, which have appeared in print elsewhere. The idea apparently is to publish these heretofore scattered products of the pen of a great surgeon in a single volume accessible to those who appreciate greatness, for Harry Cushing was not only a leading surgeon of his time but a fine character and an able writer. The material was selected for publication by the author and the editor of the *Atlantic Monthly Press* last summer, not long before Dr. Cushing's death. One would expect that the volume would be read with interest by all medical men, the younger ones particularly.

C. B. DRAKE.

OPERATIVE ORTHOPEDICS. Willis C. Campbell. 1154 pages. Illus. \$12.50. St. Louis; C. V. Mosby Co., 1939.

This book offers an exhaustive description of procedures used in orthopedic surgery. It is well illustrated. Perhaps the only criticism one could offer would be the lack of critical analysis of the results of many of the operations here represented.—S.W.S.

CANCER HANDBOOK OF THE TUMOR CLINIC
—Stanford University School of Medicine. Edited by Erick Liljencrantz, M.D. 114 Pages with fifty figures. Price \$3.00. Stanford University, California: Stanford University Press, 1939.

This manual is a syllabus on the diagnosis and treatment of malignant tumors, assembled for postgraduate instruction at the Stanford University School of Medicine. In the first chapter, the cancer problem is stated simply, yet comprehensively. Diagnosis, treatment, and prognosis of the more frequent tumors are discussed. The diagrams are excellent, but the photographs of the lesions would be more effective if they were in color. The bibliography of the more pertinent literature is appended. The index is workable and fairly complete. This volume is one of the best handbooks on the cancer problem published to date.

—CHARLES E. REA, M.D.

STANDARDS FOR THE DIAGNOSIS AND TREATMENT OF CANCER. Cancer Manual developed by the Executive Cancer Committee of the Iowa State Medical Society. 168 pages. Price \$1.00. Iowa City Iowa: Atheas Press, 1938.

The Iowa State Medical Society is to be congratulated on the publication of this splendid manual. It is almost incredible that so much regarding the symptomatology, diagnosis, and treatment of the more common

tumors could be presented in this small volume. One may wonder if the authors are not a bit optimistic regarding the prognosis of cancer of the tongue (page 30). However, as a whole, the book is conservative, up-to-date, and practical. This manual could be read with profit not only by general practitioners, but also by all interested in the cancer problem.

—CHARLES E. REA, M.D.

ESSENTIALS OF THE DIAGNOSTIC EXAMINATION. John B. Youmans, M.D., B.A., M.S., Associate Professor of New York: Commonwealth Fund, 1940. Price, \$3.00.

The book "Essentials of the Diagnostic Examination" by John B. Youmans, M.D., should prove a valuable addition to the library of the clinician. Physicians are always eager and thirsty for information that might help in diagnosis.

This compact book is divided into three parts. The first portion is concerned with the clinical history. The author in his introduction states quite clearly "The importance of the history or anamnesis can scarcely be overemphasized though, as stated in the introduction, no part of the diagnostic examination can be said to be more important than another. The reason for stressing the importance of the history is that it is so frequently neglected." This appeal in history taking should stir the practitioner who may feel that being pressed by time he finds it difficult to carry out this important procedure.

Also in part one of the book, Dr. Youmans discusses the physical examination, but the space devoted to this subject is limited. One finds many of the essentials hurriedly covered and inadequately described. The author has many references, however, to more complete works on this subject. On page 122 the author refers to a saying that "A medical specialist differs from a non-specialist in that he looks at the eye grounds and examines the rectum." This should, indeed be a challenge for more general practitioners to use the methods of specialists, and for more specialists to be specialists.

The section on the neurological examination should prove especially appealing to the general practitioner, the internist, and the surgeon alike. This section is opened by the statement that "Many physicians have a feeling of inadequacy with respect to neurology and neurological diseases. This is altogether unnecessary." With this challenge, Dr. Youmans goes on to lay down a sensible, practical, and clear method for the examination of the cranial nerves, reflexes, sensation and the mental state. The particular section should encourage the physician who altogether too frequently has regarded this portion of a physical examination as something obscure, and beyond his capabilities. Dr. Youmans' plea in this connection should not go unheeded.

In the second part the doctor discusses laboratory tests that are essential and commonly used. This section is well illustrated and the procedures are simply and very adequately described. The description of laboratory procedures is indeed timely in that the tests

for sulfanilamide and sulfapyridine blood determinations are well outlined. The doctor in practice who does his own laboratory work should be refreshed by this section.

There is nothing particularly new in this book. As the cover flap states, "This handbook sets forth procedures of the diagnostic examination that are essential to all good medical practice." The hand book follows the usual orthodox clinical and scientific plan and should be helpful in the performance of the important history taking, complete physical examination, and pertinent laboratory procedures. The hand book is adequately illustrated and indexed, and has numerous diagnostic charts that should be of help.

—SIMON G. SAX, M.D.

AN INTRODUCTION TO GASTRO-ENTEROLOGY (The Third Edition of *The Mechanics of the Digestive Tract*). By Walter C. Alvarez, New York, Paul B. Hoeber, Inc., Medical Book Department of Harper and Brothers. 778 pp. Price \$10.00.

To those who so thoroughly enjoyed the first two editions of *The Mechanics of the Digestive Tract*, this new volume should provide many evenings of delightful and thought-producing reading. In addition it is a veritable encyclopedia of fundamental and historic contributions to the physiology of the digestive tract, containing a bibliography of around 2,500 titles. This bibliography alone is worth the price of the volume, as a reference source.

The first few chapters describe the various types of motor functions of the small bowel and particularly the polarity of the bowel which waves travel more easily caudad than orad. The author and others have shown that there is a downward gradation in activity, tonus, irritability and rate of rhythmic contraction along the small bowel from the duodenum to the ileocecal sphincter (the "gradient theory"). These gradients constitute the best approach to the study of the polarity of the bowel. Other gradients have also been demonstrated, such as those of oxygen consumption and catalase content, blood supply, propulsive force, and pH of intestinal contents in many animals. Many factors tend to reverse or steepen these gradients. Flattened or reversed gradients are found in sick animals and in pregnant women, from emetics, or with rectal irritation even from use of a Murphy drip. Steepened gradients may be found from certain cathartics or from increased tonus in the upper end of the bowel due to ingestion of food. Bayliss and Starling's old "law of the intestine" is challenged, and the author proposes a new "law of the intestine" to the effect that any stimulus which raises the tonus, activity and irritability of a segment of bowel tends to slow the progress of waves and material approaching the segment on the oral side and to hurry the progress of material leaving on the caudal side. Reverse peristalsis may be a manifestation of an altered gradient in some segment of the bowel, and results in symptoms such as nausea, heartburn and bloating.

The next few chapters consider the structure of the

smooth muscle and its nerve plexuses and their relationship to the extrinsic nerves of the digestive tract. The opinion is expressed that impulses from the extrinsic nerves are transmitted to smooth muscle of the bowel largely through chemical substances formed at the ends of the nerves. The rhythmic activity of the bowel is influenced by the extrinsic nerves yet its origin is in the bowel. The function of the myenteric plexus is to expedite conduction and to correlate activities of the muscle fibres. The ganglion cells of the plexus probably function to prevent the muscle contracting into a knot and remaining that way (as in cardiospasm, and Hirschsprung's disease). The effects of extrinsic nerve stimulation are not constant—they vary with the strength of stimulus, rate of interruption, and the level of tonus of the muscle at the moment. Afferent stimuli reach the brain and may harm the animal. Thus an animal with an obstructed overly active jejunum will live longer if the obstructed segments are denervated. The author discounts the old theory of a conflict between vagus and sympathetic—they both act to restrain excessive activity of the bowel. The vagus nerves have more to do with functions of the stomach and the splanchnics more with the bowel. Both, however, influence all parts of the small intestine. The vagus reaches only the proximal half of the colon. The quieting of the bowel seen in peritonitis is largely due to nervous inhibition, being much less marked in animals previously subjected to splanchnicotomy.

The cardia, pylorus and its control, and movements of the stomach are discussed in the next four chapters. There is no specialized cardiac sphincter in man, but only a variable amount of sphincteric action at the cardia. Such a sphincter is not needed in upright animals but is very pronounced in animals hanging upside down. The vagus and sympathetic nerves have varying effects on the cardiac end of the stomach depending largely on its tonus at the time of stimulation. Cardiospasm may often be due to separation of the muscle from its ganglion cells. Gastric contraction waves usually seen beginning near the middle of the stomach arise as ripples at or near the cardia, passing on down and resulting in a systole of the circular muscle of the antrum about three times each minute. More important for emptying the stomach are the slow tonic contractions of the whole muscular wall increasing the intragastric pressure. There is a mechanism present for adjusting the tonus of the gastric wall to the quantity of food taken. Indigestion arises if one eats too rapidly to allow this mechanism to function. The stomach muscle also has a "gradient" of irritability and contractility, greatest at the cardia. The author emphasizes the almost complete separation of pyloric and duodenal muscles, lymphatics and blood vessels. Animals and man live comfortably after removal of the pylorus for gastric emptying still is chiefly regulated from the bowel. One must remember that gastric waves do not push fluids through the pylorus. Many waves cause no emptying at all of the stomach. Only with increased intragastric pressure or relaxation of the duodenum does the stomach empty. The presence of food or liquid in the duodenum, regardless of

its acidity, retards gastric emptying. Likewise distention or irritation of the lower small bowel may delay gastric emptying. Fat in the bowel slows gastric emptying. Hydrochloric or other acids in the duodenum slow gastric evacuation by increasing intraduodenal tension. Alvarez sums up the controversy over the acid-control of the pylorus by calling acid control of the pylorus unimportant, since any substance, acid or alkaline, which increases the tonus of the gastric muscle and thereby the pressure within its cavity, must tend to speed up emptying. Any substance so acid or alkaline as to irritate the duodenal mucosa will be held back in the stomach until diluted or neutralized. In addition, the pylorus acts as a small funnel passing liquids but not solids larger than its bore. Duodenal contents regurgitate into the stomach if intraduodenal pressure is increased over that in the stomach. Fear, anxiety, pain or anger often slow gastric emptying for hours. The latter is speeded by lying on the right side or by exercise after a meal.

Two chapters are devoted to the movements of a diseased stomach and to the question of ulcer pain and hunger contractions. Most evidence points to the cause of ulcer distress as being irritation by the hydrochloric acid of the gastric juice rather than merely the contraction of the muscle overlying the ulcer. One problem yet unsolved is why some patients may lose all ulcer distress on the morning of the first day of their vacation. The author mentions the damage done to an ulcer during the night hours, and suggests the value of night neutralization of acid in the stomach. A

periodic increase in the sensitiveness of the stomach or nervous system is important in explaining why ulcer pain appears at certain times. An ulcer anywhere in the stomach or duodenum may cause a hypertonic pars pylorica and thus delay gastric emptying.

The final third of the book is devoted to an unrelated group of subjects, such as vomiting, mechanics of the gallbladder, the appendix, movements of the colon, the length of the bowel under varying conditions, constipation etc.

Vomiting and diarrhea may often be associated due to emptying of the small bowel both ways from some midpoint which may be stimulated through the vagus nerves. The author emphasizes the fact that since the small bowel is more sensitive than the stomach to the nauseating effect of irritant drugs, putting such drugs in keratin or salol coating is irrational.

Present-day evidence is that emptying of the gallbladder is under the control more of a hormonal than a nervous mechanism. Decided slowing of emptying is seen after the third month of pregnancy. In emotional persons a temper tantrum may initiate an attack of gallstone colic. Colic seen in the absence of gallstones may be due to biliary dyskinesia or to failure of the sphincter of Oddi to relax with contraction of the gallbladder.

The ileocecal sphincter is not essential to good health—a simple anastomosis between ileum and colon is as satisfactory. Putting food into the stomach causes a hurrying of the residue from the ileum into the colon. Alvarez concludes that there is no pathognomonic

roentgenologic sign of chronic appendicitis. No correlation can be established between the x-ray findings on a supposed chronic appendix and the pathologists report on it after removal, for almost all appendices show slight evidence of past infection. The final test of the value of removal of a chronic appendix is to wait over a year to see if the operation cured the patient's symptoms. Improvement noted soon after surgery in these cases is often transient.

One of the main purposes of the colon is to conserve the water supply of the body. Constipation often is due to too great efficiency of the colon in removal of water from the bowel. Constipation is decidedly a disease of nervous origin—of civilization with its hurry, strain and tension. It may often be caused by too little food or too little residue in the food used. The results of stimulation of the colonic extrinsic nerves has not yielded clear-cut results. Children with megacolon usually are benefited by section of the nerves belonging to the lumbar sympathetic outflow.

The bowel in herbivorous animals is always much longer than that found in carnivorous animals. A rough indigestible diet will increase the length of the bowel in experimental animals and probably in man. In a living man the distance from mouth to anus is about 2.5 meters. In death this distance is two or three times as great.

It must be realized that a barium meal is not physiological. It passes through the bowel much faster than does most food. In normal young people colored glass beads require several days to a week for their passage through the digestive tract. The taking of much water washes food rapidly through the small bowel. This is often undesirable and results in indigestion and insomnia, and often diarrhea. Frequent feedings speed passage through the small bowel. Each new feeding gives a forward push to the residues of the preceding meal. Milk gives a bulky residue in the lower ileum and colon. Foods giving the least residue are lean meat, rice, hard boiled eggs and sugar.

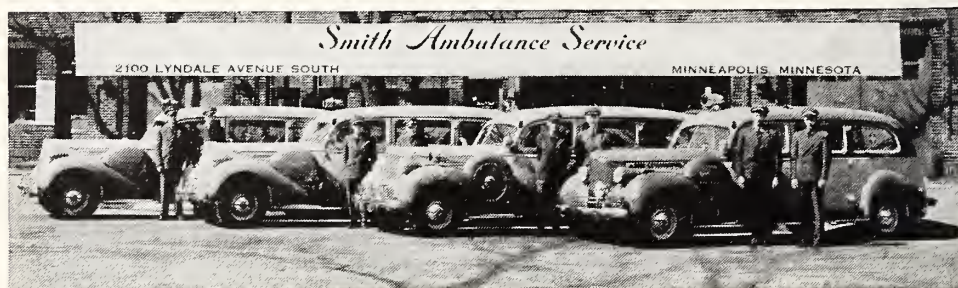

Gas in the bowel consists largely of nitrogen remaining from swallowed air. In intestinal obstruction the gas also consists largely of nitrogen. Carbon dioxide leaves the bowel by diffusion most easily of all the gases found there. Oxygen is next and nitrogen is the slowest to diffuse into the blood. Breathing pure oxygen lowers the nitrogen tension in the blood and thus the nitrogen in the bowel may be taken up by the blood more easily. There is no gas produced in the stomach by fermentation, as is the case in the right half of the colon. Heart disease, allergy and protozoan parasites are all important causes of flatulence. "Gas pains" after operation are rarely due to gas.

The hunger complex is still not entirely clear. It is not due entirely to contractions in the stomach or intestine, or to a lowered blood sugar.

In doing a gastro-enterostomy it is not essential that peristaltic waves travel in the same direction in the stomach and the attached loop of bowel. Closure of the pylorus is apt to decrease the stimulus in the duodenum to the flow of bile and pancreatic juice and thus impair digestion. An entero-enterostomy increases the incidence of postoperative jejunal ulcer by removing much of the protective action of alkaline duodenal juices from the new stoma.

Two valuable chapters bring this book to its conclusion: one describing various technical methods and apparatus, and one containing advice to a young physician on his choice of books and reading. These are followed by the tremendous bibliography used in connection with the writing of this volume. This last chapter is characteristic of the charming and human personality of the author. Those who have heard Dr. Alvarez deliver a lecture will never want to miss an opportunity to hear him again. For those who cannot hear him, this book will provide a fund of information and an insight into the mind and personality of one of the greatest physiologists and clinicians of our time.

PREVENTION AND TREATMENT OF GENITAL PROLAPSE*

FRED L. ADAIR, M.D.
Chicago, Illinois

PROLAPSE is the falling downward or outward of a structure or organ, toward, into or through a natural or an artificial orifice. The term applies to specific structures only when a descriptive adjective or phrase modifies it.

The term Genital Prolapse as used in this discussion means a downward or outward displacement of all or of any portion of the female genital structures.

Inasmuch as such environmental structures as the urethra, bladder and rectum are so intimately associated with these genital organs, it is almost impossible not to have them involved in the process. It should be clearly understood then that there really is no such condition as an exclusively genital prolapse. Even as slight an involvement as a descent of the anterior or posterior vaginal wall implies some prolapse of the urethra or rectum.

The two major etiologic mechanical factors are those opposing forces of support and of pressure. Any disturbance of the equilibrium of these forces resulting in a relative excess of pressure over support will tend ultimately to cause a sagging of the tissues to a greater or a lesser degree.

The essential methods of prevention are those which eliminate the causes of inadequate support and of excessive pressure. The procedures for cure are the establishment and maintenance of a proper balance between support and counter-pressure. It must be remembered that neither the support nor the pressure is rigid or constant but both are elastic and variable. There are complicated factors in the application of the force and

of the resistance as they are both direct and indirect and may be shear or not. There are contributing factors which tend to alter the balance by increasing the pressure, by decreasing the resistance or by altering the mechanics of their application. The major factor seems to be associated with the processes of childbearing as these genital relaxations and descents are seldom seen in those women who have born no children. Occasionally even marked degrees of prolapse are found in nulliparous women but such cases are exceptions to the rule which prove that trauma to the supporting structures is not the sole factor to be considered in the etiology of these conditions. The forces which tend to cause a prolapse are twofold, the downward pressure from above by the intra-abdominal and intra-pelvic pressure and the pull or traction from below on the pelvic structures by the force of gravity.

The supporting or resisting forces are those of balance, which tend to hold the organs and structures in poise, by acting like guys on a derrick. These are the so-called ligaments of the uterus. While the cardinal ligaments may afford a measure of support they may be regarded as the swivel upon which the uterus swings. The real support comes from the endopelvic fascia or the urogenital diaphragm and from the pelvic floor which in turn is supported by the fibro-fat pads of the ischio-rectal fossæ resting upon the powerful glutei maximi muscles. It has been mentioned that there are the forces of pressure and pull which are constantly present but are nevertheless variable in degree and in direction of application. The results vary not only because of these factors but also because of the altered relationship to the forces of resistance. The degree of the force

*From the Department of Obstetrics and Gynecology, The University of Chicago and The Chicago Lying-in Hospital. Read at the annual meeting of the Minnesota State Medical Association, Rochester, Minnesota, April 24, 1940.

of gravity cannot be altered except in accordance with the universal laws. The direction of pull could be modified by the posture of the woman, and if the erect position were not essential there would be no syndrome of genital prolapse. The effect of gravity is also modified by its relation to supporting or resisting forces as the direct pull is more effective than a shearing one. The former is seen where the inclination of the pelvic floor is destroyed by a perineal laceration and the structures are drawn downward through the vertical and widened genital canal. Less frequently one sees a prolapse where the normal inclination of the vaginal canal is preserved.

The effect of the force of gravity can be illustrated very simply by having a woman who suffers a prolapse alternately assume the standing and the recumbent position. The prolapse is obvious in the former posture and tends to disappear in the latter. Cases can arise in which the diagnosis of prolapse is missed on examination of the patient in the dorsal position. Atmospheric pressure also has to be considered. In the erect position it operates mostly through the abdominal walls, but if a woman is placed in the latero-prone, or better, in the knee-chest position with the posterior vaginal wall retracted, the effect on the normal or sagging genital structures can be easily demonstrated.

Intra-abdominal and intra-pelvic pressure is the composite result of many components, the chief of which are the external atmospheric pressure, which has already been mentioned, the action of the diaphragm, and the condition and physiology of the abdominal walls. The posture and attitude of the body has much to do with the relation between intra-abdominal and intra-pelvic pressure. In other words, the effect of the force of intra-abdominal pressure is altered by body posture.

It is apparent that certain components of intra-abdominal pressure cannot be eliminated. Atmospheric pressure is fairly constant. The muscular effort necessary to control and maintain the bodily movement and posture cannot be eradicated. Respiratory movements cannot be suspended. The physiologic activity of the abdominal muscles necessary to defecation and urination cannot be avoided. The major factor which can be controlled is that of voluntary effort or physical activity. Any severe strain or muscular effort of the abdominal wall tends to increase pressure within the abdomen. The effect of this pressure

on the pelvic structures varies with the inclination of the pelvic brim and the position and the condition of the organs and structures within the pelvis. If the posture of the body is such that the brim of the true pelvis is more nearly horizontal then the pressure is more direct while the direction is more shearing when it has its normal inclination. If the uterus lies in retroversion because of a full bladder or other reasons the pressure is so exerted as to tend to push the uterus downward along the vaginal axis. If, on the other hand, the uterus lies in its normal position of anteversion the pressure tends to push the uterus forward and downward closing the utero-vaginal hinge.

Opposed to this force we have the adequacy of the structures surrounding the hiatus urogenitalis. This adequacy depends upon the size and direction of the hiatus and canal and upon the resistant and functional competency of the sustentacular pelvic structures.

The opening may be congenitally large or be stretched by parturition. The supporting structures may be weak from either congenital or acquired conditions. Among the most essential of these structures are the cardinal uterine ligaments which suspend the uterus near its isthmus and serve as a pivot upon which it turns. Another important component of the resistant and balancing forces is the endopelvic shelf upon which the uterus and bladder rest for support and beneath which the anterior vaginal wall runs downward and forward.

The posterior vaginal wall, passing along the thin partition of prerectal fascia, parallels the anterior vaginal wall and derives its support from the perineal and levator ani muscles and fascia which rest upon the ischio-rectal pads protecting the rectum and resting as supporting cushions upon the powerful gluteal muscles. The laxity or weakness of musculo-fascial supports both above and below has a contributory effect in the production of prolapsed organs. It is easier to pour the contents out of the aperture in an inverted collapsible sack or bag than from a more rigid container as a jug or keg. The firmer and stronger the abdominal walls the greater their sustaining power on the abdominal and pelvic contents. This may be compared to the lifting or holding power obtained by a vacuum bottle or sucker. This restraining force from above is diminished if the aperture is larger or its periphery is weaker. One has to consider also

the relation between the pressure from above and the support from below because, if the former is disproportionately greater, prolapse is more apt to occur than if the latter is relatively stronger.

This rather brief discussion of some of the component etiologic and mechanical factors involved in the production of genital prolapse shows that they are manifold in degree and direction and in relative intensity of pressure and resistance. There must be as a rule certain lack of synchronization, and a persistence in the operation of these forces as the development of genital prolapse is not a sudden but a gradual process.

There is a coordinating factor which must be considered as important—when the abdominal muscles and diaphragm are thrown into action, whether voluntary or involuntary, physiologic or pathologic, there should be an equivalent timed response from the supporting structures lying below. If this were not true the pelvic structures would be forced downward. Under normal conditions this action may be compared to that of a hinge. The uterus swings forward and downward on its pivotal cardinal ligaments and acts as one leaf of the hinge. The other leaf is supplied by the levator ani and perineal muscles which tend to shut the hinge and close the opening of the lower genital canal. The resistance must be sufficient in degree and appropriate in timing to prevent the descent of the pelvic structures. It is also important that all the pelvic structures have sufficiently normal relations and be in condition to permit the physiologic operation of all these opposing but coordinated forces. Any situation which disturbs the physiologic behavior of these forces and tends to make the pressure overcome the resistance either in degree or in direction may cause a prolapse of genital structures or organs.

Prolapse is not a simple but a complex condition; it is not uniform but multiform in its manifestations. One structure or many structures may be involved, and it may be of a slight or of an extreme degree.

It is important to bear in mind that it is not a stationary but a progressive disorder because once the supporting structures are weakened and those of pressure overbalance the former the tissues and structures are gradually pushed to a lower and lower level. This is certain to occur unless something is done either to improve or supplement the support or to lessen the pressure. The former can be accomplished in various ways.

The latter can be done only to a very limited degree as only pathologic pressure can be eliminated and certain essential physiologic pressure must remain. Prolapse of the rectum, urethra or bladder unassociated with genital prolapse will not be discussed in this presentation.

The simplest and most common form of genital relaxation involves the vaginal walls, usually the anterior or posterior or both. The lateral walls rarely sag unless the uterus descends. This sagging of the vaginal walls is referred to as colpocele, either anterior or posterior, and is caused by some atrophy or injury to the fascia and muscles supporting these structures. This is commonly caused by parturition as the result of pressure by the fetal head which injures these structures by stretching or tearing or by both. During labor the bearing down effort of the mother or the traction exerted during artificial delivery may pull down on these tissues so that the reparative or involutional processes never completely restore them. Even these lesser degrees of relaxation are uncommonly seen in nulligravida though some faulty development of the genito-urinary tissues with inherent weakness may result in even an extreme degree of prolapse. Excessive strain and hard physical work may overcome the natural resistance and produce a similar result. Occasionally, faulty innervation or other developmental defect associated with spina bifida occulta may be responsible for such a condition.

From the standpoint of the woman the most important point is whether or not any symptoms result from relaxation. These subjective signs may be urinary, gastro-intestinal, genital, pelvic or general and are not infrequently of an indefinite character.

Colpoceles rarely involve the vaginal walls alone as the rectum, urethra, and the bladder are so intimately and closely associated anatomically and physiologically that there is morphologic, if not functional, evidence of their implication.

When there are no symptoms, the degree of relaxation is slight and there is no evidence that the condition will be progressive. No treatment is indicated. When there is a definite urethrocele, some sacculation develops and terminal dribbling and incontinence may arise. When there is a rectocele, some difficulty in evacuation of the rectum occurs and this leads to the use of laxatives or enemas with the development of a cathartic or enema habit. Not infrequently a spastic colitis develops which cannot be cured until the pri-

mary muscular inefficiency is remedied. This can be accomplished only by operation which restores the muscular competency of the perirectal musculature and obliterates the rectal culdesac which arrests the fecal column. Commonly these foregoing conditions, which are designated urethroceles, cystoceles, and rectoceles, are progressive and the symptoms become aggravated. They form a background for more extensive genital relaxations.

Protrusion of parts is noted by the woman and necrosis, ulceration, bleeding and infection associated with purulent discharge may result. The patient complains of a sensation of pelvic weight and drag. Over a period of years this disability may cause more general symptoms with marked fatigability, loss of weight and incapacity for the usual activities even of those which are consistent with advancing years. The diagnosis presents little difficulty as the history and bimanual examination usually settle the question. It should be kept in mind that the relaxation is not so apparent on vaginal examination with the woman in the dorsal position. It is necessary to have her strain and bear down to bring the parts into view. Occasionally, it is desirable to examine her in the erect position. The diagnosis should include such details as are necessary to determine the exact situation and condition of the genital structures of the neighboring organs and tissues. One should determine whether or not the urethra and bladder and the rectum are involved and to what extent. The condition of the uterine cervix and the position, size, etc., of the uterus must be noted. Elongation of the cervix is common and is usually the result of stretching due to the holding or supporting of the corpus by its structures while the cervix is pulled downward as the result of gravity and insufficient support of the vaginal walls which are attached to the portio. We commonly speak of degrees of prolapse, but such a classification is arbitrary and incompletely descriptive of the condition. The uterus may descend to the lower portion of the pelvic canal without appearing at the introitus or the vaginal walls may be completely everted carrying the uterus along with them so that this organ no longer remains within the pelvis.

It is necessary in making a diagnosis to determine just what the conditions are as these determine in a large measure the type of treatment to be used. The treatment may be considered under

four main headings: the prophylactic, the arrestive, the palliative and the curative. The prophylactic consists first of having women educated to assume proper posture and to secure normal physical development, and during pregnancy by early antepartum care, malpositions (as retroversions) of the uterus can be detected and corrected and the uterus can be maintained in proper position during the early months of gestation. Otherwise the tissues are soft, the uterus is growing and it may be held in the hollow of the sacrum under the promontory until the pressure of growth pushes it up and out of the pelvis. The replacement of such a retroverted uterus is usually easy and a Smith-Hodge pessary will maintain an anterior position until the uterus is large enough to ride above the pelvic brim about the third or fourth month. With the uterus in normal position the bladder and rectum can function more normally. The natural position and normal functioning of both rectum and bladder during pregnancy is important in preventing any overdistention or weakening of their walls.

During the first stage of labor it is important that the normal physiology be carried out. Any attempt to hurry or force delivery by bearing down or by traction with forceps, etc., on a cervix which is incompletely dilated may result in damage not only to the cervix but also to the surrounding and supporting structures of the upper vagina, the uterus, the bladder and the rectum.

The passage of the fetus, especially the head, through the birth canal stretches, tears and compresses the soft maternal tissues. They have excellent elastic properties but often irreparable damage is done and the supports are permanently weakened. Some but not all, of this injury can be avoided. Either too rapid or too delayed passage through the bony canal may be harmful. The former because actual tearing of tissues may result from lack of sufficient time in which to adjust themselves by gradual dilatation; the latter because of prolonged pressure with ischemia and necrosis of the tissues. In addition, there is always the question of infection which may interfere with proper tissue healing. It is difficult to lay down hard and fast rules as the proper conduct of labor is the result of good judgment and good technic. Both normal and artificial deliveries must be conducted with a proper regard not only for immediate but also for remote results.

Another important factor is the preservation of

the pelvic floor. Lacerations of varying degrees are common. It was formerly thought and taught that the criterion of a good delivery was the absence of a laceration. Very few, if any, primiparous women are delivered without some laceration or injury to the vaginal membrane, muscles or fascia of the pelvic floor or perineum. Some can be delivered without injury to the skin over the perineal body. The extent of the damage and the remote result cannot always be determined immediately. Suture of the open wounds which resulted has long been advocated. The tissues are often bruised, irregularly torn and difficult to approximate accurately. In view of the fact that these injuries are very common and cannot be avoided because they are often rather difficult to repair satisfactorily and for the reason that deeper lying tissues are often injured by overstretching, the operation of episiotomy has gained ground greatly in its use.

Median and mediolateral incisions are made; the latter is more commonly employed. This opens the pelvic floor, makes a clean-cut wound, and minimizes the amount of stretching of the musculo-fascial structures of the pelvic floor. It is easier to secure the proper apposition of the parts after an episiotomy than after an irregular laceration. One should restore the perineal wedge by reconstructing the backward inclination of the lower vagina and the introital ring. The sutures should approximate and not strangulate the tissues. Hemostasis should be complete and the perineal wound should be and should remain clean. Hematomas and infection interfere with normal healing and imperil both the immediate and the remote results.

Care during the puerperium is important as infection of lacerations and episiotomy wounds must be prevented, and if infection occurs, proper treatment by heat, drainage, etc., instituted. Strain on the traumatized tissues must be avoided as much as possible by avoiding fecal accumulation and difficult evacuation of the rectum. Overfilling of the bladder must be prevented. These measures are especially important during the first week while healing is taking place.

Exercises should be used to improve the tone and reestablish the strength of the abdominal muscles. After the first week or ten days the latero-prone position, the knee-chest position and later even the monkey walk may be successively employed.

The patient should return for a postpartum examination in a month or six weeks, and if a retroverted uterus is found, its position should be corrected and a pessary worn for several months until the round ligaments and other supports are fully involuted and have returned to relative normality.

The knee-chest position is a valuable procedure for women to follow more or less routinely, especially for those who are susceptible to retroversion. Needless to say, the optimal physical status should be maintained. If certain degrees of relaxation are found, attempts should be made to arrest their progress by the attention to the patient's general condition, her habits and by local supportive treatment. It is important to avoid strenuous exercise which increases intra-abdominal pressure, to shorten periods of time, when the woman is on her feet either standing or working, by intervals of rest in the horizontal position. These measures will not cure the condition but may arrest or slow its progress.

Palliative treatment consists chiefly of the above suggestions and the use of some of the various types of hard rubber pessaries. The type varies with the case, and it is necessary to fit them carefully and check them monthly to see that no tissue damage is produced. They may cause irritation, discharge and decubitus if not used properly. The tissues of different patients react differently to the presence of such a foreign body. Some tolerate them for months and years and others have difficulty using them at all.

The only cure is surgical, and manifold operations have been devised but relatively few have stood the test of time. One may view the cures as symptomatic relief or as anatomic restorations. The former is what the patient desires, but it is often impossible to obtain it by any anatomic restoration which approaches the normal. Formerly, many procedures were advocated by which the uterus was removed with the result that the uterus no longer prolapsed but other structures did. It was anchored to the abdominal wall, but the tissues stretched and the parts descended.

Gradually the etiologic factors have come to be better understood and methods of reestablishing proper mechanical relations have been devised. The various mechanical factors were discussed earlier and their practical application explained.

It is not possible to discuss in detail the va-

rious operative procedures which have been and can be used. The same operation cannot be used in all cases satisfactorily, but that procedure which makes it possible to use the principles to the best advantage is the one to employ in a given case. First, the tissues which support any relaxed part must be restored or so replaced as to provide the necessary support. This applies to the anterior vaginal wall, urethra and bladder as well as to the posterior wall and rectum. Second, accessory supports must also be restored or replaced. Third, provision must be made to maintain a balance between pressure and counter-pressure by a mechanism which will effectively close the hiatus when these two forces are opposed. The simile which appeals to me as most explanatory is that of a hinge. There must be some more or less fixed point on which the leaves turn. With the normal structures the uterus turns on its cardinal ligaments. Normally exerted pressure pushes it downward and forward into the uterovesical space and tends to compress the bladder between it and the endopelvic fascia. The cervix is thrown backward and upward and tends to close the vaults and tighten the vaginal walls and support the uterorectal pouch. The counter pressure from below is exerted by the levator and perineal muscles which raise the perineal body and posterior vaginal wall upward and forward to close the vagina and approximate the leaves of the hinge. If the uterus has a poor swivel, the mechanism fails, if the uterus lies in retroversion the hinge no longer closes properly, and if the lower leaf is defective the mechanism fails.

One has to consider two main facts in deciding upon an operation. One is that the childbearing function is to be preserved. The other is that no

consideration need be given to further reproduction. In occasional cases no consideration need be given to marital relations. These viewpoints often exert a determining effect on the selection of the type of operation.

It is apparent that the removal or retention of the uterus modifies the procedure to be employed. It is obvious that no type of operation can be successful which does not provide a proper hinge-like action of the pelvic structures. Whether the uterus is removed or left, this mechanism must be maintained. This means a swivel and two leaves of the hinge, the one above and the other below. The normal uterine guys or substitutes must maintain the uterus in equilibrium. The cardinal ligaments or substitutes must be provided and the anterior and posterior vaginal wall supports must be restored or replaced. If the uterus is removed, the broad, the round ligaments and other supporting tissues must replace its function. Whether the operation is done from below or above or both, these principles must be followed. It seems apparent that all the necessary steps of such an operation cannot be accomplished solely by an abdominal operation.

The technic of these operations is not easy to acquire and can only be obtained by experience and training. It is said that "practice makes perfect"; the continued use of correct technic approaches perfection, the repetition of errors never produces perfection.

It is not possible, even with the best of technic, to secure cures either symptomatic or anatomic in all cases, but careful application of correct mechanical principles and the attainment of adequate operative technic will secure satisfactory results in the great majority of even extreme degrees of prolapse.

DIGITALIS FOR OBESITY

Too much publicity has apparently been given to the reports of a method of weight reduction which involves administration of digitalis for suppressing the appetite. Whether or not digitalis can produce a loss of appetite without harmful effects is debatable. The work of Hatcher and Weiss in particular has shown that the nausea produced by digitalis is a reflex the sensory organ for which does not appear to be located in the heart. Thus the type of nausea which digitalis produces is at least partly due to factors other than gastric irritation. Indeed, nausea and vomiting are toxic symptoms of digitalis and constitute a warning to decrease or stop the administration of the drug. Confirmatory evidence for this method of reducing body weight is lacking. The method cannot be generally recommended unless its efficacy and safety have been thoroughly demonstrated by carefully controlled observations. (J.A.M.A., June 8, 1940, p. 2311.)

THE LOCAL USE OF SULFATHIAZOLE IN THE TREATMENT OF STAPHYLOCOCCAL INFECTIONS*

Preliminary Report

WESLEY W. SPINK, M.D., and JOHN R. PAINE, M.D.

Minneapolis, Minnesota

RECENT developments in the field of chemotherapy include the successful use of sulfathiazole in the treatment of staphylococcal infections. We have recently participated in the treatment of fifteen patients from whose blood streams staphylococci were isolated before instituting specific therapy with this drug. In every instance, the blood was rendered sterile following the administration of sulfathiazole. Details of this experience with sulfathiazole in the therapy of patients with staphylococcal septicemia will be recorded elsewhere. We observed that whereas blood cultures remained sterile after sulfathiazole had been administered, and the patients' general condition improved, organisms could be consistently cultured from localized lesions. In other words, the drug appeared to control the infection, but there remained the potential danger of invasion of the blood again by microorganisms existing in primary or metastatic foci. Because of our failure to sterilize these focal lesions by the oral or parenteral use of sulfathiazole, we have treated a number of individuals by the direct application of sulfathiazole to the infected areas.† Although the number of patients treated in this manner is small, the results have been so encouraging that a preliminary report is warranted.

There has existed for many years a widespread interest in the local treatment of infections with antiseptics. The most popular of these chemical compounds are those whose action depends upon the slow liberation of chlorine. They include hypochlorite solution (Dakin's solution), chloramine-T, and dichloramine-T. While it is true that the latter compounds will actually kill microorganisms and have considerable merit, their use may result in damage to the delicate granulating tissue. Cushny¹ has stated, "They act at least as strongly upon the proteins of the human body as upon the microbes invading it." Fleming² has produced evidence that practically all of the anti-

septics used in the past destroyed leukocytes. It is apparent that the ideal antiseptic would be one that injured or destroyed bacteria without causing damage to the tissues or cellular components of the host. In recent years, many investigators have advocated the treatment of infected tissues by less irritating and harmful measures. Lyth⁸ has treated a total of 1,096 patients having infected wounds by the application of a hypertonic solution of sodium sulfate to the surface of the wounds. He was impressed by the rapidity with which the local edema subsided following the use of the saturated sulfate solution. Another less drastic method of treating infected wounds has been the local application of cod liver oil dressings. Lichtenstein⁵ has recently reviewed the extensive literature on this subject and points out the advantages of employing this agent. He added experimental data of his own showing that cod liver oil is actually bactericidal for microorganisms which commonly invade injured tissue. Irradiation appeared to increase the activity of the cod liver oil. He suggested that the bactericidal action of the oil was dependent upon the organic peroxides that it contained. We have pointed out the success that has attended the use of these less irritative methods because we have utilized them in addition to the local use of sulfathiazole.

It should be pointed out that there exists some skepticism concerning the local use of sulfanilamide and its derivatives in the treatment of infections. Fleming³ observed that bacteria and peptones inhibit the bacteriostatic action of sulfanilamide. Disintegrating leukocytes in a wound liberate proteolytic ferments, which in turn break down proteins to peptones. Lockwood^{6,7} and others⁹ have also shown that peptones inhibit the action of sulfanilamide. In the treatment of wounds, Fleming² advocates the oral administration of sulfanilamide; adequate drainage; and irrigation with hypertonic solutions, which will increase the rate of transudation and aid the local action of sulfanilamide which may reach

†Sulfathiazole was supplied by the Squibb Institute for Medical Research.

the infected tissue. We have been impressed with the success that Jensen and his associates at the Minneapolis General Hospital⁴ have had following the implantation of sulfanilamide in contaminated wounds resulting from compound fractures. They have not observed a primary wound infection in thirty-nine compound fractures treated in this manner. Ninety-four open fractures treated in a similar manner but without sulfanilamide resulted in 27 per cent of the patients having infections.

Material and Methods

Sixteen patients with localized staphylococcal infections have been treated by applying sulfathiazole directly to the lesions. The following principles and procedures have been employed which appeared most likely to give the optimum therapeutic result in the therapy of these patients:

1. Depending upon the site of the lesion, immobilization and elevation of the infected area were used to enhance the return flow of the circulation. Wangenstein^{10,11} has emphasized that such a procedure alleviates pain and reduces swelling.

2. Adequate surgical drainage and debridement of devitalized tissue were utilized.

3. Sulfathiazole was applied directly to the lesions to permit a much higher local concentration of the drug than could be obtained when it was given orally. In patients acutely ill, sulfathiazole was also administered by mouth. This procedure was directed against a possible bacteremia, and to prevent an extension of the primary focus. Several methods were utilized in impregnating the infected tissue with sulfathiazole. In some instances, sulfathiazole crystals were implanted directly into the septic part. A 1 per cent aqueous solution of sulfathiazole was also employed as an irrigant and in wet packs applied to the lesion. Since, as has been pointed out, the local application of cod liver oil is attended with beneficial effects, on some occasions, one per cent sulfathiazole was suspended in cod liver oil or included in a cod liver oil ointment with vaseline as a base, and the cod liver oil-sulfathiazole mixture placed directly on or in the infected part. More specific data pertaining to the use of sulfathiazole in these patients will be presented shortly.

4. To prevent the inhibitory action of bacteria, exudate, and necrotic tissue upon sulfathiazole,

the wounds were irrigated frequently with warm, saline solution, and following each irrigation, sulfathiazole was put into the wound. In a few patients, particularly those with carbuncles, it was observed that irrigations with Dakin's solution aided considerably in the removal of purulent and sloughing material.

Results

A summary of the types of lesions treated and the results are shown in Table I. Staphylococci of the *aureus* type were isolated from every lesion. The following comments are presented to clarify the therapeutic method used in the various types of lesion:

Carbuncles.—Because of the size of the abscesses in all four patients, it was necessary to incise them and excise necrotic material. Following this procedure, sulfathiazole crystals were placed in the cavity of the wounds in three of the four patients. Additional crystals were put into the wounds daily for two to six days. It was surprising to observe how clean the wounds appeared following the application of the sulfathiazole. In treating the fourth patient, a one per cent suspension of sulfathiazole in cod liver oil was applied directly to the infected area twice daily for thirteen days. This method of application was also used in two of the three patients into whose cavities sulfathiazole crystals alone had been previously used. The utilization of the sulfathiazole-cod liver oil mixture compared very favorably with the use of sulfathiazole crystals. Two of the patients were so acutely ill that sulfathiazole tablets were administered orally. In two patients, dichloramine-T and Dakin's solution were used to aid in the removal of necrotic tissue. The lesions of three of the four patients healed rapidly without the use of skin grafts, while the lesion of the fourth patient appeared to be healing well until the use of sulfathiazole was discontinued, and suppuration recurred soon after. It is of interest that very little of the sulfathiazole appeared to be absorbed from the local area, since analyses of blood samples showed only traces of the drug present.

Operative Wound Infections.—The wounds of three of the patients were treated with a one per cent suspension of sulfathiazole crystals in sterile distilled water used as an irrigant. The wounds were irrigated two to three times daily, and dress-

ings saturated with the solution were applied. The results were highly satisfactory. The bacterial counts showed a considerable reduction in the number of colonies present within a day or two, and the degree of suppuration diminished at the same time. The wounds of two other patients were treated by applying a one per cent suspension of sulfathiazole crystals in cod liver oil to the surface. This was repeated three to four times a day for several days, and again the results were satisfactory. In one patient, sulfathiazole crystals were dusted on to the wound twice a day for ten days, following which the wound healed completely.

Decubitus Ulcers.—One patient was treated. The result was very gratifying in view of the previous attempts at therapy. The patient was a young male who had had a traumatic myelitis. Due to trophic disturbances, a large ulcer appeared over the sacral region. Staphylococci were cultured from the lesion. Attempts to control the infection included the use of packs saturated in saline solution and sulfanilamide powder dusted onto the involved area. Following this, two attempts were made to hasten epithelization with pinch skin grafts, but in each instance autolysis of the transferred skin took place. Finally, sulfathiazole crystals suspended in cod liver oil were applied three times a day for seven days to the ulcer. At the end of this time, the granulation tissue appeared clean, and an attempted skin graft was successful. The surface of the ulcer became completely epithelized.

Corneal Ulcers.—One patient with bilateral corneal ulcers was treated in coöperation with Dr. T. J. Edwards. The ulcers involved the greater part of the center of both corneæ. They had resisted several forms of local treatment over a period of a month, and it was thought for a time that the vision in both eyes would be lost. At this time, sulfathiazole crystals were dusted into each eye daily. A Saemisch section was carried out at the upper advancing margins of the ulcers of each cornea. Immediate improvement was observed, and after seventeen days of sulfathiazole therapy, the ulcers had healed completely.

Chronic Osteomyelitis.—A number of patients having chronic osteomyelitis had been previously treated with sulfathiazole administered orally.

No apparent beneficial effect was observed. Two patients were treated by placing five grams of sulfathiazole crystals into the infected area. The first patient, a seven-year-old female, had osteomyelitis of the tibia. A sinus leading to the bone and the involved portion of the bone were debrided, and then sulfathiazole placed in the bony defect. A plaster cast was placed on the extremity. Four days later, the wound was examined through a window cut in the cast. It appeared clean, but staphylococci were isolated from the wound. Additional crystals were placed in the cavity, and the patient was sent home. Three months later examination revealed the wound to have healed, and an x-ray film showed extensive replacement of the defect in the tibia by new bone. A second patient has been treated recently in a similar manner, and further time must elapse before an opinion can be expressed concerning the effect of this therapy.

Pyo-pneumothorax.—This represents another type of lesion that we have attempted to treat with sulfathiazole. One patient, an adult female, had been receiving pneumothorax therapy for pulmonary tuberculosis over a long period of time. An effusion appeared in the air-containing right pleural cavity. Purulent exudate was aspirated from the cavity, and staphylococci isolated from the material. It was decided to aspirate the cavity thoroughly, and replace it with 250 c.c. of a one per cent aqueous suspension of sodium sulfathiazole. This was done on two occasions. Sulfathiazole was also administered orally. Microscopic examination of gram-stained smears of the exudate revealed myriads of cocci, a few of them intracellular. After the introduction of sulfathiazole into the pleural space, most of the organisms were intracellular, and those remaining outside of the cells stained poorly, and appeared abnormal in shape. However, the amount of fibrin had increased, presumably because of the alkalinity of the sodium sulfathiazole solution. An aqueous suspension of sulfathiazole was then used. Following this, the number of organisms was reduced, but staphylococci were consistently isolated from cultures of the exudate. This patient's general condition improved so much that a multiple stage thoracoplasty was begun to obliterate the cavity.

Subcutaneous Abscess.—An adult male with a large subcutaneous abscess had also received sul-

SULFATHIAZOLE IN STAPHYLOCOCCAL INFECTIONS—SPINK AND PAINE

TABLE I. SUMMARY OF STAPHYLOCOCCAL LESIONS IN SIXTEEN PATIENTS TREATED WITH LOCAL APPLICATION OF SULFATHIAZOLE

Type of Lesion	Number of Cases	Results
Carbuncle	4	3 granulated in without skin grafts. 1 doubtful result.
Operative wound infection	6	All lesions rendered sterile. Healed.
Decubitus ulcers	1	2 previous attempts with skin grafts failed. After sulfathiazole, grafts successful.
Corneal ulcers	1	Sterile lesion with complete healing after sulfathiazole.
Chronic Osteomyelitis	2	1 showed extensive bone repair three months later. 1 therapy too recent to judge result.
Pyo-pneumo-thorax	1	Number of organisms reduced but cavity not sterilized.
Subcutaneous abscesses	1	Improvement. Died of leukemia.
	16	

fathiazole by mouth with no apparent effect on the abscess, but there was improvement in his general condition. Cod liver oil was applied to the subcutaneous lesion with but little improvement. Sulfathiazole in cod liver oil was then applied daily for thirty-two days. There was marked improvement following this therapy. The lesion granulated in, and partial epithelization took place. However, complete healing was not obtained. The patient expired because of myelogenous leukemia.

Comment

The ultimate goal in the treatment of all septic wounds is to control the infection and promote healing of the tissue. In evaluating any therapeutic measures, the time factor is of importance. While the observations have been few, operative wound infections appeared to heal more rapidly following the application of sulfathiazole than when other antiseptics were used. Final judgment is dependent upon comparative observations made upon a larger series of patients. The management of patients with staphylococcal sepsis must include effective therapy of localized

lesions. While it is recognized that the oral and parenteral use of sulfathiazole will control staphylococcal bacteremia, complete eradication of focal infections is dependent upon other methods. If this is not accomplished, the localized infection may be the source of repeated bacterial invasions of the blood, which in turn may be followed by metastatic foci. Staphylococcal infections are notorious for this sequence of events.

It is quite likely that the best results with the local use of sulfathiazole will be obtained in those lesions that can be approached directly, such as infections of the skin and adjacent tissue. Its use in the management and control of chronic osteomyelitis merits further investigation. It is doubtful whether sulfathiazole introduced into the pleural cavity will completely control infections in this area. The use of sulfathiazole in cod liver oil appears very promising, and it is our intention to treat a larger number of patients in this manner. Emphasis must be placed upon the necessity of employing certain general principles of therapy, along with the local application of sulfathiazole, such as immobilization and gravity drainage, removal of necrotic tissue and purulent material; and frequent irrigation of the infected area.

Summary

1. Localized staphylococcal lesions in sixteen patients have been treated by applying sulfathiazole directly to the infected area.
2. The sulfathiazole preparations used have included sulfathiazole crystals alone; an aqueous suspension of sulfathiazole used as an irrigant and for saturating dressings; and sulfathiazole suspended in cod liver oil. In acutely ill patients, sulfathiazole was also administered orally.
3. The success of the local use of sulfathiazole is dependent, in great measure, upon maintaining a lesion free of purulent and necrotic material. This was accomplished by debridement and frequent irrigations.
4. The foregoing clinical results warrant further investigation of this form of therapy.

AIR-BORNE POLLEN IN THE TWIN CITIES AREA WITH REFERENCE TO HAY FEVER*

C. O. ROSENDAHL, Ph. D., R. V. ELLIS, M.D., and O. A. DAHL, Ph.D.
Minneapolis, Minnesota

CONSISTENT success with specific pollen therapy in the treatment of hay fever and pollen asthma demands an accurate and complete diagnosis of the causes for each case. Erroneous conceptions relative to the ultimate value of the skin test in the diagnosis of hay fever causes appears to be widespread among physicians, as judged from frequent and numerous personal communications received by one of us. That skin sensitivity and clinical sensitivity do not always coincide has long been known, a fact which we have previously emphasized.^{10,11} That patients often exhibit positive skin tests to pollens which do not excite symptoms in the respiratory mucous membranes is a fact concerning which many physicians appear to be uninformed. This state of affairs would appear to indicate that the profession in general is not sufficiently informed concerning the periodicity of atmospheric pollution by the pollen of various species of plants, and considering the paucity of accurate information which has been available in this region until recently, such deficiency on the part of the general profession in the past is excusable. It is time we realize, however, that an *accurate* diagnosis of the causes of hay fever for the individual patient is possible *only when accurate data concerning the specific pollens which pollute the atmosphere in his locality coincident with his period of symptoms*, are available.

Following Blackley's work which proved the etiologic rôle of the pollens of certain grasses in connection with hay fever and seasonal asthma, evidence quickly accumulated that pollen from other plants was also involved. In the incomplete knowledge of that period the erroneous presumption arose that any plant producing pollen

is a potential cause of hay fever. This early and somewhat hasty extension of Blackley's work led to many erroneous notions which are still widespread among the laity and also to an undesirable extent among physicians. The next important advance came with the realization that significant atmospheric pollution results only from those plants which pollinate through the agency of wind and hence only these are important potential causes of hay fever, which fact was pointed out by Scheppegrell¹⁸ in 1917. Showy plants, such as roses, goldenrods, dandelions, daisies, and others which are often accused, were exonerated by the critically minded when it became recognized that the pollen of such plants is not wind carried. The significance of Scheppegrell's contribution deserves emphasis since it provided a basis for compilation of lists of wind-pollinated and therefore the potentially true hay fever causing plants in any particular region. Such lists were derived from botanical works and often with inadequate field observations. Following extensive field observations over a period of many years, such a compilation of the potential causes of hay fever for the State of Minnesota was published by us¹⁰ in 1933. Notwithstanding a certain value attached to this kind of information, it leaves much to be desired, since it must be admitted that such evidence as related to hay fever is entirely circumstantial for it does not disclose whether as a fact or to what extent pollen of the plants listed actually pollute the air.

The application of the method of air analysis by means of pollen counts marked the next advance in knowledge of hay fever causes, and has supplied data of a more exact nature. The method which appears to have been devised by Airy,¹ involves the exposure of microscope slides coated with a viscous material for a definite time (twenty-four hours) and subsequent identification and

*From the Department of Botany and the Students' Health Service, University of Minnesota. This study was financed in part by a grant from the research fund of the Graduate School, University of Minnesota.

enumeration by microscopy of the various kinds of pollen present on a definite area of slide surface. The date on which pollen grains of a given species first appear on the exposed slides determines *exactly* the beginning of atmospheric pollution by that species, the number over a given area of surfaces furnishes a quantitative index of the pollution and its complete disappearance indicates that the period of bloom of the species which produced it has ended.

It can be expressed as a dictum that the period during which the atmosphere contains appreciable quantities of pollen of a given species is to be regarded as the effective clinical period for the species. The thesis of this study has thus been one in which the data would give a diurnal measure of *all* kinds of pollen present during the entire season of pollination (late March through mid October in this region). It is only on such a basis that data, permitting the complete and accurate diagnosis of pollen sensitivity can be obtained, for as we have previously pointed out,^{10,11} a positive skin test does not always indicate clinical sensitivity.

Methods

In obtaining daily records of the pollen content of the air, the so-called gravity method was used. This simple method consists of the exposure of an ordinary microscope slide (viscous coated) in the horizontal position, to the atmosphere for twenty-four hours. The material used for coating the slides was a mixture of three parts of petrolatum, one part of liquid paraffin oil, and one part xylol. If the ingredients are placed in a beaker and gently heated, a uniform mixture is obtained. This preparation is especially useful where prepared slides are being sent to distant stations for exposure. In order that slides might be obtained on rainy days, all slides were exposed under a protective cover, about 10 inches above the slide, which allowed free passage of air but yet excluded most of the rain. The enumeration of each kind of pollen was carried out as follows: Twenty-five microscopic fields (low power, 100X) systematically distributed across the width of the slide in five strips (Fig. A) were examined and the number of pollen grains of each kind recorded. The data thus accumulated may be used to express a quantitative estimate of the amount of atmospheric pollution during the period for which the slide was exposed.

Some workers¹² prefer to present this kind of

data on the number of grains per square centimeter of surface, and Feinberg⁶ has recently expressed the view that, of the several methods, this

Fig. A. Position observed on exposed, oil-coated microscope slide (each circle represents a low-power field having, in our study, an area of 1.55 sq. mm.).

is the most practical and recommends its adoption as standard. The number of pollen grains per square centimeter of surface may be calculated as follows:

Area of 1 microscopic field (100X) in sq. mm. (1.55 sq. mm. in our study) X 25 (number fields counted) = area examined.

Since 1 sq. cm. = 100 sq. mm., then

$$\frac{100}{\text{Area examined (sq. mm.)}} = \text{Factor (F}_A\text{) by}$$

which the number of pollen in twenty-five fields must be multiplied in order to obtain the approximate number occurring in one square centimeter of exposed surface.

Since Scheppegrell¹⁹ devised the method, it has seemed desirable to express atmospheric pollen pollution in terms of the approximate number of pollen grains per cubic yard of air. This kind of information appears to be somewhat more tangible than the amount per surface area, notwithstanding the fact that the surface area values serve as the basis for the calculation of the pollen-grain-per-cubic-yard-of-air values, (application of Stokes' Law). Confusion recently has arisen concerning this method of expression of data, since Cocke^{5,6} has called attention to certain errors in the factors devised by Scheppegrell¹⁹ and our own investigations indicate that Cocke's corrected factors were also incorrect in certain instances. Detailed discussion of the controversies involved are beyond the scope of this paper; however the factors, recalculated and checked, used in calculating the pollen-grain-per-cubic-yard of air values, expressed as the B values in the accompanying figures, are presented in Table I. There is obviously a great need for a standard pollen count formulæ and it is hoped that the recently organized Committee on Aerobiology of the National Research Council will assist in bringing order to a rather uncertain state of affairs. It is pertinent to point out that from

TABLE I. FACTORS FOR CALCULATING APPROXIMATE
NUMBER OF SMOOTH POLLEN GRAINS PER
CUBIC YARD OF AIR

(Revised from Cocke)

If n = pollen grains per cubic yard, N = pollen grains per sq. cm. in twenty-four hours, and $F_{(B)}$ = the calculated factor, then

$$n = N \times F_{(B)}$$

a clinical standpoint it is of importance that pollen data demonstrate the following facts:

1. The approximate time (variability is not great) at which a specific kind of pollen annually makes its appearance in the air and when it reaches clinically significant concentration.

2. The duration of the period for which clinically significant amounts are present.

3. The date (approximate) at which the concentration drops below the level of clinical significance.

Regardless of the unit employed in the recording of data, when graphically portrayed most of these requirements are satisfied. Uncertainty and difficulties arise only in comparisons of data recorded by one investigator with that of another when different standards are employed.

In view of the present uncertainty of methods of calculation, we are expressing our data as shown in the accompanying figures on the following bases:

A. The number of pollen grains per square centimeter of slide surface exposed for twenty-four hours.

B. Pollen grains per cubic yard of air as calculated by Cocke's factors (Revised by the authors).

C. Pollen grains per cubic yard of air as calculated by Scheppegrell's factors.

The letters designating the above bases correspond to the respective values as they appear in the accompanying graphic presentations (Figs. 1 to 19). The values stated are the means of data collected at two stations: No. 1—Botany Building, University of Minnesota, exposure about 60 feet above ground; No. 2—Residence, South Minneapolis, exposure 15 feet above ground.

At Station No. 1, simultaneous exposure of slides at 20-foot and 60-foot levels have given evidence of a remarkably uniform concentration of pollen up to a height of about 60 feet. Scheppegrell²⁰ has stated that up to a height of about 150 feet pollen concentration is essentially uniform. Station No. 1 serves to give evidence of conditions in rather weedy areas since it is adjacent to such areas which border the Mississippi River. Conditions at Station No. 2 are more or less typical of the usual residential sections where waste places are not frequent, and weedy growths are kept fairly well in check. The data of these two stations do not differ greatly, but it is assumed that the mean of observations at these two localities probably represents average conditions prevailing in a large portion of the Twin Cities area. While the amounts of pollution as recorded in this study cannot be strictly applied to other localities in the state, the period of pollution, which is more important, is known to be the same in those regions which do not vary greatly as to latitude.

Various kinds of pollen (representing approximately sixty genera in about twenty families) found to contribute to pollution of the atmosphere, can be arranged into sixteen clinically convenient groups, as presented in a previous publication.¹¹ Present state of knowledge indicates the hay fever exciting substance in the pollen of closely related species to be the same. Patients sensitive to tall ragweed without exception exhibit positive skin tests to short ragweed, marsh elder, and other related weeds. A patient sensitive to oak pollen is sensitive to all species of oaks, et cetera.

The problem of diagnosis is greatly simplified through the reduction of a large number of species to a relatively few antigenic groups. The soundness of this principle has been proved through several years of application in the treatment of hundreds of cases.

Although the bulk of the data is presented in graphic form (Figs. 1 to 19) some discussion seems essential. The groups are presented in essentially chronological order, that is, from the standpoint of season. Plants are referred to by names which appear in Gray's Manual.¹⁷ Likewise, the authors of the botanical names are those given in this work.

Group 1.—Maple, Box Elder Group (Family Aceraceæ)

Of this group, Soft Maple (*Acer saccharinum*) and Box Elder (*A. Negundo*) are of greatest importance, since they produce most of the pollen recorded. Box Elder is the only strictly wind-pollinated member of the group, the others being mostly insect-pollinated. Soft Maple is noteworthy since it is the first plant to shed pollen in this region. Field studies show that pollination may occur as early as March 12^{18,19}. Pollen concentration in the vicinity of Soft Maple trees would definitely be rather high, but since its rather large pollen grain (40 μ) lacks buoyancy, it is not carried for very great distances. Both stations have few Soft Maples in their immediate vicinity, and, as a consequence, the pollen count is low; the highest concentration for any twenty-four-hour period being 34 grains per square centimeter on April 9, 1933. The concentration of Box Elder pollen is strikingly different, for the highest count was 285 pollen grains on April 29 in 1934. Here would appear to be a good example of the rôle which mode of pollination plays in the provisions of the sensitizing agent for, as was stated earlier, Box Elder is strictly wind-pollinated while other maples are almost wholly insect-pollinated. The period April 21 to May 1 represents the time during which the pollen concentration is critically high. It is worthy of note that the records for three out of the four years are quite similar. In 1934 a cold, late spring caused the peak of pollen production to come about one week later than usual (Fig. 1). Such variations in temperature are of importance, since they are correlated with rather marked changes in pollen concentration.^{7,19}

Group 2.—Birch, Hazel, Ironwood Group (Family Betulaceæ)

Members of this group are not overly abundant in the areas immediately surrounding the two stations, which fact probably accounts for the variability seen in the data. Pollen grains of birch and its allies (which average about 30 μ in diameter) are quite buoyant and are therefore carried by winds for some distance. Indeed, pollen grains of the birch family have been caught 34.1 miles out in the sea and at heights of more than 2,000 feet in the air.⁴ Likewise Erdtman¹³ has observed occasional pollen grains of Alder at a distance of more than 400 miles off the coast of Newfoundland. It is thus to be expected that alteration of either wind velocity or wind direction and the occurrence of rain would contribute to the variability seen in the pollen concentration (Table II). Relatively high pollen counts are attained during the period April 28 to May 11. The entire pollinating season extends from April 7 to May 30 (Fig. 2).

Group 3.—Poplar, Willow Group (Family Salicaceæ)

Cottonwood (*Populus deltoides*), which belongs in this group, produce large quantities of pollen. At the peak of pollen production in 1934 (April 28), the concentration was 1,013 grains per sq. cm. The extent of the season during which the pollen count is of importance is about ten to twelve days, beginning with April 20. High concentrations were observed on April 23 and 24 during three out of the four years. The willows are largely insect-pollinated and their pollen never fills the air to the extent that cottonwood pollen does. Since the exine (outer wall) of their rather small pollen grains (25 μ in diameter) is finely ridged (striate-reticulate), most of the pollen occurs in masses heavy enough to fall rather quickly to the ground. However, some pollen of various species of willow (Pussy-willow—*Salix discolor*, sand-bar willow—*S. Longifolia*, Peach-leaved willow—*S. amygdaloides*, Weeping willow—*S. babylonica*, et al) are consistently found on the slides. During the first half of May the maximum concentration may be as high as 74 pollen grains per square centimeter (May 3, 1935). Since various kinds of willows pollinate throughout May, they serve to prolong the pollination period of this group (Fig. 3).

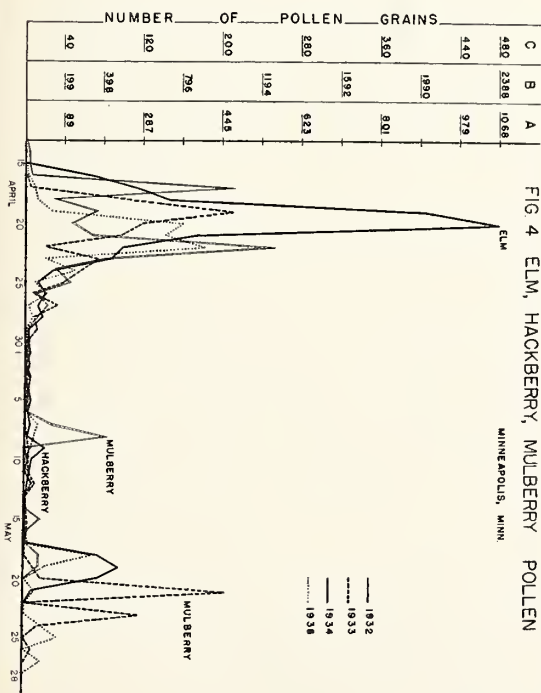

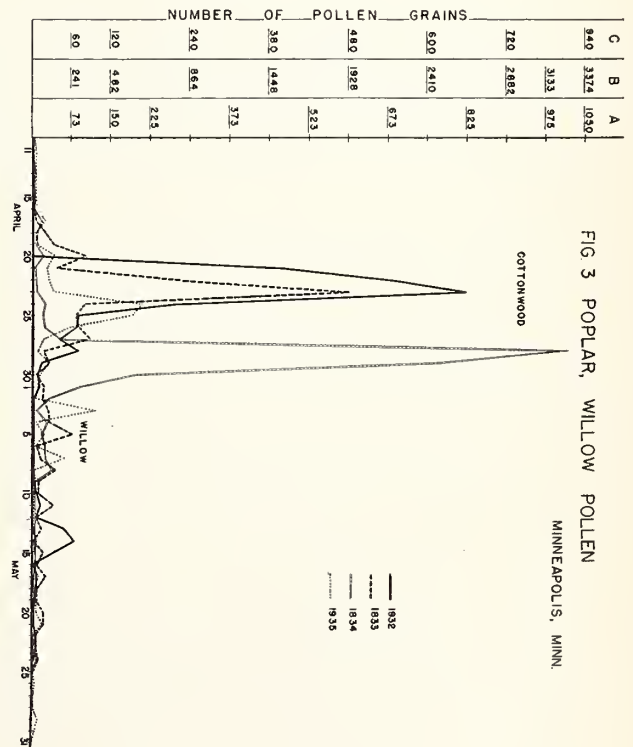

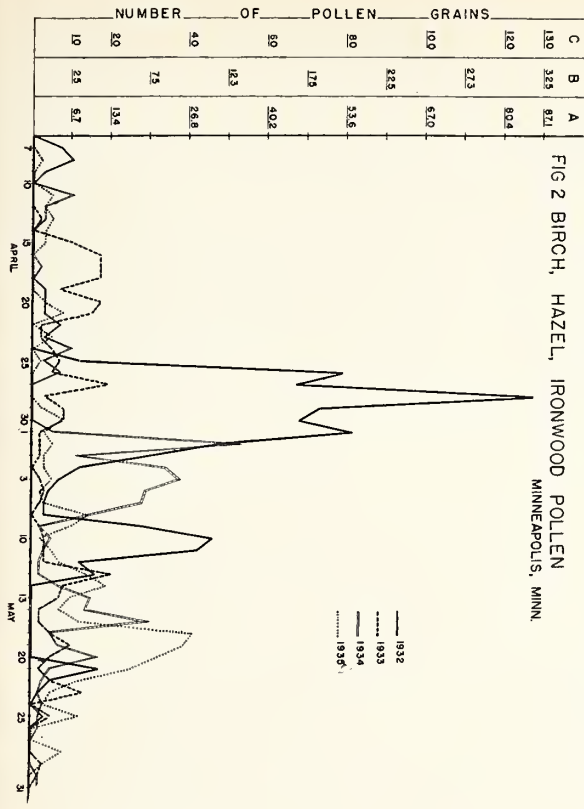

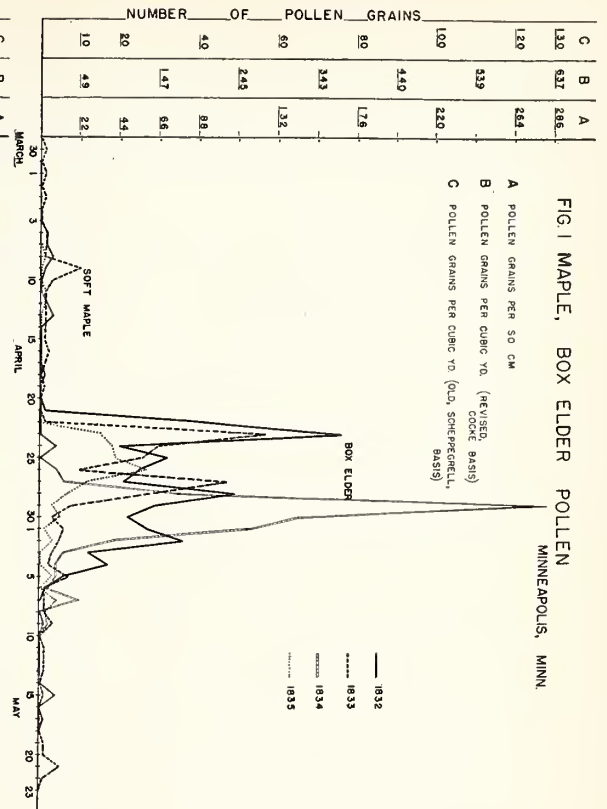

TABLE II. DATA SUMMARIZING THE BEHAVIOR OF AIR-CARRIED POLLEN

GROUP	TOTAL POLLEN COUNT (Summation of daily 24-hour concentrations) (number per sq. cm.)				Duration of pollination (four years' data)	Date of Highest Pollen Count (Mean of two stations)				Highest 24-hour Count (in pollen grains per sq. cm.)

Group 4.—*Elm, Nettle, Hemp Group* (Family *Urticaceæ*)

The various plants placed in this group all belong to the Nettle family; but since their season of pollination variously occurs from April through September, they have been placed into two subdivisions (Fig. 4—Elm, Hackberry, and Mulberry; Fig. 5—Nettle and Hemp). The Elms (*Ulmus americana* and *U. fulva*) pollinate within the period April 15 to 30, the maximum concentration being observed on about the 20th (1,062 pollen grains per square centimeter of surface April 20, 1932). These trees are capable of producing large quantities of buoyant* pollen and are relatively important since they are widely planted.

The explosive flowers of Mulberry (*Morus alba*) produce quantities of small pollen grains (16 μ in diameter). The latter half of May represents its normal pollination period; although in

1934 its maximum (25 pollen grains on May 8) came about two weeks earlier than usual. Hackberry (*Celtis occidentalis*) pollen has not been abundant on the slides. The highest concentration observed (usually occurring about May 10) was 25 pollen grains per square centimeter on May 9, 1932. Its pollination season extends throughout the first half of May (Fig. 4).

Nettles *Urtica gracilis*, *U. dioica*, *Laportea canadensis*) produce the smallest sized pollen grains noted in this survey (15.8 μ in diameter). They are common, widespread weeds (cf. distribution map¹¹) which normally produce pollen from about the first of July to September 10. Maximum pollen production has been observed about July 25 in 1932 and 1934, while the years 1933 and 1935 have shown highest counts during August 29, 1933; August 11, 1935). The pollination period of Hemp (*Cannabis sativa*) is essentially the same as for nettle. Its pollen grains, which are about twice the size of those of nettle, have been relatively sparse, 23 being the highest twenty-four-hour count (August 6, 1934). Max-

*The occurrence of elm pollen grains on the slides a month in advance of their normal appearance very definitely suggests that they can be transported for rather great distances. During this period elms were shedding pollen in the vicinity of Chicago, Illinois.

imum pollen production is attained during the first half of August (Fig. 5).

Group 5.—Sedge, Bulrush, Cat tail Group (Families *Cyperaceæ* and *Typhaceæ*)

As a group, these plants have never been thought of as of any great significance in the causation of hay fever. The fact remains that numerous patients are sensitive by skin test to the group (24.7 per cent of 936 cases. See Table III). Further, plants belonging in this group are often abundant in places frequently used as summer resorts or "hay fever havens."

Pollen grains of various sedges (*Carex pendunculata*, *C. longirostris*, *C. pennsylvanica*, *C. vesicaria*, et al.) have been noted during the period May 4 to June 5 (1934 and 1935). A low maximum of 8 pollen grains per square centimeter was noted on May 18, 1935.

Cat tail (*Typha latifolia*) produces large quantities of pollen grains, which usually remain together in groups of four (quartets or tetrads). Its season of pollination extends from June 10 to about the middle of July with highest concentration occurring with the close of June (June 26, 1933). During approximately the same period, pollen of various species of Bulrush (*Scirpus validus*, *S. fluviatillis*, *S. atrovirens*, et cetera) occurs in the air. It is most abundant around the 18th of July (Fig. 6).

Group 6—Ash Group (Family *Oleaceæ*)

Data of the first three years of this survey suggest that the usual period during which various species of Ash (*Fraxinus pennsylvanica* var. *lanceolata* and *F. nigra*) pollinate is from April 25 to May 17. During 1935, with rather cold, rainy weather, the pollination season persisted until the end of May. Highest pollen concentration (e.g., 99 pollen grains per square centimeter on May 4, 1932) is usually attained during the first week in May (Fig. 7).

Group 7.—Oak Group (Family *Fagaceæ*)

Various oaks (White Oak—*Quercus alba*, Bur Oak—*Q. macrocarpa*, Hill's Oak—*Q. ellipsoidalis*, and Red Oak—*Q. borealis*) are important hay fever causing plants during the month of May. They produce large quantities of pollen and are widespread in their distribution. Pollination extends throughout May. In 1932 a maximum concentration of 1,303 grains per sq. cm.

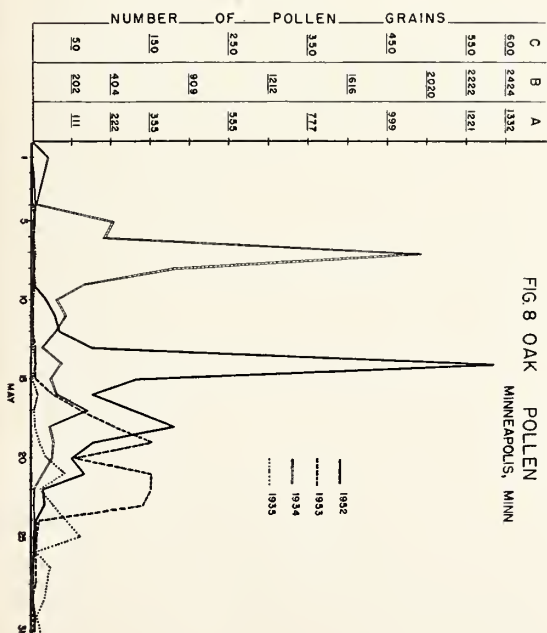

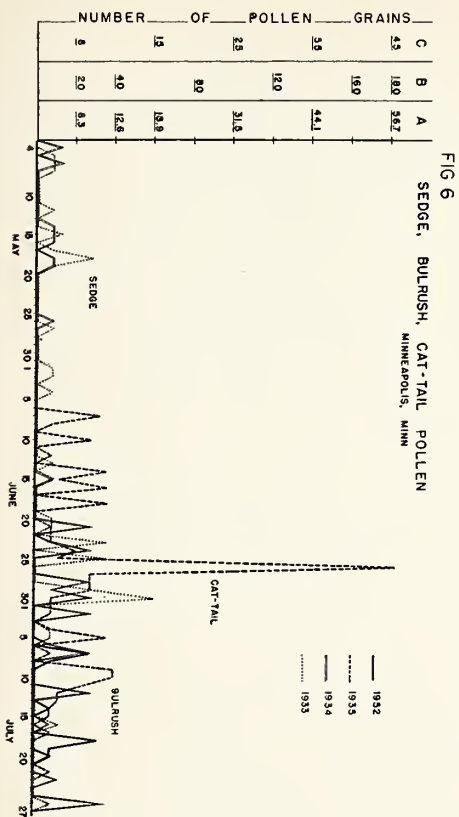

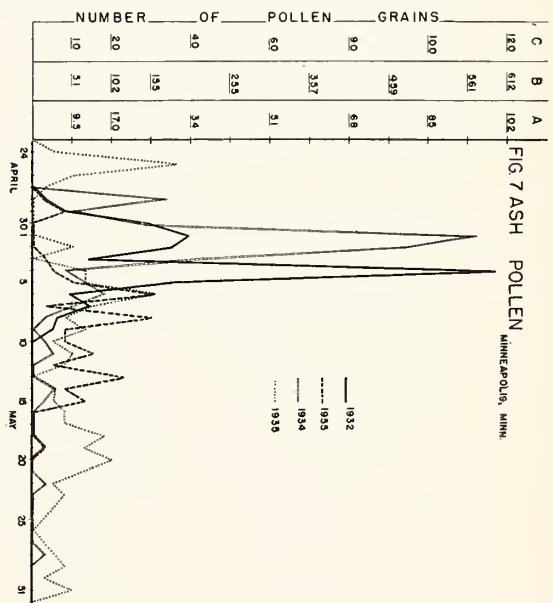

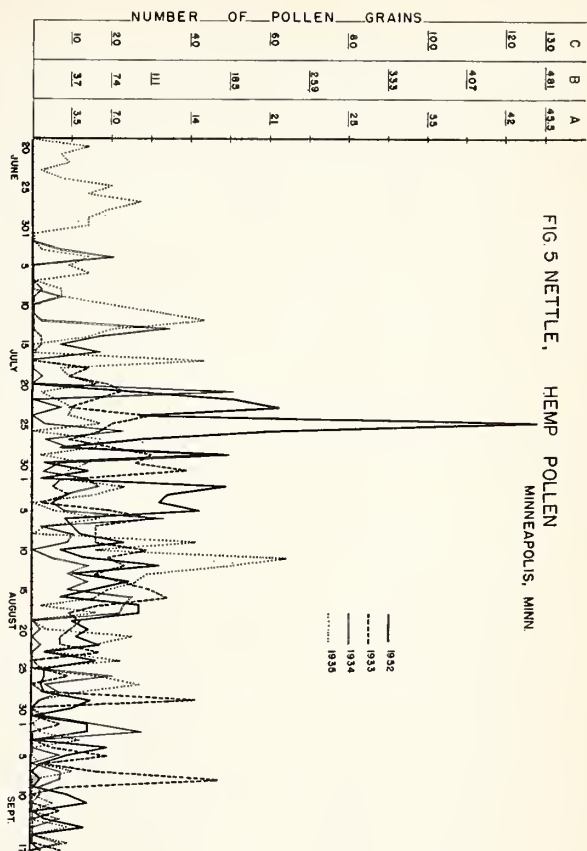

occurred on May 14. With excessively high temperatures in 1934 a peak of 1,083 pollen grains was observed on May 7, while in 1935 rather cool, rainy weather delayed the appearance of the very low peak until May 25 (Fig. 8).

Group 8.—Grass Group (Family *Gramineæ*)

During the very last days of May and pre-eminently throughout June, pollen of this very important group is predominant in the air. Seasonal maxima have occurred on June 7 (in 1932, 213 pollen grains per square centimeter) and on June 13 (in 1935, 403 pollen grains). It is during this period that the very abundant grasses such as June Grass (*Poa pratensis*), Spear Grass (*P. annua*), Hungarian Brome Grass (*Bromus inermis*), Orchard Grass (*Dactylis glomerata*), and Reed Canary Grass (*Phalaris arundinaceæ*) come into their period of most profuse flowering. Timothy (*Phleum pratense*) and Quack Grass (*Agropyron repens*) begin pollination during the last days of the month (Fig. 9).

The period during which this survey has extended has been most interesting for the tendencies especially evident in this group, and also in two others which are to be subsequently mentioned. During the period 1932 to 1934 there was a very distinct and increasing deficiency in the amount of precipitation. The devastation which this factor brought to our grassland pastures needs little emphasis. Reference to Figure 9 will show that the pollen curve for 1932 does not approach the base line until July 2, while in 1933 and 1934 the curves closely approach or coincide (note the 1934 curve) with the base line much of the time. Correlated with a distinct increase in the amount of precipitation during 1935 is a striking change in the pollen curve for this year. Indeed, the highest twenty-four-hour concentration of grass pollen ever recorded in this survey came during this year on June 13. This striking occurrence may well serve to exemplify the drought-resistance of the grasses. The total grass pollen count recorded for each of the four years in Table II indicates how markedly pollen production has varied.

Pollen of the various late-pollinating grasses (Grama or Mesquite Grass—*Bouteloua curtipendula*, *B. hirsuta*; Satin Grass—*Muhlenbergia mexicana*; Blue Stem—*Andropogon furcatus*, Sand Reed—*Calamovilfa longifolia*, et al.) are present in the air, though in rather small quan-

tities, during July, August, and September. This fact very definitely suggests that grasses must be considered as possible contributors to late summer hay fever. In the past their omission, as well as of other so-called "minor" groups, has resulted in an inadequacy of diagnosis and consequently of treatment of such cases.

Group 9.—Butternut, Walnut, Hickory Group
(Family *Juglandaceæ*)

Slides exposed during the period May 8 to June 19 have shown pollen grains of this group. The rather large grains which these trees produce (*Juglans*—39 μ in diameter, *Carya*—53 μ in diameter) have not been very abundant. On May 23, 1932, a peak of 27 pollen grains was noted, while in 1934 a peak of 38 grains occurred on May 17 (Fig. 10).

Group 10.—Plantain Group (Family *Plantaginaceæ*)

Except for observations during 1932, pollen grains of plantain (*Rib* grass—*Plantago major*, *P. Rugelii*) have been very occasional. During the last three years of the survey the number of plants occurring in the vicinity of the exposure stations has been markedly reduced by weed cutting and by extreme drought. Pollen is shed from mid-June to the first part of August with a maximum concentration being attained by the 24th of June (Fig. 11).

Group 11.—Dock, Sorrel Group (Family *Polygonaceæ*)

Included in this group are various species of Dock and Sorrel (*Rumex acetosella*, *R. mexicanus*, and *R. crispus*). The unusually high concentration noted in 1932, as compared to the very low counts recorded in the three years that followed, appears to be due to the same factors discussed in the previous group. Pale Dock (*R. mexicanus*) in the immediate vicinity of Station No. 1 was especially productive of pollen during 1932. Pollination has been noted from May 20 to July 22, with the peak of pollen production occurring between the 7th and 17th of June (Fig. 12).

Group 12.—Sweet Clover, Alfalfa Group
(Family *Leguminosæ*)

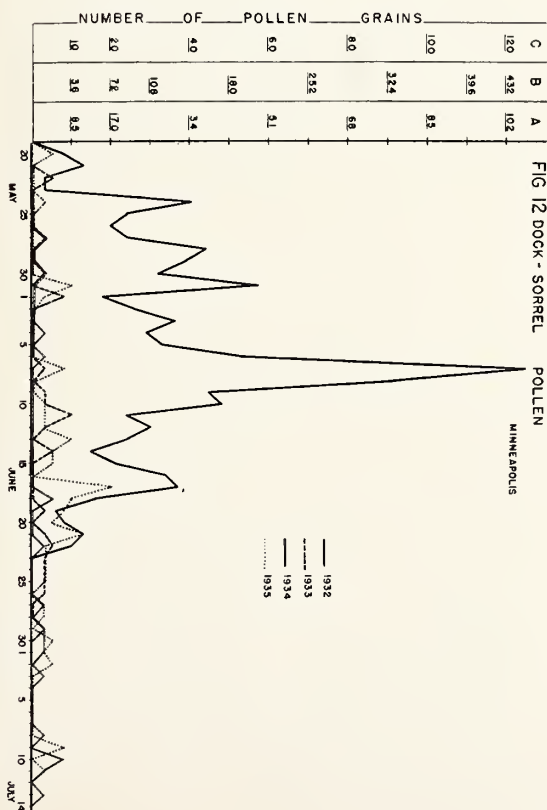

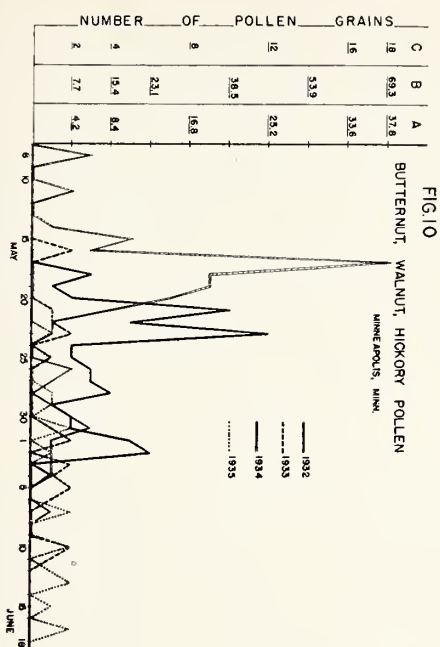

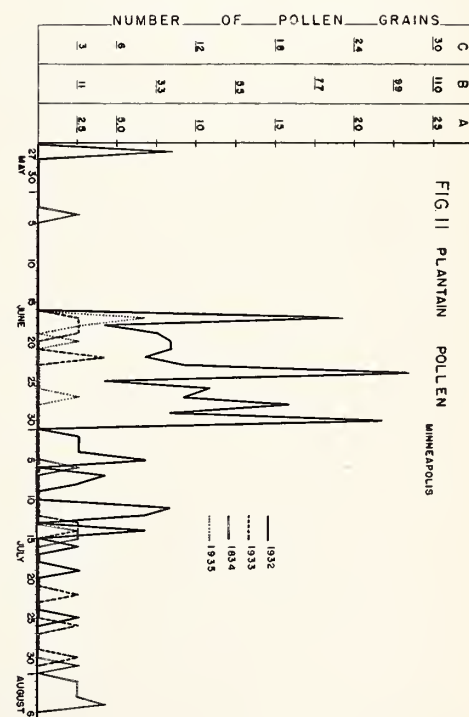

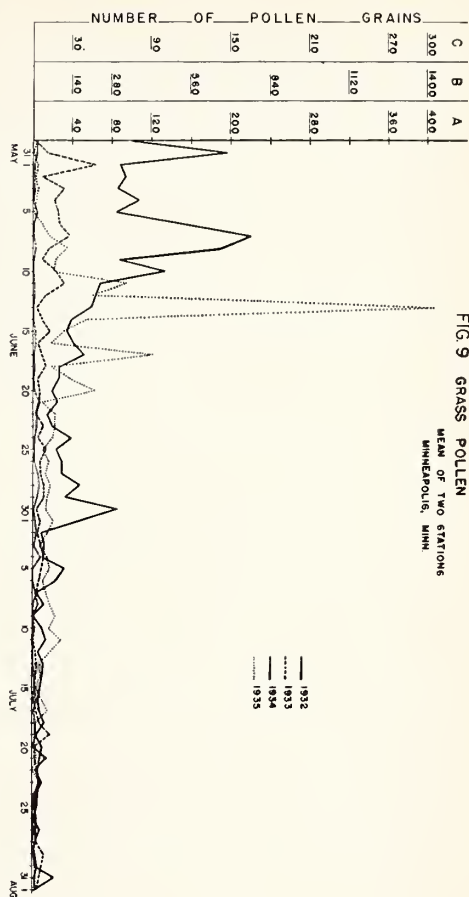

Since Sweet Clover (*Melilotus alba*, *M. officinalis*) and Alfalfa (*Medicago sativa*) are in-

sect-pollinated plants, it is somewhat strange that they should receive consideration in this communication. However, their flowers are so constructed that a mass of rather small, dry pollen (32 μ in diameter in *Melilotus*) is ejected whenever insects visit ("trip") them. This would mean that in rural regions where these plants are abundant, pollen concentration can attain sizeable proportions. On slides exposed at the two stations Sweet Clover has been observed only during 1934 and 1935, within the period June 26 to July 22. The highest concentration noted was 6 grains per square centimeter. (Fig. 14).

Group 13 and 14.—Chenopod Group (Families *Chenopodiaceæ*, *Amaranthaceæ*)

Abundant and widespread weeds of importance as causes of hay fever belong to this group. The pollen grains of the *Amaranthaceæ* are not distinguishable from the *Chenopodiaceæ* (cf. Wodehouse²⁵) and as a consequence Figure 14 gives a summary of both groups. In general, the period July 1 to September 25 represents the period during which critical concentrations are attained.

During July, Russian Thistle (*Salsola Kali* var. *tenuifolia*), Pigweed (*Amaranthus retroflexus*), and Lamb's Quarters (*Chenopodium album*) rank as being of greatest importance. Pollen of Burning Bush (*Kochia scoparia*) usually attains its greatest frequency during August. Maxima for the group have occurred as follows: On August 16 in 1933 (57 pollen grains), on August 21 in 1934 (82 pollen grains—the highest count observed during the four years), on August 29 in 1932 (59 grains), and on September 24 in 1935 (65 grains). Of the total pollen production for the season 49.1 per cent occurs during August. During 1935 high concentrations (up to 46 pollen grains) also occurred during mid-August. As with the grasses, a comparison of the yearly totals (Fig. 18) reveals a striking relationship between the amount of pollen and the lack of rainfall, though in a different manner. With increasing dryness there is noted an increase in the total amount of pollen. This fact finds explanation in the tremendous increase of Russian Thistle (*Salsola Kali* var. *tenuifolia*) in areas ordinarily occupied by grasses during years with normal rainfall.¹⁹ With an increase in precipitation during 1935 there was a decrease in total amount of Chenopod pollen which is correlated with the fact that conditions were again

suitable for other plants in addition to the Chenopods.

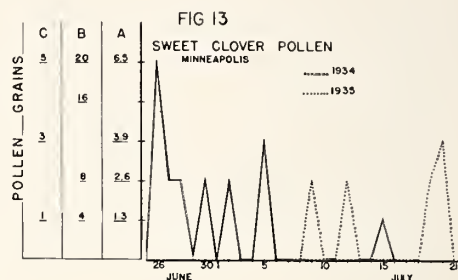

Group 15.—Wormwood Group (Family Compositæ)

While the pollen concentration of this group has never been as high as that observed for such groups as Ragweed, Chenopod and Grass, it still must be considered as a rather important element involved in many cases of late summer and fall hay fever.^{9,10,11} The various kinds of Wormwood or Sage (*Artemisia vulgaris*, *A. dracunculoides*, *A. caudata*, *A. biennis*, *A. frigida*, and *A. ludoviciana*) contribute to a rather long season of pollen production (from July 6 to October 7). Seasonal maxima may occur after the middle of September (September 17 in 1935—25 grains per square centimeter; September 23 in 1932—44 grains). This fact takes on greater etiologic importance when it is realized that 75 per cent of the cases sensitive to the Ragweed Group are also sensitive to this group. Wormwoods can thus serve to prolong the potentially troublesome season (Fig. 15).

Group 16.—Ragweed Group (Family Compositæ)

In number of cases in which it is involved, this group very definitely ranks first. Common and widespread members of this group include Common (short) Ragweed (*Ambrosia artemisiifolia* or *A. elatior*), Giant Ragweed (*A. trifida*), Western Ragweed (*A. psilostachya*), Marsh Elder (*Iva xanthifolia*), and Cocklebur (*Xanthium canadense*). Maps presenting the distribution of these throughout the state of Minnesota have been published in previous communications.^{10,11} From August 10 to September 25 the air is predominantly occupied by pollen of this group. Pollen grains have been caught on the slides as early as July 2 (1935), but no sizeable count occurs until August 10. It is worthy of note that August 15, in general, represents the first day on which a pollen concentration of over 100 grains per sq. cm. of surface is attained. This fact appears to be significantly correlated with the incidence of first marked hay fever symptoms by so many ragweed sensitive cases. A concentration of between 100 and 200 grains may be thought of as something like a threshold value. It must be added, however, that since most ragweed cases are also sensitive to at least one other group,^{8,10,24} the atmospheric concentrations of other groups

must be considered in making a detailed analysis of symptoms. For example, August 15 also represents a period of comparatively high pollen production for the Chenopod group and consequently

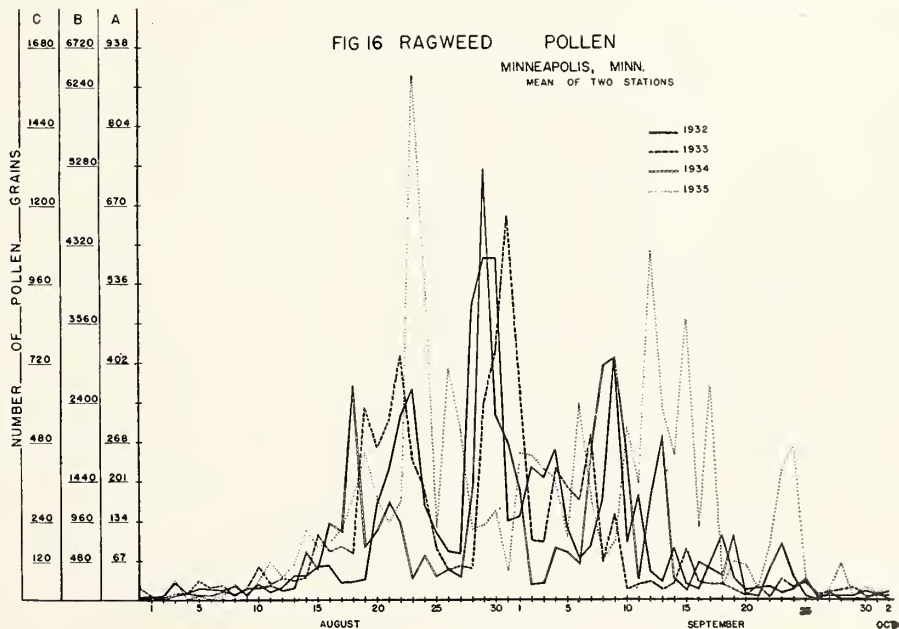

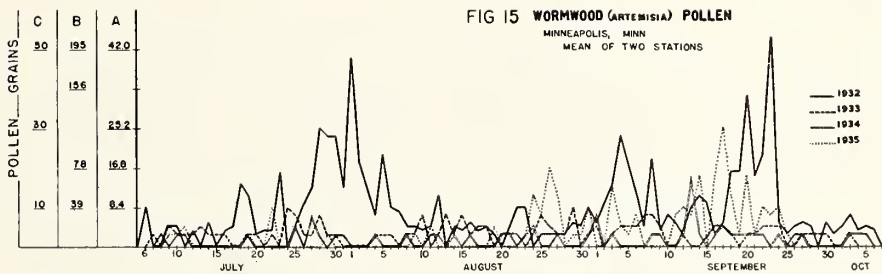

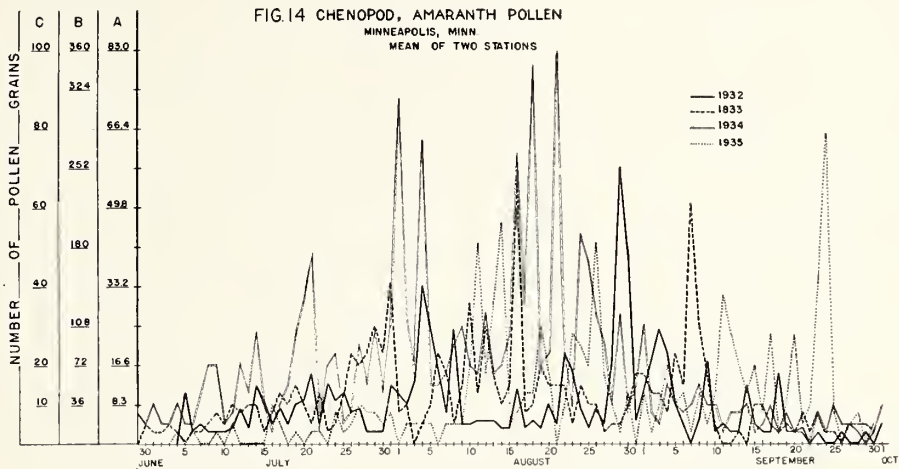

severe symptoms on this date could well be due to one or the other, or both groups. Data of the first three years on this survey have demonstrated the occurrence of three distinct critically high peaks of pollen production. The first of these, representing a concentration of approximately 378 pollen grains per square centimeter, has occurred as follows: August 18 in 1934, August 22 in 1933, and August 23 in 1932 (Fig. 16). The maximum pollen production of the season represents the second of these peaks (with an average count of 650 grains exclusive of 1935 data). For the first three years of the survey this concentration has been consistently noted between the 29th and 31st of August. The third marked peak (averaging 364 grains and thus quite similar to the first peak) has occurred on the 7th and 9th of September during the three years.

The data for 1935 indicate somewhat different conditions. High temperatures served, in general, to accelerate pollen production. On August 14 the concentration was 116 pollen grains per square centimeter, while the highest twenty-four-hour mean pollen count ever recorded in this survey (883 grains, mean of the two stations) was noted on August 23. As has been already noted, the maxima for other years occurred about one week later than this (August 29, 31). The days during the latter part of August and the first part of September were cool, and consequently the pollen count was rather low. However, strikingly high concentrations were again attained on September 6 (the period of the third peak of pollen production of the other years), and on September 12 the pollen count was way out of proportion to any experienced this late in the season. For the latter date a maximum con-

centration of 275 grains might have been suggested, but actually the count was 587 grains. In addition, unusually high concentrations were ex-

perienced on the 15th, 17th, and 24th days of this month. The last peak (258 grains) is of further etiologic interest since it came on the same day

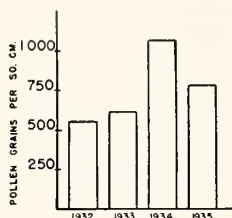

perienced on the 15th, 17th, and 24th days of this month. The last peak (258 grains) is of further etiologic interest since it came on the same day

single group during the same twenty-four-hour period is obviously an important fact where multiple sensitivity (commonly the case) is involved.

Group 17.—Miscellaneous Group

A varied assemblage of air-borne particles can be grouped under this heading. Among those consistently present are pollen grains of Pine (*Pinus Strobus*, *P. resinosa*, *P. Banksiana*, and

FIG 17 CHENOPOD POLLEN
AUGUST - SEPTEMBER TOTAL
MINNEAPOLIS, MINN

occasionally *P. montana*, *P. sylvestris*, and *P. nigra*) and Basswood (*Tilia americana*).

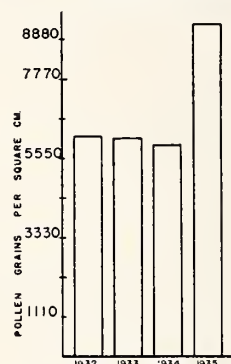

While pine pollen is most abundant during the latter part of May (average monthly total, 296 pollen grains), it is only slightly less so during June, whose average monthly total is 243. Greatest seasonal production of pollen was seen in 1933, when the annual total (820 pollen grains) was 35 per cent in excess of the average yearly total (607). The maximum twenty-four-hour count of 190 pollen grains per sq. cm. occurred during this year on May 30. It is of interest to note that occasional or "relic" pollen grains have been observed during every month of the year except January. Furthermore, the incidence of pine pollen grains could be, in many instances, related to severe atmospheric disturbances, especially with those that involved the descent of upper strata of air. Pine pollen grains, which possess bladder "wings," are quite buoyant, and Scheppegrell²¹ has noted them on slides exposed 17,000 feet above the earth during September. The relationship of pine pollen and hay fever appears to be very slight indeed for sensitivity to this group has been rarely if at all noted. Pollen of various kinds of Juniper (Cedar), which plants belong in the allied Cypress Family (*Cupressaceæ*), have been involved in some cases on record.² Very occasional grains of Juniper were noted during May of the last three years of this survey. Sporadic pollen grains of Fir (*Abies*), Spruce (*Picea*) and Tamarack (*Larix*), which are members of the Pine Family (*Pinaceæ*), also occurred on the slides.

While basswood or linden (*Tilia*) is insect-

pollinated, it possesses flowers which are favorably placed for the introduction of pollen into the air currents. It is fairly abundant, both as native and cultivated trees, and should be considered as a possible though minor factor in sensitivity. While the pollen count has never been high (maximum twenty-four-hour count—31 pollen grains), it should be noted that it occurs during a time when the total pollen content of the atmosphere is comparatively low.

During the period June 23 to 30, the unexpected occurrence of a few pollen grains of the Mustard Family (*Brassicaceæ*) was noted. The grains were of two sizes (27 μ , 37 μ), the small-

FIG 18 RAGWEED POLLEN
AUGUST - SEPTEMBER TOTAL
MINNEAPOLIS, MINN

er of which agreed with those of Tumble Mustard (*Sisymbrium altissimum*); the larger being those of common mustard (*Brassica nigra*). Investigation of patches of these common weeds demonstrated that very small quantities of pollen could be carried away from the opened flowers by strong air currents. This incidence, along with that of occasional Hop (*Humulus*), Grape (*Vitis*), Sumac (*Rhus*), Apple (*Malus*), Plum (*Prunus*), Sunflower (*Helianthus*), Aster, and unidentified *Compositæ* pollen grains, can only serve to point out some of the possible kinds of pollen which occasionally get into the air currents (Fig. 13). Hockey and Harrison¹⁴ observed apple pollen on slides placed at a distance of 135 feet from the trees. Since these pollens have not been consistently noted as being in the air, they would appear to be of only occasional clinical importance.

Discussion

The importance from a clinical standpoint of the data presented is obvious. Before a specific pollen or antigenic group of pollens can be con-

sidered to have significance even as a potential cause of hay fever (or asthma) for an individual or a group of patients, it must be established that the pollen in question is a pollutant of the atmosphere during the period when symptoms are complained of. The importance of a careful history as to period of symptoms is also apparent. A positive skin reaction has no diagnostic significance except it be shown that the pollen which induced it pollutes the atmosphere coincident with the period of symptoms of the patient. The discrepancy between skin sensitivity and clinical sensitivity is wide. It is notably greater in connection with some antigenic groups than with others, but is quite significant in all. The importance of recognizing the limitations of the skin test will be apparent from a study of Table III. This analysis of 936 consecutive cases of our own shows the number and percentage of patients reacting by skin test to each group, the number and percentage of the total who are clinically sensitive, and the percentage of those with positive skin tests who are clinically sensitive. For example, 425 (45 per cent) of the total (936 cases) exhibited positive skin tests to the Maple group, while only forty-five (4.8 per cent) of the total cases are clinically sensitive. In the case of the ragweed group (No. 16) the correlation between skin sensitivity and clinical sensitivity is higher and yet the difference is significant. Eight hundred and thirty-five (89 per cent) of the 936 cases gave positive skin tests to ragweed, but only 776 (83 per cent) of the total had symptoms during the August to frost period. Ninety-three per cent of those with positive skin test to this group of pollens are clinically sensitive. On the basis of the skin test alone the diagnosis would have been incorrect in fifty-nine (7 per cent) cases. The need for accurate data in regard to atmospheric pollution with which the period of symptoms may be correlated is obvious. The data herein presented supplies this need.

Concerning the exact amount of pollen which is clinically significant, no absolute values can be stated. It is important to recognize that this varies with different patients, dependent upon the degree of clinical sensitivity. For example, one patient sensitive to ragweed may regularly exhibit symptoms in the last few days of July, when the quantity of ragweed pollen in the air is slight, while a second does not show symptoms until

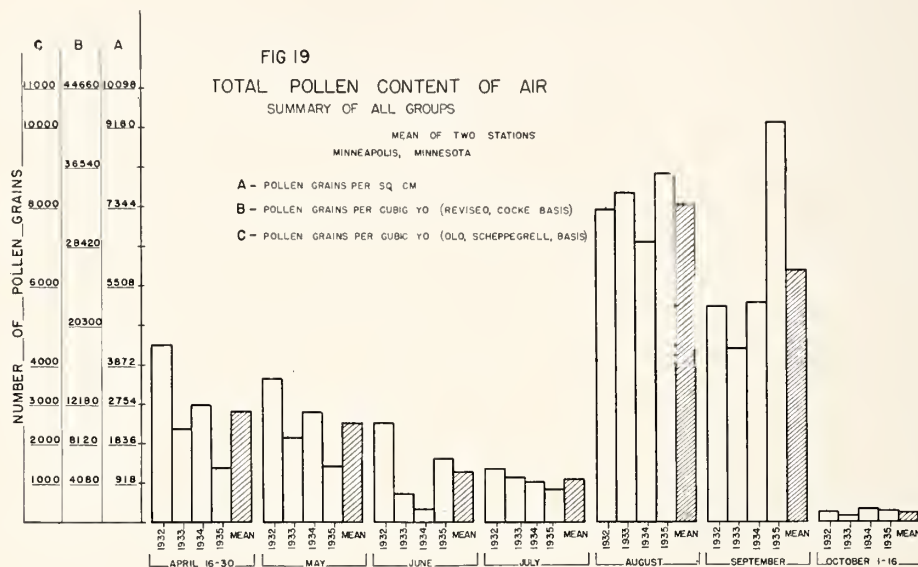

August 15 or later, when the amount of pollution is large. However, the patient clinically sensitive to a given species or antigenic group will exhibit symptoms during the period of greatest atmospheric concentration and when correlation to this extent does not exist, he must be considered as *not* clinically sensitive to the pollen in question, regardless of the fact that the skin test may be positive.

If the sixteen groups are arranged first, in order of number of cases in which they are involved, and, secondly, in order of their pollen production, it is noted that seven out of the ten most important groups from a clinical standpoint also rank among the ten most abundant pollen producers. It would appear that the total amount of irritative substance to which the patient is exposed is an important factor which enters into the problem. However, perfect agreement between number of cases and total amount of pollen is not to be expected, for such factors as potency of the pollen and duration and time of blossoming season are, in all probability, also involved.

It is reasonable to suppose that the maximum number of pollen units given in successful treatment during one season may not be specifically adjusted to conditions prevailing the next season, especially where such abnormally high peaks occur as they did on August 23, September 12, and September 24, in 1935. A maximum dosage, for example, which has given complete protection during a season in which the highest daily pollen count was 800 pollen grains per square centimeter may not be adequate for a season during which a count of 1,224 occurs. It is for this reason that in Table II the highest individual (not mean) daily count is given for each Group. These figures, together with the date of highest pollen count, serve to measure and point out in a general way the most critical period for those patients who are sensitive to the Group. Obviously, maximum dosage in treatment should be attained before this period. The dates given as covering the duration of the pollination season do not indicate the period during which pollen is present in the atmosphere for any one year, but rather mark the possible limits of the pollinating season as evidenced from this survey. The yearly total pollen production for each Group is also given in Table II, since it is indicative of a seasonal variability which possesses clinical importance, as has been already suggested. Such climatic fac-

tors as rainfall, temperature, and wind are naturally concerned with the presence of pollen in the air, and variation of these will be reflected in the pollen curves (Fig. 19). For example, de-

area to another. Elm pollen grains were observed on slides exposed during mid-March (March 14-20, 1933), which is just a month in advance of their normal period of incidence in this region.

creases in pollen concentration, which are striking when seen in graphic form, may be directly correlated with rainfall.

A rise or fall of temperature may be respectively associated with an increase or decrease in pollen concentration. This relationship appears to be related to the fact that temperature is concerned with the progress of cellular activity²² and thus with the actual production and release of pollen. Further, variable convection currents, which are related to various temperatures, are apparently important in the rise and fall of pollen grains, and thus with their incidence on the slides. It is of interest to note that Markow and Spain¹⁴ have noted a suggestive relationship between daily symptoms and temperatures. A correlation analysis^{7,19} of the data for 1932 demonstrated that highest correlation between the daily pollen count and daily temperature was seen at times during which temperature is essentially a limiting factor, i.e., during April, May, September and October (mean $r = 0.602$). During these periods daily wind velocity was not significantly related to the daily pollen counts (mean $r = 0.162$).

Throughout the text, reference has been made to pollen counts obviously related to wind direction and velocity. Winds are especially concerned with the movements of masses of pollen from one

Their presence can be related to a period of strong, south winds. At this time Elms were pollinating in the vicinity of Chicago, which would suggest that these pollen grains had been carried a distance of approximately 300 miles (Fig. 3).

Additional evidence may be cited for the widespread dispersal of pollen. Chenopod pollen grains as well as spores of *Alternaria* and *Puccinia* were caught on slides exposed aboard a boat traveling from Duluth, Minnesota, to Ft. William, Ontario. Likewise, during this same period (August 17 to 20, 1934), slides exposed at Isle Royal, Michigan, showed very occasional grains of grass, chenopod, ragweed, pine, fir, and alder pollen. Perhaps of greatest interest in this connection is Erdtman's¹³ notation of a wide variety of pollen grains midway between Iceland and Ireland. He observed pollen representing such families as birch, pine, poplar, oak, willow, basswood, nettle, chenopod, mustard, sedge, heath, and grass. Stakman, et al²³ have observed that spores and pollen grains are relatively abundant up to a height of 11,000 feet.

A series of slides exposed from August 12 to September 4, 1934, on an island in Poplar Lake are of interest since, excepting for eight days during which there was a southwest wind, no ragweed pollen was found. Poplar Lake is north of Lake Superior (Grand Marais, Cook County,

Minnesota) and ragweed does not occur in the region. On days during which ragweed and chenopod pollen occurred on the slides exposed at Poplar Lake, high pollen concentrations of these groups were also observed at stations located further south, in Duluth, Moorhead, Minneapolis, and Montevideo. Strong southerly winds would come from regions richly supplied with ragweed pollen (cf maps¹¹) and would thus serve to spread pollen-laden air beyond the limits of actual plant distribution. Similarly, winds would function in carrying pollen into regions where the plants were no longer actively pollinating, thus prolonging the troublesome season.

Summary

1. Pollen data based upon the study of atmospheric slides, exposed daily for four consecutive seasons in Minneapolis, Minnesota, are summarized under seventeen generalized group headings.

2. In certain of these groups uniformity of seasonal behavior has been noted, whereas in others marked variability has been seen. The clinical importance of this fact is obvious.

3. Important clinical aspects of these data which have been considered include:

- a. The kinds of pollen present in the atmosphere for the entire growing season.
- b. The time when a specific kind of pollen first appears in the air.
- c. The period during which clinically significant concentrations exist.
- d. The period of most critical (highest) concentration.
- e. The time at which a pollen is no longer a factor in the atmosphere.
- f. The fallacy of conclusions as to clinical sensitivity when based on skin sensitivity alone.

g. The importance of correlating the period of symptoms with data in regard to atmospheric pollution.

4. It is concluded from a brief review of existing methods of calculation that at present it is desirable to utilize the unit area basis for expressing pollen concentration.

MANAGEMENT OF TETANUS WITH REPORT OF USE OF HYPERTHERMIA IN ONE CASE*

PHILIP H. HEERSEMA, M.D.

Rochester, Minnesota

IT IS a tribute to the medical and surgical practice of today that the incidence of tetanus has been so materially decreased by prophylactic procedures, such as the proper care of wounds and administration of prophylactic antitoxins. The widespread occurrence of the *Clostridium tetani* in black dirt, garden mold, manure and putrefying liquids, as well as in the excrement of horses and man, indicates that the prevention of tetanus by elimination of its bacterial source is impractical. Therefore, the problem of tetanus must be dealt with from the standpoint of prophylaxis and treatment in those cases in which the infection breaks through even the most favorable prophylactic policy.

The efficacy of strict prophylaxis is demonstrated by the number of cases of tetanus among soldiers of the United States in the World War:¹ a ratio of 0.16 cases per 1,000 cases of injury in battle—actually only thirty-six cases associated with 223,067 cases of injury. This rigid form of prophylaxis cannot be followed in civil practice, nor is it altogether desirable even if it were possible. The incidence of serum sickness and the possibility of anaphylactic shock are features which occasionally may place the overly cautious physician in an unfavorable light with some of his patients because of the discomfort of the serum reaction as well as the expense of the serum. As with any other procedure, intelligent discrimination must be employed, based on reliable histories and competent evaluation of the injury. Whenever any doubt exists regarding either the history or the wound, prophylactic measures are indicated.

The advent of alum-precipitated tetanus toxoid gives sufficient promise both in protection and ease of administration to warrant its trial and probable acceptance in a military crisis. However, for civilian practice except in especially exposed occupations, it is practically impossible to put into effect such extensive prophylaxis against tetanus that the necessity for perfecting the technique of treatment would be obviated.

I wish to mention one particular point in regard to the administration of tetanus antitoxin for prophylaxis. It has long been held that narcosis would confer protection from anaphylactic shock in administering serum to a previously sensitized individual. Not infrequently a patient will be brought into a doctor's office with numerous injuries suffered in an automobile accident. Frequently, the repair will be so extensive as to require narcosis, probably by ether inhalation. The finishing touch often will be the administration of 1,500 units of tetanus antitoxin. In a recent publication¹¹ it was pointed out that although ether narcosis substantially reduced the percentage of deaths from anaphylaxis in previously sensitized animals, yet a mortality of 23 per cent existed. This mortality indicates the risk associated with indiscriminate administration of antitoxin when given without skin tests or conjunctival tests to determine the individual's sensitivity. It is possible that the mortality would not be as high in man under the same conditions. Since we do know that it does occur, this danger can easily be avoided by the usual skin test or conjunctival test that is employed for the conscious patient.

Mortality from tetanus is sufficiently high to justify the universal fear regarding the onset of symptoms. Generally speaking, once the symptoms set in, the die is cast. Improved symptomatic treatment and the use of antitoxin, of course, have improved mortality figures somewhat but it is rather startling to note the results in 642 cases reviewed by Huntington, Thompson and Gordon⁹ in 1937, for the purpose of evaluating results of use of antitoxin. In a control group of seventy-two cases in which no antitoxin had been given the mortality was 65 per cent. The remaining 570 cases were divided into five groups according to the amount of intravenous and intraspinal antitoxin which had been given. In these groups, the mortality ranged from 58.6 to 66 per cent. In each of these cases, antitoxin had been given within twelve hours after the patient's admission to the hospital, so it may be said that this was given

*From the Section on Neurology, The Mayo Clinic, Rochester, Minnesota. Read at the seventy-first annual meeting of the Wabasha County Medical Society, Lake City, Minnesota, October 5, 1939.

as early if not earlier than antitoxin usually is administered. The comparison of the mortality in this group with that of the control group tends to support the idea that once the symptoms have set in, the odds are against cure with the present therapeutic methods.

Prognosis

Prognosis in tetanus depends on the length of the period of incubation, the rapidity of progression of symptoms once they have begun and the location of the initial infection.

In the aforementioned 642 cases, it was noted that for all cases in which the period of incubation between the initial injury and the onset of symptoms was less than seven days, mortality was 76 per cent; when the period of incubation was from eight to fourteen days, mortality was 64 per cent; when it was from fifteen to twenty-one days mortality was 40 per cent. These mortality figures were entirely without relation to the amount of antitoxin which had been administered, but since the mortality for the group in which the antitoxin was used was so similar to that for the group in which it was not used, this grouping in terms of period of incubation is probably valid from the standpoint of prognosis. The rapidity of progression of symptoms once they have become evident presents the same prognostic significance as may be noted in any infectious disease in which fulminating and subacute or chronic types may occur. In regard to prognostic importance of the location of the injury, it may simply be said that since there often appears to be a local tetanus in addition to the general reaction, an additional complication may result if the injury occurs in a critical place, such as the head, by reason of the greater accessibility to the central nervous system.

Limitations of Antitoxin in Treatment

There is a danger in medicine of placing too much faith and dependence in specific remedies with too little regard for the conditions of administration. This has been true of tetanus antitoxin and it has taken many years to learn that it is not the unqualified specific that was hoped when it was first introduced.

In the review by Huntington and his co-workers, the best results were obtained in cases in which less than 10,000 units of tetanus antitoxin

were given. In this group also the antitoxin was given intravenously and none was given intraspinally. It would appear from these studies that huge amounts of antitoxin and its intraspinal administration are contraindicated. However, it is reasonable to suppose that the patients who received smaller amounts of antitoxin were the ones who had less serious symptoms and, as we know from experience, had the best opportunity of recovering with symptomatic treatment alone. Very slight if any advantage could be noted from the use of intraspinal administration of the antitoxin. Studies by Abel and associates² which refute the blood cerebrospinal barrier idea give adequate evidence of the futility of intraspinal injection. The remarkable value of tetanus antitoxin as a prophylactic agent is too firmly fixed in our experience, however, to allow us precipitately to discontinue the use of antitoxin as a therapeutic agent. Studies by Abel and his co-workers within the past few years indicate that tetanus antitoxin plays a lifesaving rôle in treatment if it can be given early enough. If there is any one cardinal rule which should be brought before the general practitioner, it would be to give an adequate amount of tetanus antitoxin at the first sign, symptom, or, I should say, as soon as he sees a patient with symptoms.

Arbitrarily, one may say that there is little need in giving more than 100,000 units in any circumstances. This at the current cost of tetanus antitoxin amounts to \$35, certainly not prohibitive from the economic standpoint. Cables⁵ reported the case of a patient who recovered from tetanus after being given a total of 3,460,000 units of tetanus antitoxin over a period of forty-one days. The rationale behind this is highly questionable from the economic as well as the serotherapeutic standpoint. The cost of antitoxin alone in this case at the current price would be \$1,200. In addition to this the patient received each day a total of 24 c.c. of 25 per cent solution of magnesium sulfate intramuscularly for a period of twenty-five days in 2 c.c. doses. I am sure that this played a substantial, if not the major, rôle in the control and eventual recovery of this patient by effecting symptomatic relief from the muscle spasm.

Merkert¹² in an able review of the ten years' experience with tetanus in two Minneapolis hospitals concluded that there was no value in heroic doses of tetanus antitoxin.

Pathogenesis

It has long been assumed that tetanus toxin has been produced at the site of the injury after sufficient period of incubation and from there would attack the nerve trunk traveling proximally to the central nervous system, from whence the toxin would be disseminated to adjacent motor nerve cells and result in a generalized reaction. In addition to this hypothesis, there was the hypothesis that the blood-cerebrospinal barrier prohibited the larger molecule of the antitoxin from reaching the smaller molecule of the toxin which has already combined with the nervous tissues. In other words, the only effect that antitoxin could have in intravenous administration would be to neutralize the freely circulating toxin present in the blood. Hence, intraspinal administration has been entertained by many in the hope of reaching affected areas more easily in spite of lack of supportive evidence that this was true, and in spite of the difficulties attendant to such procedures.

During the past five or six years, a series of interesting studies have been performed by Abel² and his associates in regard to this particular question. By a number of substantial experiments they support their argument that tetanus toxin is blood-borne and that the action is essentially central. This was postulated by Robertson¹³ in 1916, when he concluded on the basis of his observations and his objections to current theories that the toxins pass throughout the body exclusively by the blood and lymph streams. Harvey,⁸ in 1939, emphasized the fact that muscle rigidity depends on the integrity of the motor nerve endings in the muscle, and therefore tetanus toxin exerts a peripheral action also and not simply action on the central nervous system.

The studies of Abel and his associates offer experimental evidence that the toxin is blood-borne and a blood-cerebrospinal barrier does not actually obstruct the action of antitoxin. From some of their experiments,³ with dogs, there is evidence that the antitoxin actually does attack and neutralize toxin which has supposedly been "fixed" in the nervous tissue. As might be supposed, the time element or the period of "fixation" is of primary importance in effecting a favorable antitoxin attack on the toxin.¹

By an ingenious method of bleeding and subsequent infusion of dogs who had been infected with a liberal dose of tetanus toxin, Abel and his

associates were able to recover more than 50 per cent of the toxin about ten hours after the injection of the toxin. By definite assay of the blood at this time, it could be learned that a very small, practically negligible, amount of toxin still remained freely circulating. Other dogs in the series which were given about 65,000 units of tetanus antitoxin at this time recovered without symptoms. The dogs which were not given antitoxin died from fulminating tetanus within seventy-two hours. Therefore, it was assumed that the antitoxin must have attacked the so-called fixed toxin of the nerve tissue, thus proving, first, the efficacy of antitoxin if given within sufficient time (in these cases ten hours from the injection of the toxin), secondly, that it could penetrate the so-called blood-cerebrospinal barrier since the antitoxin was given intravenously and the toxin in the blood had been washed out. This, of course, cannot be directly applied clinically since the controlled injection of toxin is a far different problem than the accidental introduction, into a wound, of tetanus spores from which the toxin has yet to be formed. These experiments give us a new hope that antitoxin may reach both the circulating and so-called fixed toxin and under proper conditions, chemical, physical, or both, a more effective neutralizing action may result. Obviously, these are extremely important facts since they open up the field of research for methods of attacking the toxin fixed in the tissue through some mediating or catalytic agency even though a considerable period has elapsed since the onset of symptoms. From the practical standpoint, prophylaxis is satisfactory and our chief concern must lie with the management of those patients who have full-blown symptoms when first seen, which, as has been already stated, is at a time when "the die is cast." There is practically no way of determining, when the patient is first seen with definite symptoms, whether his nervous tissues have a lethal or a less than lethal dose. In other words, our therapy consists more or less of routine control of symptoms plus the injection of tetanus antitoxin, the therapeutic efficacy of which we have reason to doubt on the basis of statistics I have mentioned.

The following case is offered as an example of employing a physical (thermal) agent in addition to the immunologic agent (antitoxin). So far as is known, this is the first case to be re-

ported in which artificial fever therapy has been employed in any capacity in the treatment of tetanus. No great claims are made for this method; it is presented for the speculation it may incite as well as to record the management and a good therapeutic result in an always to be feared disease.

Report of Case

The patient, a married farmer aged thirty-one years, was in good health until May 23, 1939, when he stepped on a nail and sustained a deep puncture wound in the ball of the left foot to which he paid no particular attention at the time. May 29, he felt rather sleepy, yawned most of the day and May 30, the seventh day after the injury, he complained of stiffness in his jaw. At this time, he was given 1,500 units of tetanus antitoxin, but the symptoms continued to progress and two days later, June 1, he was referred to the clinic and was admitted to the hospital.

At this time, stiffness of the jaw was graded 2 on a grading basis of 1 to 4; there was a partial risus sardonius. Rigidity of the muscles of the neck grade 2 to 3 and grade 3 of the muscles of the abdomen and back, and definite opisthotonos were present. The puncture wound in the left foot was explored but no inflammatory reaction was demonstrated. However, a small foreign body was found and sent for culture which later demonstrated green-producing streptococci and some Gram-negative bacilli which were not identified. Within two hours after admission to the hospital, the patient was given 40,000 units of tetanus antitoxin intravenously, and four hours later another 40,000 units. The patient had been tested initially for sensitivity and demonstrated no reaction to serum. This same day another 20,000 units was given intramuscularly. One and one-half grain (0.1 gm.) of pentobarbital sodium was administered every two hours as an antispasmodic. This was supplemented by 1/6 to 1/4 grain (0.01 to 0.016 gm.) of morphine sulfate when necessary to control the pain. No improvement was noted and the next day the patient was given an additional 80,000 units of tetanus antitoxin, making a total of 180,000 units, all of which had been given intravenously or intramuscularly. During this second day in the hospital, calcium gluconate was given intravenously in an attempt to obtain some relaxation of the skeletal muscles, but no objective improvement was noted.

By this time the patient's condition had progressed to the point of acute, continual pain and inability to swallow; alternate doses of 1 1/2 grain (0.1 gm.) of pentobarbital sodium and 1/4 grain (0.016 gm.) of morphine were given at least every two hours. On this date, urinalysis revealed nothing abnormal with the exception of occasional pus cells; the concentration of hemoglobin was 15.5 gm. per 100 c.c. of blood and there were 4,810,000 erythrocytes and 7,400 leukocytes per cubic millimeter of blood.

Because of the patient's critical condition, Dr. Wolt-

man suggested the use of hyperpyrexia in the hope of increasing the neutralizing effect of the antitoxin on the toxin. With the use of a general anesthetic (chloroform) Dufour and co-workers^{6,7} had noted that the efficacy of tetanus antitoxin administered intraspinally seemed to be increased. It was later advocated that ether be used as an alternate for chloroform, and although neither method gave conclusive results, each warranted consideration. Supposedly, the chemical effect of the general anesthetic was beneficial in effecting more complete toxin-antitoxin neutralization. This suggested that an empirical method, physical rather than chemical, might be used in the hope of producing some beneficial catalyzing effect through the agent of fever therapy.

Under the direction of Dr. Krusen and his associates in the Section of Physical Medicine, with special supervision by Dr. C. J. McLoughlin, the patient was given four hours of artificial fever produced by physical means, with a systemic temperature ranging between 105° and 106° F. He tolerated the fever treatment very well after the first hour and it had the definite effect of relaxing his muscles. He was given 1,000 c.c. of a solution of 5 per cent glucose in saline intravenously, in addition to about 800 c.c. of water which he took quite easily by mouth. Following the treatment his condition returned to its pre-fever status of muscular spasm in about two hours and he was put on a regimen of 1 1/2 grains (0.1 gm.) of pentobarbital sodium every two hours with 1/2 grain (0.02 gm.) of pantopon as a supplement. The next morning he had had three stools in which gross blood was demonstrated but it was decided to go ahead with the fever treatment, keeping a careful watch on him for evidence of shock. Three and a half hours of fever at a temperature of 105° F. was given. The treatment was borne as well as on the previous day and with comparable relief during the session. That evening, however, it was necessary to give the patient 2 1/2 grains (0.162 gm.) of pentobarbital sodium intravenously to put him to sleep. By the third day, a definite improvement was noted although he still had considerable pain and sedatives and hypnotics were necessary to treat these symptoms. Because of the beneficial effect of relaxation from the fever, he was placed in a pack at the end of the session of artificial fever and allowed to cool off over a period of four or five hours. This practice was continued from the second treatment throughout the rest of the course.

The stools grossly appeared normal within two days after the first evidence of gross blood on June 3. Results of benzidine tests on stools were positive for three weeks longer but results of tests with guaiac were negative, which indicated control of serious bleeding. Fortunately, no other symptoms developed to indicate a surgical abdomen. The patient was given a total of twelve sessions of fever, each of which was tolerated progressively better. These were given at approximately two-day intervals and he received the last fever treatment June 23, 1939. During this period, his fluid intake was kept up very well, largely by administration during the fever treatment, at which time he was

able to drink with comfort. Subjective improvement kept pace with objective improvement. Throughout this entire period, urine was not abnormal except for a trace of albumin, the value for hemoglobin did not go below 15.8 gm., the erythrocyte count was normal and the leukocyte count ranged from 7,400 to 10,900. Administration of pantopon was discontinued from the eleventh day in hospital and the dose of pentobarbital was decreased to about $7\frac{1}{2}$ grains (0.482 gm.) per day. June 27, the twenty-fifth day in hospital, the patient was discharged as essentially recovered, with a minimum of spasms. He returned to the clinic, July 5, with a minor complaint of some epigastric and abdominal pain. Roentgenologic examination of the stomach and esophagus was performed with negative results. An examination of the stools at this time for occult blood also gave negative results. He was given practical suggestions for diet and reassurance and sent home.

The patient returned again on July 25, 1939, with some complaint of sternal pain which had the earmarks of anxiety symptoms. These were cleared remarkably when the patient was reassured that his five-year-old daughter who had stepped on a nail about a week previous had been adequately protected with a prophylactic dose of 1,500 units of tetanus antitoxin. The patient was seen on one other occasion early in August, at which time he subjectively admitted complete recovery.

Comment

Numerous avenues of thought are opened when evaluation of this technic is attempted. On the face of this report, it borders on absurdity to make conclusions on a single case but it may be reasonable to point out a few inferences that may be drawn.

In the first place, this method must rest for the present on its merits as a means of symptomatic control of the painful spasms of tetanus which contribute, through exhaustion, the greatest problem and danger of this infection.

Relief from the terrifying spasms, even at the cost of any discomfort of the heat therapy was welcomed by the patient and throughout the entire course the patient was able to be more coöperative on smaller amounts of hypnotics than is usually experienced. In addition to these benefits, the more coöperative attitude of the patient is believed largely attributable to his relative freedom from fear and panic during the sessions of fever. The increased metabolic rate is passively achieved; that is, with minimal demands on the body. Although I hesitate to speculate on the detailed workings, it is not impossible to postulate a more effective inter-relationship of the toxin and antitoxin facilitated

by the hyperthermia. For the present, however, the symptomatic relief obtained is sufficient to warrant further trial of this method. There was no doubt of this patient's improvement by the third day of treatment, whereas the clinical course before initiation of hyperthermia was definitely downward. Prognostically, however, this case was borderline in terms of period of incubation and rapidity with which symptoms progressed. Also the initial injury was in the least dangerous location. Certainly, this emphasizes the need of a number of cases properly to evaluate the rôle of hyperthermia in tetanus, but in this case the evidence is in favor of its value.

Some rather intriguing ideas may be offered as to the *modus operandi*, such as mobilization of resistive forces and rendering the tissues, containing the toxin, more permeable, permitting increased toxin-antitoxin combination and consequent neutralization. Still another theory is that the heat may produce some of its benefits through other agents. In this regard, it is interesting to note that vitamin C (ascorbic acid) has power to inactivate tetanus toxin *in vitro*.¹⁰ Furthermore, one notes that values of ascorbic acid in blood are unusually low with fever resulting from infection, as well as low in urinary excretion during this period. In other words, in an infection the ascorbic acid demand must be greater and the destruction greater either owing to fever, the infectious agent or both. Kligler and his associates¹³ stated that vitamin C (ascorbic acid) combines with the toxin in tetanus cultures and both are destroyed, resulting in depletion of vitamin C content of blood and detoxification of the tetanus toxin. This detoxification varies with temperature, time and concentration of the broth but as a rule is more efficacious at the higher temperatures (well within the point of thermolability of vitamin C, of course). The value of ascorbic acid in prophylaxis against current infections has been recently emphasized by Smith.¹⁴ It does not appear to be borrowing too much to postulate some integral relationship among these factors such as the fever serving to speed up an ascorbic acid reaction of detoxification of the tetanus infection.

A comment would appear to be in order to explain the melena which occurred the second day of the treatment and persisted for a few days. The vitamin C level in the blood is usually about 0.5 mg. per 100 c.c. (normal 1.5 mg. per

100 c.c.) when the temperature rises to 103° F. It is possible that higher temperatures might depress this level even further and bring it close to the level at which hemorrhage may occur. Melena on this basis may have been corrected as the patient's intake of food increased after the third day, at least enough to hold a minimal level and avoid further hemorrhage.

Unfortunately, these speculations were not made until after the patient had recovered and his case was reviewed, so no estimations of the concentration of ascorbic acid were made. These clinical determinations, a procedure that can be effected with a minimum of effort, must be obtained in future cases.

Melena is not a common complication of artificial hyperpyrexia. It has occurred in only one other case at the clinic to the extent of being an actual clinical consideration. This was in a case of undulant fever and the only factors common to these two cases were that both were infections and both were treated with hyperpyrexia.

Summary and Conclusions

Review of recent literature points to the inadequacy of tetanus antitoxin as a specific therapeutic measure in a full-blown case of tetanus unless early administration of moderate amounts of the serum is possible. Large amounts of serum and its intraspinal administration appear to be contraindicated.

Management of symptoms is still of primary importance in the treatment of tetanus. The relief from muscular spasm during the period

of elevated body temperature, the lessened danger of a complicating toxic reaction by reason of smaller sedative requirement, and the coöperative emotional reaction largely owing to lessened fear and panic—all of these may be considered as benefits directly related to the hyperpyrexia.

The possible relationship of ascorbic acid and hyperpyrexia to tetanus toxin is offered as a matter for speculation. Clinical studies will be conducted with a view to proving or disproving this relationship.

COMMUNICATED INSANITY

An Instance of Folie à Cinq

THEODORE L. L. SONIAT, M.D.† and BENJAMIN F. SMITH, M.D.‡
Rochester, Minnesota

COMMUNICATED or induced psychosis (*folie à deux*) has been defined as "a mental disorder occurring in two or more predisposed individuals who have been intimately associated with each other, the predominating feature being delusions, particularly of a paranoid type, which

are transferred from one to the other patient."¹ This condition was first described accurately by Lasègue and Falret in 1877. They used the term *folie à deux* to designate it although the condition had been mentioned previously by Berlyn in 1819, Ideler in 1838, Hoffbauer in 1846 and by Baillarger and others.¹

Stoddart stated that for such a condition to

†Fellow in Neurology and Psychiatry, The Mayo Foundation.
‡Superintendent of Rochester State Hospital.

develop, the patients should have many interests in common, view life from similar standpoints, and should have isolated themselves from the outside world. Accordingly, the condition is most common among persons living secluded lives, and the usual subjects of the condition are parent and sibling, two or more siblings, husband and wife, or friends of the same sex who live together closely. According to Hays,⁷ it seems necessary that the individual (inductor) who is the originator of the set of ideas be a person of striking personality or of unusual mental attainments; at least, a person who is able to convince others of the validity of his beliefs. The inductor usually is considered to be an authority by the person (receptor) who accepts his ideas. The receptor must have an inherent willingness to receive the suggested or observed psychotic pattern. Craig pointed out: "that a man believes the statements of his insane relative to be true does not constitute insanity; but if he not only believes them, but acts upon the belief and regulates his life and conduct accordingly, then he too, must be adjudged to be of unsound mind." According to Bleuler, the inductor and receptor coöperate in morbid reactions to the outer world (such as querulousness, cursing, or violence) or they withdraw together, restricting contact with the world to a minimum.

Communicated insanity usually occurs as *folie à deux*, but instances of *folie à trois*, *quatre*, and *cinq* have been reported. Brussel, in reviewing the literature from 1900 to 1937, found that during this period forty-six papers had appeared on the subject, with a total of fifty-eight reports of cases. There were two instances of *folie à trois*, one of *folie à quatre*, and one of *folie à cinq*.

Tuke pointed out that we have no good corresponding English term for *folie à deux*, and that the term "communicated insanity" does not include those cases in which the disorder is not, strictly speaking, communicated, and which the French do include in *folie à deux*. The four varieties of *folie à deux* usually described^{1,3,6,7} are as follows:

1. *Folie imposée* (Lasègue and Falret³) consists of a mental disorder in which one psychotic person imposes his delusional convictions on a sane individual who is, intellectually and morally, a weaker person. It has been said that if the pair is separated, the receptor tends to discard

TABLE I. FIVE PATIENTS IN ONE FAMILY OF SEVEN ADMITTED TO HOSPITAL FOR *folie à cinq*, DATES AND AGES AT ADMISSION

Patient	Birth, date	First admission to hospital	Age on admission, years
Mother	12-27-1883	5-18-1933	50
Daughter	6-13-1913	9-17-1936	23
Daughter	2- 6-1915	5- 6-1937	22
Son	2-20-1917	5-21-1937	20
Daughter	2-24-1919	5-21-1937	19

the beliefs of the stronger personality (the inductor).

2. *Folie simultanée* (Regis³) is characterized by the simultaneous appearance of a delusion, by reciprocal influence, in predisposed associated individuals.

3. *Folie communiquée* (Marandon de Montwel³) is the condition in which the receptor accepts the delusional ideas of the inductor only after prolonged resistance, and in which psychosis persists even after the patients have been separated.

4. *Folie induite* (Lehmann³) consists of the addition of new delusions to an existing psychosis as a result of association with other patients.

Grover pointed out that in the opinion of some writers, the classification of *folie à deux* into different forms is confusing and unnecessary. According to Stoddart the simultaneous occurrence of insanity in two members of the same family as a mere coincidence does not necessarily constitute an instance of *folie à deux*; Stoddart believed that it is essential that the mental disorder of one patient be directly caused by the persuasive influence of the other.

Report of Cases

This report concerns a family of seven, in five of whom psychosis has developed. The patients were admitted to the Rochester (Minnesota) State Hospital. The parents were born in Czechoslovakia, but the five children (three daughters and two sons) were born in the U. S. A. The mother, the three daughters, and one son have become psychotic, participating in *folie à cinq*. For the orientation of the reader, the dates are given in Table I.

Case 1.—The mother apparently always had been suspicious of her husband and his association with

other women, and for several years prior to her admission to the hospital she had refused to see her few friends, believing that they really came to see her husband and not her. In March, 1933, she began to accuse her neighbors of "wickedness," to distrust her family, and to express her "hate" for her husband and for women in general. She would allow no one to enter her home. Her strange conduct progressed, so that by May, 1933 (time of admission to the hospital), she thought she was receiving messages from God and that she could feel the presence of God inside her body. She returned to her home in November, 1933, against the advice of physicians. On September 1, 1934, she was returned to the hospital with the information that she exerted a strange influence over her three daughters, in that they were entertaining the same ideas as their mother possessed. When someone came to their house, the four of them (mother and three daughters) would run upstairs so as not to be influenced by the visitor's "wickedness." The husband could do nothing with the daughters because the mother had firmly convinced them that he was wicked. She constantly warned the daughters against the father's supposed sexual advances and accused him of infidelity. She thought that at night the father would take two women to bed with him in addition to herself. She was returned to the hospital when it was found that because of her strong will and accusations, the girls remained in the house all the time, refusing to see anyone or to talk to their father. In the hospital she constantly said, "Only God and I are right and the rest of the world is bad." The condition of this patient slowly deteriorated and on September 27, 1935, she was transferred to another hospital for custodial care.

Case 2.—Daughter C, in 1933, became obviously suspicious of her father and antagonistic toward him. She soon began to voice the belief that he had been unfaithful to the mother and to accuse him of making sexual advances toward her. Her symptoms progressed so that by the time of her admission to the hospital (September 17, 1936), she thought her food was poisoned, spent her days in bed, going out only after dark, and said she saw "spirits." The social service report had said of her that "she talks in the same vein as the mother, as though memorized," and "patient dominates her two younger sisters." The situation had reached the point at which the girls refused to have anything to do with the father and stayed in their bedroom constantly. Daughter C was considered to be the "ringleader."

Case 3.—Daughter D always had appeared to be intelligent, capable, and more socially inclined than the other three siblings, in whom mental symptoms developed and who were of a shy, defensive nature. She had always loved her father and was in the habit of kissing him goodnight. In the early part of 1934, however, she ceased this practice, saying that her father only pretended to like her and that he never could be trusted. She became very sensitive and seclu-

sive, adopting a defensive attitude. She slept with C and eventually shared C's beliefs and expressed the same fears regarding the father. She accused him of practicing witchcraft. The social service report had said of her that "she is most susceptible to suggestions." She heard voices, thought her mind was being influenced and her thoughts read, and that she was being watched constantly. She spent her days in bed, and if anyone called at the house, would hide under the bed. After C went to the hospital, D took her place as "ringleader." On D's admission to the hospital on May 6, 1937, she admitted that the father had never "touched" her but she knew "what he was thinking."

Case 4.—Daughter F, who had been shy and unhappy in grade school, visited an aunt in another town, where the girl seemed lively and apparently normal. On returning home, she again became asocial. In about 1935, she became stranger, left school, and joined her sisters in their asocial way of living and in their delusional ideas. She became so antagonistic toward the father that she had to be placed in a home for girls. She thought her father had poisoned her and that he had sexual designs on her. She said that she had been drugged so as to make sexual assault on her possible. By the time of her admission to the hospital (May 21, 1937) her behavior had come to resemble that of her sisters to a startling degree.

Case 5.—Son E became actively delusional in 1935 and 1936 but no doubt had shared the sisters' false ideas before that time. On admission to the hospital (May 21, 1937) he explained his commitment by saying that his father "had it in for him" and his sisters. He accused his father of being wicked and practicing witchcraft, and stated that ghosts under his father's direction would awaken him and the sisters at night by "tapping" on them. He said that daughter C had been the first sibling to notice that the father practiced witchcraft and that she had called the attention of the others to it. Often the children discussed the various observations each had made about the father, since one of them would watch his every move while he was at home. In these conferences his actions would be "interpreted" by them. Son E believed that his father wanted to control his thoughts and actions. Five months before admission to the hospital he saw his first "vision," in a mirror before which his father had just been standing. He was seclusive, evasive and extremely untidy.

Each of the four psychotic siblings and the mother were diagnosed as having the paranoid type of schizophrenia.

The father was a hard-working, sincere, bewildered, little man who could not understand why members of his family should be so strange. He worked in a coal yard as a common laborer. His family usually received aid from welfare agencies. He had a strong sense of loyalty and

for a long time had resisted suggestions that the daughters be sent to a mental hospital. But when they began to sleep all day and play the radio all night so that he was physically worn out, he finally consented to their commitment.

At the time of the mother's first admission to the hospital (1933), son G was ten years old. He was almost fourteen years of age in May, 1937, at which time he was the only sibling remaining at home with the father. He was described by the social service worker as being a bright, likable boy who did well in school and had numerous friends. He was a Boy Scout and a member of the school police. He was devoted to his father and they took great pride in their joint cooking and housekeeping. In November, 1939, we learned that he was "getting along fine at high school."

At the present writing (November, 1939), son E has been at home since November 7, 1937. He is working with the National Youth Administration, earning twenty dollars a month. Social service follow-up work reveals him to be at present agreeable, alert, and polite, apparently reacting favorably to his work and adjusting himself well at home. He is the "housekeeper" of the home shared by his father and brother and maintains it in a degree of neatness unusual in a home cared for by men only. When interviewed, he spoke very kindly of his father, which was in direct contrast to his previous attitude.

The mother and three daughters are still hospitalized. The mother has gradually deteriorated. The daughters have received both insulin and metrazol shock therapy and are somewhat improved in that they are more efficient with the ward work and are more tidy than they had been. However, they are still delusional and lack insight.

The important part played by suggestibility in the genesis of so-called communicated psychosis is mentioned by Henderson and Gillespie and by Grover. Brill⁶ believed that an unconscious identification is at the basis of all instances of *folie à deux*. Grover's patients were suffering from schizophrenia and he stated: "The fact that schizophrenia may be precipitated by suggestion leads us to think that the relationship of schizophrenia to hysteria is closer than we have generally believed." Brill,⁶ in discussing Grover's paper, pointed out that Kraepelin spoke of the

close relationship between the two maladies and that hysterical reactions are invariably observed in the initial stages of schizophrenia. Jung, in his *Psychology of Dementia Praecox*, devoted a chapter to the parallelism between schizophrenia and hysteria (as concerns the disturbances of the emotions, characterologic abnormalities, intellectual disturbances, and stereotypy). Jung stated that in both hysteria and schizophrenia are found one or more complexes which become tenaciously fixed, but that between hysteria and schizophrenia there is no identity, but only a resemblance, of the psychologic mechanism. In schizophrenia these mechanisms reach much deeper. According to Grover schizophrenic psychosis produced by suggestion does not differ in symptoms or prognosis from that developing in the usual way.

Comment

The purpose of this presentation has been to call attention to the occurrence of communicated insanity and more specifically, to the occurrence of schizophrenia among five members of one family. On the basis of a study of these five patients, it is apparent that the psychosis each member had was similar, with identical delusional features. It would appear, as has been emphasized by other writers, that the psychosis was induced in the siblings by their unusually close contact with one another and also by the influence of the mother, who very early instilled in the children a dislike for, and fear of, the father. The youngest child, because of his age, did not come under this influence and has escaped any evidence of psychosis.

THE MEDICAL AND SURGICAL TREATMENT OF PROSTATISM*

GERSHOM J. THOMPSON, M.D.
Rochester, Minnesota

DURING the past several years the treatment of prostatism has been discussed widely. A great deal has been said, alternately commendable and critical, about transurethral resection. Some physicians suggest that it is an operation devoid of all risk and that the procedure can be performed within a few minutes on any patient not yet bedridden with miraculous effect not only on vesical function but also on all other physiologic mechanisms resulting in fancy, if not in fact, in rejuvenation. Others, having tried transurethral resection, emphatically assert that there is no virtue in it and ardently champion perineal and suprapubic prostatectomy, sometimes with such fervor as to lead one to suspect that recent infrequent acquaintance with these open operations makes it difficult to recollect several obnoxious features that have been associated with such open operations in the past. The patient who has the advantage of consulting his levelheaded family physician is particularly fortunate because his needs can be sanely judged and perhaps, even though he has prostatism, treatment short of operation will bring relief. In the great majority of cases surgical measures are elective and are not emergency procedures. It seems worthwhile to review briefly, first, medical treatment, and, second, surgical alternatives.

Medical Treatment

A brief review of medical history indicates that obstruction to the vesical neck has been an affliction of man since time immemorial. The ancient physician first tried indirect methods of treatment. Drugs such as niter, asafetida, copper sulfate, camomile and aromatic oils were employed internally during the days of Hippocrates. Counterirritants applied in and near the genitalia were in vogue in the early part of the Eighteenth Century, according to Prout (1826) who employed plasters and hot fomentations to the perineum and rubbed the thighs with camphor or cantharides. Later, the attachment of leeches to the perineum or even the application of cautery to this portion of the body were methods which

physicians used because they did not recognize the real offending organ. The use of hot sitz baths and of rectal lavage with ice water later gained favor.

As medical treatment improved, more or less direct methods of attacking the prostate gland were developed. Physick devised the method of hydraulic compression of the neck of the bladder by inserting into the urethra a distensible bag made of gut which he filled with water, hoping to force apart the offending structures which had occluded the urinary passages. Heine (1874) injected iodine and ergotine into the prostate gland, hoping to cause shrinkage in its volume which might have occurred in some instances as a result of the formation of infarcts which later became fibrotic and actually were the means of reducing the size of the gland.

Later, the use of catheters which emptied the urine from the bladder and which could be left inlying for varying periods came into vogue. Some of these because of their size and structure caused ulceration which possibly resulted in canalization and finally in some reduction of the diffuse congestion in the gland. At about this time, prostatic massage through the rectal wall, irrigations of the bladder and the instillation of soothing or irritant drugs into the posterior urethra began to be used. Dilatation of the urethra with various ingenious devices which were thought to compress or depress the prostate gland were final direct methods of treatment which stopped just short of being actual surgical procedures. That many of these methods of treatment were helpful cannot be denied although one questions the wisdom of employing some of them. Certainly it seems that extreme discomfort often resulted instead of relief.

Today there is no doubt that many patients are treated by variations of these somewhat antiquated methods. In some instances, benefit accrues especially when judgment is employed in the particular selection of a method of treatment for each case. For instance, it is undoubtedly true that prostatic massage may benefit the infected prostate gland which is but little enlarged. However, when calculi are present in the gland

*From the Section on Urology, The Mayo Clinic, Rochester, Minnesota. Read before the annual meeting of the Minnesota State Medical Association, Rochester, Minnesota, April 22, 1940.

or when it is of the large, benign, so-called succulent type which ordinarily causes considerable retention of urine in the bladder, only false optimism would lead one to persist with treatment by massage. The use of a catheter either intermittently or inlying for the patient who is suffering with an acutely congested prostate gland sometimes is miraculously beneficial, symptoms often being ameliorated for relatively long periods.

The injection of sclerosing agents directly into the prostate gland as a rule will cause only further discomfort. The instillation of soothing or irritant media into the bladder or posterior portion of the urethra is done at the risk of inducing or increasing infection both local and systemic and should be avoided in most instances.

An agent which can now be used but which was not available to the physician of ancient times is the roentgen ray. In the case of a large, soft, nonmalignant prostate gland which is causing incomplete retention of urine and considerable perineal and rectal distress roentgen therapy may be helpful. I have seen a number of patients whose symptoms hardly demanded surgical treatment in which great comfort was obtained by appropriate roentgen therapy. That the patient who is suffering from cancer of the prostate gland may obtain great benefit from intelligent radiation therapy is known to almost everyone. However, if one is deluded by a hope of cure and if intense radiation therapy is given, in my experience only additional suffering will result.

In the last few years the subcutaneous injection of male hormones in concentrated form has been popularized. Diminution of nocturia, slightly more forceful urination and reduction in the amount of residual urine have occurred in several cases in which I have given treatment with these preparations. However, I have been unable to confirm the enthusiastic reports of those who first described these preparations. As a matter of fact, these preparations are rather expensive and are a poor substitute for other reliable methods. I believe that, occasionally, the use of testosterone propionate is warranted especially in the case of an extremely aged man whose principal symptom is nocturia. In several such cases, the results of treatment have seemed very much worth while.

It can be stated without much fear of contradiction that medical methods of treatment must be given serious consideration in any case of

prostatism. Operations for this condition are never in the nature of an emergency. It is always desirable to reserve surgical treatment for those patients in whom nonsurgical methods have failed to effect worthwhile relief. So-called prophylactic operations done for early symptoms of prostatism cannot be condoned, and should be avoided. Great satisfaction to both physician and patient will result from adherence to the principle of deferring an operation of questionable necessity until the indications are definite.

Surgical Treatment

Ancient surgical remedies for patients afflicted with obstruction at the neck of the urinary bladder included attempts to pierce this region with long thorns, sharpened reeds and other similarly ingenious instruments which were passed into the urethra. These fell into the classification of direct methods of treatment and not long afterward, methods of ligating pedunculated portions of the prostate gland were devised. Guthrie and Civiale invented instruments with which to divide the bar at the neck of the bladder by sense of touch, there being no method then available for visualizing the region of the incision.

Surgeons then switched in the next few decades to indirect methods of attack on the prostate gland and resorted to castration (White), ligation of the vas deferens or vasectomy (Steinach) and even to ligation of both internal iliac arteries, hoping in this way to shut off the blood supply to the gland, thus causing it to become atrophic. The mortality rate from the latter procedure was frightfully high as might be expected.

What was said to be complete prostatectomy gradually came into practice at the turn of the century although incomplete prostatectomy was done through a perineal incision by Covillard as early as 1639 and by the suprapubic route, in 1832, by Amussat. Goodfellow, Fuller, Belfield, Young, Alexander and many others contributed to perfection of both the perineal and suprapubic operations. All of these authors stressed the thought that they were removing the entire prostate gland. Nevertheless, recurrences of obstruction were by no means rare and it was finally apparent that only the adenomatous tissue which lay within the true anatomical limits of the prostate gland was really enucleated by means of any of these operations. Since the bladder was inevitably opened, a period of urinary drainage

through the incision or through tubes placed within the bladder was unavoidable. Ideas of asepsis were rather sketchy or at least difficult to put in practice and much hit or miss effort was the rule in nursing attention. The great improvement in nursing methods and increased appreciation for the value of aseptic methods in the care of the bladder which accompanied the development of transurethral surgery have been infinitely valuable to the general surgeon.

Caulk, almost two decades ago, advanced the idea that relatively large amounts of prostatic tissue could be removed safely with a punch instrument. Before that time, Young had advocated the punch operation for median bar types of obstruction. Very few, if any, urologists could duplicate Caulk's results which he obtained by skill and persistence. His operations were done blindly and most surgeons felt unwilling or were not bold enough to follow his lead. Finally, a little more than a decade ago, technical advances in the fabrication of instruments resulted in the production of both lens and direct vision resectoscopes which made possible the visualization of the vesical neck during the entire course of operation. This started a revival of transurethral prostatic resection which, at the present writing, seems to have largely replaced other methods of prostatectomy.

In contrast with suprapubic prostatectomy, the performance of which is not difficult for the average surgeon, transurethral resection requires for its safe usage a long period of training during which time the surgeon must become able to recognize anatomic landmarks which are often distorted by various bizarre enlargements of the prostate gland. It is not enough to have dissected many cadavers or to have performed several hundred cystoscopies in the normal or nearly normal subject. Sufficient skill to perform safely a transurethral resection of the prostate gland can be acquired only at the expense of much thought, considerable eyestrain and tedious effort. It is an operation which the average general surgeon does not have sufficient patience to learn. Only a few will have the courage to master it in the face of all the handicaps which finally can be overcome by those fortunate enough to develop sufficient interest and opportunity.

Our experience at The Mayo Clinic with transurethral prostatic resection continues to be very favorable. Of chief interest to me is the fact that

during the past decade we have been able to perform the operation successfully and safely on many hundreds of patients who were formerly denied restoration of vesical function. Those afflicted with urinary retention and at the same time with complicating factors which prevented suprapubic prostatectomy or even sometimes cystostomy have proved, almost without exception, to be safe candidates for transurethral resection. Advanced renal disease, severe cardiac disorder, extreme age and so forth no longer are contraindications to surgical removal of the obstructing portion of the prostate gland. It is well recognized that patients more than eighty years of age are not the best risks for operation but during the year 1939 alone, we performed transurethral prostatic resection on forty-five such patients.

Of secondary interest is the fact that the period of hospitalization for patients undergoing transurethral resection continues to be much shorter than that formerly required for prostatectomy. This is important to all of us and in particular to the patient and his family. During 1939, the large majority of 1,000 patients operated on spent less than one week in the hospital. This, of course, was possible only by virtue of the fact that there is no external wound; hence, the patient need be in bed only on the day of operation. Dr. C. H. Mayo once stated that like a foundered horse, if old patients once get down it is very difficult to get them up. Each year, I realize more and more the wisdom of his sage observation.

The relief of symptoms following transurethral prostatic resection is the third point of great interest. With very few exceptions, nocturia is practically eliminated, the urinary stream returns to full size and force and general health and vigor are strikingly improved. Pyuria continues in only a small minority of cases in which great deformity of the bladder has existed for many months or years prior to operation.

It is, of course, essential that the transurethral resection be thorough and be accomplished without damage to the urethra. Postoperative stricture of the urethra can be avoided by making the proper choice of instruments, by not grasping the penis during operation and by the use of catheters of reasonable size during convalescence. If the anterior portion of the urethra is very small the resectoscope can be passed through an incision made in the perineal portion which is always

of sufficient caliber to obviate the formation of stricture.

The fourth and perhaps most attractive feature about transurethral prostatic resection is the low mortality rate following operation. During 1939, of the 1,000 patients operated on, a total of nine patients died, a mortality rate of less than 1 per cent. This was in spite of the fact that we subjected to operation many who would have been denied any other type of prostatic surgery. This minimal death rate results principally from thorough preliminary study, which allows recognition of degenerative disease that may be a potential cause of postoperative complications: expeditious operative technic which includes the restriction of the scope of operation to only what is necessary, the proper choice of anesthetic agents and the use of supportive therapy on the operating table if the need arises; meticulous attention to postoperative nursing during the entire convalescence including care of the catheter, attention to regulation of the bowels, special care to avoid fecal impaction and finally of great importance, the will of the patient to get well, an intangible factor which I believe must be important, for with it some patients survive very adverse complications. Daily visits to encourage the patient are unquestionably beneficial.

Recurrence of urinary obstruction due to regrowth of adenomatous tissue has been observed following all types of prostatectomy in a small proportion of cases. It has long been recognized that carcinoma of the prostate gland may develop years after either perineal or suprapubic enucleation and such cases have been reported by several authorities. These facts indicate the futility of referring to any form of prostatectomy as a complete operation, for the anatomical prostate gland is always left behind as the so-called surgical capsule. That portion of the gland which is ordinarily enucleated when the suprapubic or perineal procedure is used, can be, if it is deemed necessary, just as thoroughly removed by the transurethral route. However, the decrease in mortality accompanying transurethral surgery may be partly owing to avoidance of complete prostatectomy in the decrepit individual. It is certainly true in my experience that prolonged transurethral operations increase morbidity and

mortality. It seems justifiable, therefore, to use some judgment in each case and if it is deemed safer for the individual, the operation should be restricted and one should risk the reappearance of urinary obstruction. We have followed this principle in recent years and have no reason for regret. Some patients have returned after several years and have stated that obstruction to urination was again developing and almost without exception they have preferred another transurethral resection rather than enucleation. A few patients have suffered with hematuria occasionally; the bleeding arose from remnants of prostate gland left at the time of transurethral resection. This is, of course, a very disturbing symptom but it can be eliminated in almost every case by further resection.

It seems justifiable to conclude that the results of transurethral resection warrant its continuance in the future as the operative method of choice in any case of prostatism that requires surgical treatment.

Conclusions

1. Treatment for prostatism should be undertaken only after intelligent consideration of each individual case. This cannot be done by rule of thumb, or on the basis of wishful thinking.
2. Medical methods of treatment should always be tried if there is doubt concerning the necessity of surgical methods. Prophylactic operations done for very early symptoms are to be condemned.
3. When surgical treatment is definitely indicated the several methods available include suprapubic prostatectomy either in one or two stages, perineal prostatectomy and transurethral prostatic resection. Equally good functional results can be obtained by these several methods. However, the mortality rate of transurethral prostatectomy at the hands of an expert is much less than that of the other methods.
4. Judging from the history of the treatment of prostatism no surgical method which has failed to produce consistently good results survives.
5. Transurethral resection at expert hands is beyond any doubt the preferred surgical method of treatment for prostatism.

CASE REPORT

DISLOCATION OF THE HEAD OF THE FIBULA

Report of Two Cases

W. E. MACKLIN, M.D., C. M. HARTMANN, M.D., and H. O. PETERSON, M.D.
Minneapolis, Minnesota

TRAUMATIC dislocation of the proximal end of the normal fibula without any underlying pathology being present occurs rather infrequently. It is supposed to occur much more commonly in association with other conditions such as fractures of the leg, osteomyelitis, tumors, in amputation stumps and associated with disturbances in bone growth. A review of the literature indicates that about forty-nine cases have been reported of simple dislocation of the superior tibio-fibular articulation. Lyle in 1925 collected thirty-nine cases from the literature and added two of his own. He is one of the few individuals to have seen and reported two of these cases. Since 1925 six cases have been reported by six authors and Speed refers to one case in his textbook on "Fractures and Dislocations" published in 1935. He discusses the condition in considerable detail referring largely to Lyle's paper. Christopher's "Minor Surgery" gives a brief but complete discussion. Key and Conwell's text mentions the subject rather briefly and refers to one case, and Wilson and Cochrane merely say the condition is very rare because of the anatomy of the superior tibio fibular joint, which protects it from most injuries. Other texts such as Scudder's, Böhler's, and Jones and Lovett's make no mention of this type of dislocation.

The superior tibio fibular articulation is a true joint with a joint capsule and synovial membrane which sometimes communicates posteriorly and superiorly with the knee joint. The fibula is rather firmly attached to the tibia by the joint capsule and the anterior and posterior tibio fibular ligaments, which are further supported by the fibular collateral ligament and the anterior and posterior divisions of the attachment of the biceps tendon. The head of the fibula is further protected by lying somewhat behind the lateral condyle of the tibia. These are the reasons which are given in Wilson and Cochrane's text to explain the infrequency of dislocation of this joint.

The dislocation may occur posteriorly or anteriorly or upward. The anterior dislocations must also be displaced laterally, since the head of the fibula lies behind the lateral condyle of the tibia. The upward dislocations are said to be extremely rare and always associated with injuries about the ankle joint. The anterior dislocations have been reported about twice as frequently as the posterior. Posterior dislocations are the most serious since the four cases of chronic dislocation and the two of peroneal nerve injury all were in this group.

Pain occurs immediately and is localized to the region of the head of the fibula. The pain is usually aggravated by motion of the knee joint and the head of the fibula is tender to pressure. The leg feels best with the knee slightly flexed. Usually the patient cannot walk. Anteroposterior and lateral roentgenograms show the displacement quite clearly but the diagnosis may be readily overlooked even on careful examination of the films if one has no previous knowledge of the condition. A few cases become chronic and these patients are said to complain of a feeling of weakness of the leg.

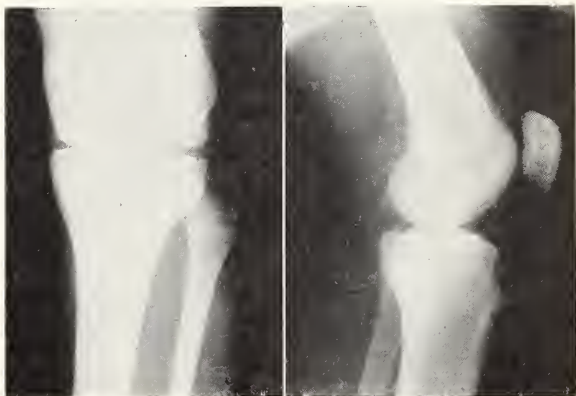

Fig. 1. In the anteroposterior projection the upper end of the fibula is seen to be situated lateral to the condyle of the tibia rather than posterior and lateral, which is normal. In the lateral view the head of the fibula lies too far anterior. The osteochondroma of the lower end of the femur on the medial side is an incidental finding.

The dislocation follows two general types of injuries. A fall on the inverted extended foot or with the leg doubled under the body is the most common type of injury. Less often the dislocation follows a direct blow on the head of the fibula. Occasionally as in one of our cases the injury is produced by a muscle pull initiated by a twisting motion.

Reduction is supposed to be accomplished quite readily by manual pressure directly on the displaced head. This should be done with the knee flexed to relax the biceps. General anesthesia has been necessary in some cases. One case reported by Small had to be pounded back with a mallet after all attempts at manipulation had failed. On the other hand what might be termed spontaneous reduction has been observed in fifteen cases. In many of the reported cases and in our two cases a loud, snapping sound was heard just as the re-

CASE REPORT

duction took place. Most authors advise fixation by a plaster cast for from four to six weeks. However, some of the cases have been completely free of symptoms from the time of reduction without any fixation. The head of the fibula may be pegged to the tibia, sutured to the tibia or an arthrodesis of the tibiofibular joint performed in cases of chronic dislocations. All of the cases requiring some type of open fixation were posterior dislocations. In this connection a case reported by Schoolfield is of considerable interest although it was not a traumatic dislocation. His patient was a seventeen-year-old boy who had bilateral relaxation of the superior tibiofibular articulation with pain in this region on the right side. The heads of the fibulae could be readily moved about and roentgenograms showed

Fig. 2. After reduction the position of the upper end of the fibula is normal.

lateral separation of the right fibula from the tibia. An arthrodesis on the right resulted in complete relief of the pain.

The prognosis is excellent. Only two cases are reported with any serious sequelae. These two cases developed a paralytic foot drop from injury to the peroneal nerve. These were also cases of posterior dislocations.

Case 1.—A sixteen-year-old boy reached upwards, backwards and to the right while standing with his feet firmly placed on the ground in order to catch a football. He felt a sudden pain in the right knee and on attempting to walk fell down. He noticed a lump on the outside of his knee. Examination a few minutes later by Dr. Macklin confirmed the presence of the lump which was due to the prominence of the laterally dislocated fibula. He was having severe pain and was unable to bear his weight on the right leg. The biceps tendon was unusually prominent and taut. There was localized tenderness over the head of the fibula. The x-rays before and after reduction are shown in Figures 1 and 2. The leg was flexed and the foot slightly inverted and direct pressure applied to the proximal end of the fibula from in front. This resulted in immediate reduction accompanied by a loud snapping sound. No anesthesia was required. A rubber sponge was applied over the fibula and held in place with an elastic bandage. The patient used crutches for three

weeks keeping the knee slightly flexed. There have been no complaints referable to the knee in the past seven months following the reduction.

Case 2.—A young woman, aged eighteen, slipped on some ice and fell. She did not remember exactly how she struck the ground but she experienced immediately a severe pain in the right knee and was unable to bear any weight on this leg. She was examined about fifteen minutes later by Dr. Hartmann. The upper end of the fibula was unusually prominent, protruding anteriorly and laterally. Roentgenograms (Fig. 3) showed the

Fig. 3. Note again the extreme lateral and anterior position of the head of the fibula indicating a dislocation.

head of the fibula to be dislocated anteriorly and laterally without any fracture accompanying the displacement. The knee was flexed, the foot dorsi-flexed and pressure applied directly to the head of the fibula causing it to slip back into normal position. A loud snapping sound was heard as the reduction took place. A cast was applied for two weeks and an elastic bandage for three more weeks before weight bearing was allowed. The patient then began to walk without any support and has had no discomfort of any kind in the knee since.

HISTORY OF MEDICINE IN MINNESOTA

HISTORY OF MEDICINE IN WINONA COUNTY

(Continued from August issue)

Biographies

Franklin Staples, M.D., was born in Raymond (now Casco), Cumberland County, Maine, on November 9, 1883. He received an academic education, then began the study of medicine in the office of Dr. Charles S. D. Fessenden of Portland, Maine, in 1855. He attended lectures at the medical department of Bowdoin College in 1856, and was one of the first students in the Portland School for Medical Instruction. During a period of four years, Dr. Staples was head instructor of the Old Center grammar school in Portland (since 1900, the Staples school). The year previous to his arrival in Winona, Dr. Staples spent at the College of Physicians and Surgeons in the City of New York, and, after graduating, became for a time an assistant in the Maine Medical School as demonstrator of anatomy. At the age of twenty-nine he established himself in Winona. During the first few years after his arrival he was a partner of Dr. J. D. Ford. He became well liked and highly respected in the community. Ford soon gave up practice and, in 1867, Dr. Staples formed a partnership with Dr. Wm. H. H. Richardson, a new arrival. Dr. Staples already held a leading position in his profession.

Aside from medical affairs, Dr. Staples had an interest in the religious and educational activities of the community. In 1883 he was elected superintendent of the First Congregational Sunday School and continued in that position until 1871. The school attained its highest attendance during the period of his leadership. He was also a member of the Board of Trustees and served on many of the active committees.

Dr. Staples' interest in educational affairs was manifested in his service as school director in Winona during the years 1877-1879. It is also of interest that he gave an address before the Teachers Institute as early as 1872 on the "Importance of Some Knowledge of Physiology and Chemistry as a Means of Preserving Health."

Dr. Staples was one of the founders of the Winona Preparatory Medical School, and was active as an instructor there. He was a member of the first Winona Medical Society and a charter member of the later organization of 1869. In the years 1874 and 1885, he served as president of the Winona County Medical Society. He was also a member of the State Medical Society and in 1871 became president of that organization. For many years he was a member of the State Board of Health, and held the position of president from 1889 until his death. He was elected to membership in the American Medical Association about 1870, and held offices as a member of the judicial council and as vice president. During the years 1883-1887 he held the chair of the practice of medicine in the medical department of the University of Minnesota, when the faculty of the University constituted

the medical examining board of the state. In 1883 he received an honorary degree from the Saint Louis College of Physicians and Surgeons.

Dr. Staples' writings on medical and surgical subjects were published in various scientific and professional journals. Among them are: "The Climate of the Northwest" in the *Northwestern Medical Journal* for August, 1871; his report on "The Influence of Climate on Pulmonary Diseases in Minnesota," published in the *Transactions of the American Medical Association* in 1876; and a series of published reports to the Minnesota State Medical Society included nearly every year from 1876 to 1885.

He was unusually prolific in his reports and essays. The records of the State Board of Health, of which he was a member from 1874 until 1901, contain interesting and varied reports by him in nearly every issue. Dr. Staples served also on the local Board of Health, starting in 1866 and continuing in that position for some time. During his entire professional career he was one of the most prominent physicians in Minnesota. His death occurred in 1901 in Winona.

John Steinbach was a well known ophthalmologist who practiced medicine at Winona for twenty-nine years, coming there in 1891. He died at his home in Winona, at the age of sixty-four years, on April 28, 1920.

Hiram Stevens was a Winona County physician about 1864.

Darwin Adelbert Stewart was born at Croyden, New Hampshire, on April 5, 1842. At the age of five years he was taken by his parents to Montpelier, Vermont, where he spent the days of his boyhood. After receiving the usual preparatory education, he entered Kimball Union College at Meriden, New Hampshire, and graduated in 1863. Soon afterward he visited the western part of Minnesota and "laid" two land warrants which his father had purchased from Revolutionary veterans. As the result of this trip, there was laid out the village of Stewart, in McLeod County. While in Minnesota, Mr. Stewart taught school in the village of Plainview in the winter of 1863-1864. He then returned East and entered the Eastman Business College at Poughkeepsie, New York. In the following year he became an instructor in a similar institution in New Haven, Connecticut. In 1867 he entered the medical department of Columbia University in the City of New York. Two years later he was graduated, and then took a year's course in the old New York Hospital, now known as the Roosevelt Hospital. Immediately upon the expiration of his term as an interne in this hospital, he came west and on January 1, 1870, selected Winona as his permanent location. He opened an office and soon built up a large practice. In 1871 he became a member of the Winona County Medical Society, and served as president in 1875. He was elected to membership in the Minnesota State Medical Society in 1872. For five years, from 1875 to 1879, he served as city physician. During the seventies he was also active as an instructor in the Winona Preparatory Medical School. He served for ten years as County Coroner; and later in life he held the office of president of the school board, and as mayor of Winona (1902-1903). Dr. Stewart was local physician for the Chicago, Milwaukee, and St. Paul railroad for more than thirty years, and for the Green Bay and Western railroad for nearly forty years. He was prominent in both the Elks and Masonic fraternities.

Dr. Stewart died at St. Barnabas Hospital in Minneapolis on November 30, 1914, at the age of sixty-nine.

T. Stringer was a physician and surgeon at Utica about 1878-1879.

Absalom Boyles Stuart, M.D., was born at Williamsburg, Pennsylvania, August 27, 1830. He attended Lewisburg University and received his degree of M.D. from the Berkshire Medical College in 1856. After receiving his degree, he began practice in West Hampton, Massachusetts. In 1858 he moved to Macomb, Illinois. In August, 1861, he was commissioned assistant surgeon of the Tenth Missouri Infantry, U.S.V., and was appointed superintendent, on behalf of the Federal Government, of the hospitals established at Iuka, Mississippi, by a cartel between General Rosecrans and General Price. In April, 1863, he was promoted to be surgeon of the First Alabama Cavalry (white), U.S.V. In January, 1864, he resigned from the army. In March, 1866, he graduated from Bellevue Hospital Medical College, and soon thereafter took up the practice of his profession in Winona. While engaged in general practice, he gave especial attention to surgery, and had charge of a number of notable cases. He was a member of the Massachusetts State Medical Association, a charter member of the Winona County Medical Society, and president of that organization in 1872. He was also a member of the Minnesota State Medical Society in 1870 and served as vice president in 1874 and 1876. In 1873 he was secretary of the State Medicine and Public Hygiene Section of the American Medical Association. He was instrumental in securing the establishment of the Minnesota State Board of Health in 1872. That year he was elected teacher of surgery in the Winona Preparatory Medical School, and in 1873 he became president of the institution. It is interesting to note that he served on a committee of the State Board of Health in 1872 to inquire into methods of teaching hygiene in the normal schools.

In 1876 Dr. Stuart was a delegate to the International Medical Congress at Philadelphia. Some of his more important professional publications were: Annual Report, Minnesota State Board of Health for 1873 and "Report of a Case of Supposed Separation of the Upper Epiphysis of the Radius," in the Transactions of the Minnesota State Medical Society, 1876.

About 1878, Dr. Stuart moved to Santa Barbara, California, where he practiced for a short time. After a few years, he moved to Santa Rosa, in the same state (1881), where he died on July 27, 1887.

Dr. Stuart was married in 1857 to Anabel, daughter of Hugh F. McGaughey, then of Doddsville, Illinois. She received her early medical education in the Woman's Medical College of Philadelphia, and graduated from the Medical College of the Pacific, San Francisco, in 1878. Mrs. Stuart practiced successfully for many years in Santa Rosa.

J. H. Sudduth, physician, surgeon, and druggist, came to Saint Charles about 1863. About 1869-1870 he and Dr. Slagle practiced as partners. From 1872 to 1876, approximately, Dr. Sudduth and Dr. Bibbins were partners in a drug business. In 1877 Dr. Sudduth took his brother, H. H. Sudduth, into the drug business with him. Dr. Sudduth probably practiced medicine at the same time. In 1878-1879 Sudduth and Boyd engaged in the drug business together. A notice of 1883 states that Dr. Sudduth had resumed the prac-

tice of medicine in Saint Charles. Dr. Sudduth died in Saint Charles, November 24, 1884, at the age of seventy-one.

T. J. Swan was listed as a Winona County doctor in 1865.

Jerome B. Tamblin, M.D., came to Winona in 1867 and published the following card upon his arrival.

JEROME B. TAMBLIN, M.D.

Physician and Surgeon

Recently of New York, has had twelve years' experience as a practitioner. Particular attention given to the treatment of diseases of women and children. Calls in city and country promptly attended to.—Office in Ford's New Brick Block, Second Street, Winona, Minn., Residence 159 3rd Street.

In 1869, Dr. Tamblin moved to Saint Charles to practice and to engage in the drug business with Dr. Guthrie. It was during that year that the Winona County Medical Society, of which he was a charter member, was organized. In 1871 he became a member of the State Medical Society. During the term of his practice in Saint Charles, Dr. Tamblin was often called out of town to attend cases at Elba, Utica, and the surrounding country. He was always an active politician in the county. In 1882 he moved to Lanesboro, Minnesota, and in 1885 he was living at Lincoln, Nebraska.

D. L. Taylor was listed as a Winona County doctor in 1865.

Rudolph C. Teschan graduated from the University of Basle and from the University of Michigan. Before coming to Winona in 1882, he had occupied the position of Inspector of the National Board of Health. He came to Winona from Detroit, Michigan, to succeed Dr. Lessing, who went to Philadelphia to spend the winter. In 1885 he became a member of the Winona County Medical Society and of the Minnesota State Medical Society. Aside from his practice, Dr. Teschan was vice president of the Winona "Adler" publishing company, organized in 1885.

J. Thomas was a doctor in Minnesota City in 1857.

J. Thompson, physician, lived at Rollingsstone in 1860 and died there in 1861. Possibly he is confused with Dr. Thomas.

Isaac W. Timmons, homeopathic physician, came to Winona about 1875. About 1878 he moved to Chatfield, but returned to Winona to practice in October, 1884.

(To be continued in October issue)

President's Letter

CALL TO SERVICE

THE draft act may or may not be passed when this issue of MINNESOTA MEDICINE is off the press; but the ground work will have been laid, in any case for medical participation in draft board activities.

The contribution of medicine to the defense of the nation was never confined exclusively to service for the fighting men, of course. But the importance attached to physical fitness and to the careful selection of men for military services has grown to large scale proportions in this new effort to prepare our nation.

Proceeding from lessons learned in the last war, the draft boards of 1940—if they should indeed be set up—will require far more careful sifting of enrollees than ever before. And no time is being lost by physicians in Minnesota in providing, beforehand, the machinery that will be ready when Congress and the President say the word.

There will be 122 draft boards in Minnesota with three members on each board, officers of the association were informed at a recent conference. One examining physician will serve with each board and his rate of pay will be \$1.00 an hour for each hour he is actually engaged in making physical examinations for the board but not to exceed \$10.00 a day.

Plans call for thirteen medical advisory boards of specialists to whom draftees will be referred by these boards. These boards will be located in Minneapolis, St. Paul, Rochester, St. Cloud, Mankato, Willmar, Crookston, Bemidji and Duluth, and the members will serve without pay.

All appointees must have indicated their willingness to serve. They must be over thirty-one years of age and they must not be officers in the reserve.

Selection will be made from recommendations by presidents and secretaries of county medical societies and councilors of their respective districts.

Two or three names will be submitted for each position according to present plans and they will be submitted in turn to the Governor. Appointments will be made by the President from recommendations by the Governor.

The importance of securing well qualified physicians for these appointments goes without saying. Also the importance of speed in selecting them in case the draft is passed.

Here is another avenue of service for organized medicine, another chance for the Minnesota State Medical Association to show responsible state officials its effectiveness as an instrument of public service.

Instructions will be mailed to county officers immediately as they are received from the Governor and it is certainly not out of place, even in advance of action by the Congress, to urge promptness upon our society officials in answering that call.

B. S. ADAMS, President
Minnesota State Medical Association

SULFATHIAZOLE

THE chemical products sulfanilamide and sulfapyridine have proven to be phenomenally effective in various types of bacterial infections. Their use has been somewhat limited by their toxicity. To maintain proper dosage and avoid toxic effects, certain laboratory procedures, not always easily accessible, are necessary.

In an effort to maintain the very useful action of these products and at the same time reduce the risks, some new variants have been evolved. Sulfamethylthiazole and sulfamidathiazole have undergone extensive clinical trials, in various types of infections, to determine their usefulness, dosage and dangers. These trials have been carried on under the direction of the Federal Food and Drug Commission.

Sulfamethylthiazole has proved to be effective in the control of streptococcal, pneumococcal, and staphylococcal infections. However, in effective dosage it has also shown a tendency to cause toxic neuritis, of an extent and permanency not yet fully determined. Sulfathiazole, now released and on the market, has proved effective in the control of the same types of bacterial infections; and has shown a much lower toxicity. Its rate of excretion appears to be rapid and much more uniform than that of sulfapyradine. It is eliminated principally through the intestinal tract, only about 33 per cent passing through the kidneys. Its necessary level of concentration in the blood for effective action is lower than that of either sulfanilamide or sulfapyradine.

It is tasteless and easy to handle, and has much less tendency to disturb digestion. It has not shown the tendency of sulfanilamide to cause cyanosis; nor the tendency of sulfapyradine to acetylate and disturb the kidneys. Apparently sulfathiazole is a much safer chemical to employ than sulfanilamide or sulfapyradine, and therefore can have a much wider use.

There is a class of patients partially disabled by chronic bacterial infections in whom it is highly desirable that some form of chemotherapy be used. In the last six months I have employed sulfathiazole in the treatment of a group of twenty-five such private patients. Long continued bacterial infections of the urinary tract proved suitable for the purpose of study, both because of the ambulatory nature of many of them, and because of the comparative ease of checking the effects of the drug.

The bacterial agent was found, and blood and urine cultures made before any drug was given. The blood level of the drug was determined in forty-eight hours, and cultures again made of the catheterized urine. Frequent blood counts were had and any untoward symptoms noted. When cultures became negative, the dosage was immediately reduced sharply, and continued laboratory and clinical evidence gathered.

The first cases were chronic kidney infections in which the agent was *Streptococcus fecalis*. Uniformly rapid and satisfactory control with

no undesirable side effects was attained in these urinary infections; and the drug was then applied in pneumococcal and staphylococcal infections. Again the result was favorable comparing well with previous experience with sulfanilamide and sulfapyradine.

From this experience I am able to predicate that the effective sulfathiazole level for bacteriostatic control of urinary infections with *Streptococcus fecalis* and *Bacillus coli* is an initial blood level of about 4 mg. per centum of blood. In adults this can be reached by a daily dose of 6 to 8 grams for forty-eight hours, followed by a maintenance dose of 3 to 4 grams for two or three days; and then dropped to 1 or 2 grams daily at which dosage the blood level is less than 1 mg. per centum.

In pneumococcal infection the blood level of sulfathiazole should be around 6 mg. per centum, and can be rapidly reached by a daily dosage of 8 to 10 grams. If, after this level is maintained twenty-four hours, clinical improvement is not evident, the type serum should be employed in moderate dosage. The drug should be reduced immediately to one-half the initial dosage, and further reduced to 1 to 2 grams per day when the temperature has returned to normal. Initial dosage for children under twenty-five kilos in weight should be based on 1.5 to 2 mg. of sulfathiazole per kilo.

Ample water should be provided with each dose of sulfathiazole; the tablets should be either well chewed or broken up before administration. The minimum daily dosage should be continued for a week or so after the acute symptoms have subsided.

Recurrences in both acute and chronic infections are common if the drug is stopped too soon, but the bacteriostatic action is maintained by dosage of 1 to 2 grams daily after the initial necessary blood level has been maintained for forty-eight hours.

With any drug of this chemical group there will be individuals who react badly. The dosage must therefore be as carefully controlled with sulfathiazole as with sulfanilamide or sulfapyradine. However, the present evidence is that sulfathiazole is an active bacteriostatic agent in a wide group of bacterial infections, and that it can be effectively employed with less chance of disturbance of the blood, kidneys, or the digestive system than occurs with sulfanilamide

or sulfapyridine; and that its desirable action can be attained with blood levels much lower than either of them.

W. B. ROBERTS.

THE SULKOWITCH TEST FOR EXCRETION OF CALCIUM

THE medical profession is indebted to the group of workers in the Massachusetts General Hospital who have added so much to our knowledge of metabolism of calcium. It is this group which has taught us methods for the early diagnosis of hyperparathyroidism, thus permitting the early removal of hyperfunctioning parathyroid glands.⁴ These workers also have performed detailed studies of cases of parathyroid insufficiency and have discussed the best methods for raising the concentration of calcium in the blood.⁵ They have discussed the formation of renal stones¹ and have outlined a nonsurgical treatment for certain types of renal and vesical stones.⁶ Moreover, they have described an entirely new syndrome, which is being referred to as "Albright's syndrome."³

One of the greatest contributions of this group has been to present to the medical profession a simple, effective and inexpensive method of observing excretion of calcium in the urine. The test can be performed by any physician, without the use of extensive or expensive laboratory facilities. The method consists simply in adding the reagent to an equal amount of urine. The reagent, named "the Sulkowitch reagent," is described in a brief article by Albright.² He stated, "The Sulkowitch reagent* is a solution containing oxalate radicles buffered at such a pH that when equal amounts of the reagent are added to urine the calcium will almost immediately come down as a fine white precipitate of calcium oxalate. If there is no precipitate there is no calcium, and the serum calcium level is probably from 5 to 7.5 mg. per hundred cubic centimeters. If there is a fine white cloud, there is a moderate amount of calcium and the level of calcium in the serum is in the satisfactory range. If the precipitate looks like milk, the danger of hypercalcemia is present."

*Two and five tenths Gm. of oxalic acid, 2.5 Gm. of ammonium oxalate and 5 c.c. of glacial acetic acid are dissolved in distilled water and made up to a volume of 150 c.c. (Barney, J. D., and Sulkowitch, H. W.: Progress in the Management of Urinary Calculi, Jour. Urol., 37:746, (June) 1937.)

This test is valuable for determining excessive excretion of calcium in the urine in cases of hyperparathyroidism. It is of equal value in regulating the treatment of parathyroid insufficiency. In this connection Albright concluded by stating:

"The patient does his own tests and modifies the dose according to the results. I usually prescribe about 3 c.c. of dihydrotachysterol a day until calcium appears in the urine and then I drop the dosage to a maintenance level of about 1 c.c. from three to five times a week.

"This discussion has been slightly oversimplified. There are a few 'ifs' and 'buts' that must be added. Occasionally a normal person who happens to be on a very low calcium diet will show in a single specimen of urine practically no calcium. Almost any normal person shortly after drinking a large amount of milk will show an excess of calcium in the urine. Since one keeps one's patients with hypoparathyroidism on a high calcium diet, one would expect them always to show hypercalciuria if their levels of serum calcium are normal. It thus turns out that if the dosage is reduced when a large amount of calcium appears in the urine the blood calcium will be kept at a slightly subnormal level. Such is the case. This is probably all the better, since it further guards against hypercalcemia, and slight hypocalcemia is not deleterious."

THE FIRST CHOLECYSTECTOMY IN AMERICA

THE first successful cholecystectomy in Minnesota, in fact, the first in this country, was performed on September 24, 1886, at St. Joseph's Hospital, Saint Paul, Minnesota, by Dr. Justus Ohage. It seems that the anniversary of this important surgical milestone should not pass unnoticed.

Langenbuch, in 1882, was the first to remove successfully the human gallbladder. The cholecystectomy by Doctor Ohage was the twenty-second case reported in the medical literature.

At that time cholecystotomy was considered to be the procedure of choice in disease of the gallbladder; Lawson Tait described cholecystectomy as being "intrinsically absurd." At that, cholecystotomy was not performed very frequently. Only eight years before, in June, 1878, the first successful cholecystotomy had been performed by Kocher. Up to 1886, there had been only fifty cases reported in the literature with thirty-nine recoveries and eleven deaths, a mortality of 22 per cent.

Doctor Ohage's patient was a white woman, thirty-five years old, who had had attacks of gallstone colic for three months. In the right hypochondriac region there was an oblong tumor that could be felt. It was freely movable and painful to touch and its lower pole reached almost to the iliac fossa. On the morning of the operation there was a feeling that something "daring" was to be performed. Certain physicians had warned Doctor Ohage that he might be indicted for manslaughter if the operation should fail. Doctor Ohage was assisted by Doctors Nelson, Schulin, Dedolp, Jr., Denny, and the house surgeon, Doctor Welsh. Ether anesthesia was used. The operation was performed under "strict antiseptic precautions, no spray." Doctor Ohage, like many surgeons of that period, believed more in antiseptic than aseptic surgery. The washing of the peritoneum and viscera with 1:2000 corrosive sublimate solution at the end of an operation was a common practice as well as the dusting of iodoform over the wound after closing the abdominal layers. Sisters Christina of St. Joseph's Hospital, who remembers the period well, says that surgeons upon closing the abdominal wound often applied a layer of borated or iodoform gauze on the skin and then a dressing of non-sterilized absorbent cotton. The use of the carbolic acid spray seemed to have enjoyed but brief popularity in Minnesota, and its use was on the wane at the time of this operation.

The incision was a vertical one, about six inches long, on the outer border of the right rectus muscle. Upon opening the peritoneal cavity, a hydrops of the gallbladder was found. There was a stone in the cystic duct which was manipulated back into the gallbladder. After the cystic duct was ligated with carbolized silk, the base of the gallbladder was incised and more than a pint of mucoserous fluid evacuated. The cystic duct was then cut close to the ligature with a cautery,

and the gallbladder removed. It contained one hundred and thirty-five stones. After washing the liver and the bowels with a 1:2000 corrosive sublimate solution, the whole wound was closed with deep and superficial silk sutures. Iodoform was dusted freely over the wound, a large pad of absorbent cotton applied and held in situ by a binder. It is interesting that no drainage tube was used.

The patient made an uneventful recovery. Her temperature never rose to over 101 degrees, nor her pulse over 90 beats per minute. A dose of calomel was given on the fifth day to relieve constipation. On the eighth day, the dressing was removed for the first time. There was no drainage on the dressing. All the sutures were removed. The patient was discharged from the hospital on the thirteenth day after operation. She remained well until her death nine years ago.

In his paper written in the *Medical News* for February 19, 1887, Doctor Ohage discussed somewhat his indications for cholecystotomy and cholecystectomy. "In old decrepit subjects where the disease (cholelithiasis) is probably ended, et cetera," "he favored cholecystotomy." In healthy young subjects where the stone formation is probably not yet ended, et cetera," he favored cholecystectomy. In later years, however, he extended his indications for cholecystectomy to even old subjects.

Those who knew Doctor Ohage best say that he was of a modest, self-effacing nature. In 1912, Dr. William Mayo asked Dr. J. Ohage, Jr., "Did you know that your father was the first to perform a cholecystectomy successfully in this country?" It was only after this that the senior doctor told his son about the operation. Probably very few know that Doctor Ohage ran away from home in Germany at the age of fourteen years, and came to this country. He fought with the Union Army during the Civil War. After several years as a sailor and working as a medical assistant on a railroad, he was graduated in 1880, from the University of Missouri Medical School at Columbia. His postgraduate work was obtained under Esmarch, Virchow, Bernard von Langenbeck and Keyes. Returning to this country he practiced in St. Paul, Minnesota, where he was known not only as a skilled surgeon, but also as

an efficient health officer and lover of the out-of-doors. He continued in his practice until a year before his death in 1935.

The "first" operation or surgical procedure is often a matter of chance. However, the successful cholecystectomy performed by Doctor Ohage was not a matter of luck or chance, but was the result of a thorough surgical background. Minnesota has been fortunate in always having had good medical men like Doctor Ohage. His achievement adds luster to the medical history of this state.

CHARLES E. REA

DESOXYCORTICOSTERONE

The Council on Pharmacy and Chemistry reports that it has had under consideration for some time preparations of the adrenal cortex. When desoxycorticosterone was synthesized and marketed as an acetate for clinical use, it was anticipated that much of the inaccuracy and unreliability of adrenal cortex therapy associated with the use of extracts of the adrenal cortex gland would be eliminated, since the administration of this potent steroid on a basis of dosage by weight appeared to offer advantage over the administration of adrenal cortex extracts, which are rather unsatisfactorily assayed on laboratory animals. The early reports of dramatic clinical success in the treatment of Addison's disease were held most promising. Soon after desoxycorticosterone was employed in Addison's disease, the Council learned of the occurrence of significant untoward reactions and, in several cases, actual fatalities. One of the most striking effects obtained with this substance was hypertension, which in some cases resulted in cardiac failure and death. There has been sufficient confirmation of these results to warn against the indiscriminate and excessive use of this substance in routine therapy. Adequate evidence of another sort has also led to the conclusion that desoxycorticosterone acetate does not possess all the properties of the adrenal cortex gland and that the synthetic principle, therefore, does not furnish complete replacement therapy. In view of the possible widespread use of desoxycorticosterone acetate, the Council requested Dr. Edgar S. Gordon of the University of Wisconsin Medical School to prepare a review of the physiologic and clinical data obtained with this substance up to the present time. The Council authorized publication of Dr. Gordon's article "The Use of Desoxycorticosterone and Its Esters in the Treatment of Addison's Disease" and it appears as a part of the Council's report. (J.A.M.A., June 29, 1940, p. 2549.)

MEDICAL ECONOMICS

Edited by the Committee on Medical Economics
of the

Minnesota State Medical Association

W. F. Braasch, M.D., Chairman

DEFENSE RECORD FOR MINNESOTA

Minnesota ranks second among the eight states of the Seventh Army Corps Area in the number of medical preparedness questionnaires so far returned to the American Medical Association headquarters.

This record, as reported recently by Dr. R. W. Fouts of Omaha to Chairman F. L. Smith of Minnesota's Committee on Medical Preparedness, is regarded as highly satisfactory. Top rank now belongs to Nebraska, however, with South Dakota, North Dakota, Iowa, Kansas, Missouri and Arkansas following Minnesota in the order listed. The entire Corps Area is among the top five in the United States and the average is 11.3 per cent above the rest of the country.

Physicians of Minnesota are being congratulated by defense authorities upon the promptness and wholeheartedness of their coöperation, therefore, although a considerable number still remain to be heard from. The actual number of cards mailed to the State Office as evidence that the obligation has been fulfilled was 1667 when this issue went to press.

A special appeal is accordingly being made to the others by officers of the association as well as by the committee in charge to supply the information requested and to send their cards to state headquarters at once. Minnesota will not remain at its present position long unless all remaining questionnaires are returned.

In the new organization for defense the Surgeon General of the Army depends wholly upon American Medical Association lists to supply medical personnel for every branch of preparedness at home as well as in the field. It is the individual responsibility of each physician to supply information needed for those lists.

Additional copies of the questionnaire are available for those who may have mislaid them from the State Office at 493 Lowry Medical Arts

Building, Saint Paul, or from Chairman F. L. Smith at Rochester.

INOOPORTUNE

The American Medical Association goes on trial on the charge of violating the Sherman anti-trust law on October 21 in Washington, D. C.

At the same moment, the government which, through one arm has brought a criminal indictment against the officers and two component units of the association, will through another arm be asking and receiving essential aid to the defense of the United States.

The organization and discipline which is regarded as criminal by the justice department will be thankfully and eagerly put to use by the War Department in the selection of the men who will serve in the defense forces, in medical care for armed forces and in maintaining services for the civilian population.

If the usual procedure is followed, officers of the American Medical Association will be required to remain in Washington for the duration of the trial, a period that may run into weeks and months. At the same time, they will be forced to exert every effort at long range, to assemble and tabulate the enormous amount of information about the medical men of the country that was asked of them by the Surgeon General of the Army at the New York meeting.

The burden placed upon them at this critical time will seem the more indefensible to casual observers in view of the fantastic nature of the charges against which they are now called upon to defend themselves.

SICKNESS INSURANCE IN WISCONSIN

Experiments in sickness insurance in Wisconsin are now approaching a point where valid estimates can be made on their comparative popularity and soundness.

Several other states are also engaged in medically sponsored experimentation in this type of insurance but in no other state have three different plans been set up on a definitely experimental basis. Wisconsin's experience as set forth in extensive reports prepared for the September meeting of the House of Delegates of the Wisconsin State Medical Society therefore provides by far the most interesting information yet made available to students of new forms of payment for medical services.

Douglas County Coöperative

The first of these experiments was placed in actual service operation in Douglas County on July, 1939. It was a plan for prepaid medical care as conceived, organized and managed by a coöperative lay group. Contract provisions, premiums, benefits and similar items were accepted by the medical profession "without expression of judgment." Membership was open to any resident of Douglas county. Premiums as established by the lay group were \$2.90 per month per family; \$2.25 per month for man and wife and \$1.50 per month per single person. Each person applying was required to give a medical history in writing and to submit to and pay for a special physical examination. The subscriber was then eligible to complete physician's care without limitation as to extent or quantity.

Demand Limited

Committee comments in brief on a year's experience are as follows:

1. There is a very limited demand for medical care on a prepayment basis. After intensive and continuous membership drives, there were only 235 members at the end of June, 1940, a gain of only 97 over the subscribers in August, 1939. Most of them, furthermore, were in the income group above \$1,200 and all were of the "prompt pay class."

2. Physicians were paid an average of 71 per cent of normal charges in private practice; but the average would have been 55½ per cent if the plan had not received administrative contributions from the State Society. Contrary to predictions by coöperative association leaders, receipts were below what the same physicians would have received from the same patients in private practice.

3. Widespread duplication of the Douglas county plan would be feasible only if there were

large reserves of cash to draw upon or if a \$15 initiation fee were to be charged for each subscriber unit.

4. There was no evidence to indicate that there was a larger use of preventive measures by subscribers to the prepaid service than by others or by the same patients previous to entry into the plan. At the same time there was no marked nuisance demand for physician's care in this group which, in any case, could be placed definitely in the category of substantial, honest and reliable people.

Milwaukee Plan

The second experiment was placed in operation in Milwaukee on November 1, 1939. This plan was under direct sponsorship of the Milwaukee County Medical Society and its distinguishing feature was that each subscriber unit was obliged to pay the first \$24 worth of service from a physician member of the panel before he became eligible for services under the plan. After the initial payment, subscribers were entitled to unlimited care throughout the year so long as premiums were paid. Subscribers are selected on a group basis. Premiums are \$1.00 per family, 75 cents per month for man and wife, and 50 cents per month for a single person.

After an exhaustive campaign for subscribers, the required minimum of 200 was secured at Greendale, a Federal Government Housing project near Milwaukee, but further solicitation of other groups and of a large number of Milwaukee industries failed to secure a sufficient number of subscribers to warrant extending the plan to them.

During the first three months only one statement of \$57 of which \$24 was paid by the patient, met the qualifications. During the second quarter seven became eligible and at the beginning of the third quarter, 21, or 10 per cent, had met all the demands. On July 1, 36, or 21 per cent, had met the demands. By the end of the second quarter an estimated \$1,500 worth of service had been rendered to 21 subscriber families eligible for service under the plan. Of this amount a net of \$1,200 was paid to participating physicians.

Interest Slight

Comments by the committee follow:

1. Limited experience with this plan indicates that the deductible feature is basically sound and

should be included in some manner in future experimentation by the society.

2. The fact that there is very little uncultivated demand was shown in Milwaukee county as in Douglas county. The same lack of interest was noticed in the industrial groups solicited as at Parklawn where the requisite 200 subscribers were finally secured out of 600 families.

3. In this instance there was a notable lack of interest and coöperation among some of the physicians, also, particularly, those associated with industrial plants.

No Sale in Rock County

The third experiment initiated in Rock county by the physicians was never placed in actual operation because of lack of subscribers, but was offered for sale August 16, 1939. The plan was designed by the local medical profession, 75 per cent of whom participated. The premiums were set at \$3 per month per family, \$2 for man and wife, and \$1.50 for single persons. Selection of subscribers was based upon the group theory. Any group organized on other than a health basis was eligible if 50 per cent of the group participated. The medical service committee of the medical society directed solicitation. They were assisted by the assistant secretary of the State Medical Society of Wisconsin and an energetic campaign of personal solicitation and letters was carried on. Meetings were organized to explain the plan to industrial groups, pamphlets were distributed in pay envelopes and in doctors waiting rooms.

Chief Reaction Indifference

The committee said:

1. Virtually the only interest shown in the plan came from those with incomes above the limits set by the physicians. The reaction of others was chiefly one of indifference.

2. Several employers declared they would prefer to purchase insurance from a company with an established financial reserve in spite of the fact that the physicians themselves represent the actual and definite reserves of the plan proposed.

In no case were 50 per cent of the members of any group willing to join in the plan.

Reason Why

Just what the delegates to the House of Delegates of the Wisconsin Society will do with this

report is uncertain. They may or may not discontinue the experiments in September.

It is clear, however, that the popular demand for sickness insurance which the enthusiasts have always cited does not exist in three typical sections of Wisconsin. The probability is that it does not exist in Minnesota, either, nor anywhere else in the United States.

Reasons given by individuals who rejected the invitation to participate in these three plans were essentially economic in nature. They are summarized by the committee this way—

1. Lack of proper appreciation or evaluation of the comparative values of budgeting for medical care and of budgeting for such obligations as radio, appliances and automobiles.

2. Physicians' services during the past several years have not averaged the annual premium costs of \$36 a year.

3. Lack of funds on the part of some prospective subscribers.

4. Premiums are too high in the opinion of others.

IS IT CRIMINAL TO SAVE?

[Monthly Editorial Prepared by the Medical Advisory Committee]

Vital statistics show that a remarkable change in death rate in most diseases is taking place in this country and that consequently the span of life is increasing. Certainly this can be credited in great part to the type of medicine that is being practiced by our profession in the United States.

From hospital statistics, no less noticeable is the fact that fewer and fewer amputations are being performed in the cases of badly injured extremities. To those men who have practiced for a quarter of a century or more, the picture of the amputating knife is a familiar one; the painful stump, a "bug bear" and the artificial leg or arm, a commonplace.

Today, owing to the knowledge of asepsis, debridement, extension and the newer drugs employed, the mangled, torn, compound comminuted fracture is brought into alignment and a fairly serviceable extremity is the result. It is an acknowledged fact that a live leg or arm which has 75 per cent of its former efficiency is much better than the best that the most pro-

ficient artificial limb-maker with his mechanical skill can produce.

Yet, the medical man who not only saves the life of the patient but also gives him a good leg to use may be subjected to a malpractice suit because he could not again reproduce *in toto* the fine anatomic relations which prevailed before the accident. Why men who do remarkable restorations in these cases should be exposed, as any criminal might, to court ridicule is beyond the comprehension of your Medical Advisory Committee.

—B. J. B.

MINNESOTA STATE BOARD OF MEDICAL EXAMINERS Saint Paul, Minnesota

Julian F. DuBois, M.D., Secretary

Scott County Drug Addict Committed to Willmar State Hospital

Re. State of Minnesota vs. Merten J. Stratton.
On August 7, 1940, Judge F. J. Connolly of the Probate Court of Scott County, made an order committing the above defendant, who is 45 years of age, to the State Hospital at Willmar, Minnesota, for treatment of drug addiction. Stratton, who resided at Belle Plaine, Minnesota, pleaded guilty on April 2, 1940, in the District Court of Scott County, to an information charging him with the crime of obtaining narcotic drugs by fraud and deceit. Judge Joseph J. Moriarty of the District Court, sentenced Stratton to a term of not to exceed 5 years at the State Prison at Stillwater, and suspended the sentence upon the condition that Stratton, who has used narcotics over a period of the past 20 years, be admitted to the Federal Hospital for Narcotics at Lexington, Kentucky, for treatment. Stratton made application to that hospital and was admitted on May 8, 1940.

Notwithstanding the fact that Judge Moriarty had provided in his order that Stratton was to remain at the Federal Hospital until he was certified by the proper authorities of that Hospital as cured, Stratton left against medical advice on July 31, 1940. He returned to Belle Plaine where he was found asleep in the reception room of a physician's office on August 4, 1940. The Minnesota State Board of Medical Examiners was notified and following a conference between Harry A. Irwin, County Attorney of Scott County, Judge Moriarty, and Mr. Brist representing the Medical Board, Judge Moriarty made an order revoking Stratton's suspended sentence, and providing that he be taken to the State Prison at Stillwater, Minnesota, unless, within 10 days, Stratton had been committed by the Probate Court of that County to the State Hospital at Willmar, for treatment of his drug addiction. On August 7, 1940, Judge F. J. Connolly of the Probate Court of Scott County, made an order committing Stratton to the State Hospital. Judge Moriarty's order also provides that unless Stratton remains at that Hospital for not less than one year, he must serve his sentence at the State Prison.

In Memoriam

William A. Beach

Dr. William A. Beach, Mankato, died following a stroke June 12, 1940, at the age of seventy-one.

Dr. Beach was born at Ionia, Michigan, in 1868 and came to Minneapolis with his parents at the age of eleven. He graduated from the homeopathic department of the University of Minnesota medical school in 1893 and practiced for a short time at Windom and Saint Paul before locating in Mankato more than fifty years ago.

Dr. Beach was mayor of Mankato in 1921 and again in 1925 and served as city health officer from 1933 to 1935. He was also a member of the Mankato board of education over a long period of years. His extensive career as a public official was marked by the ardor with which he supported his convictions. For years he campaigned for regulation of the city's milk supply, urging city inspection of dairy herds and compulsory pasteurization of the milk supply of the city.

Dr. Beach is survived by his widow and two children, William E. Beach, Mankato and Mrs. William Lloyd, Albert Lea, and two step-daughters, Mrs. J. S. Graham, Minneapolis and Mrs. Theodore Wells, Grand Forks, North Dakota.

Frank W. Brey

Dr. Frank W. Brey of Wabasso died June 8, 1940, after suffering from a brain tumor for some nine months.

Dr. Brey was born in Lafayette township on March 22, 1886. He graduated from high school in New Ulm in 1904. He graduated from the medical school of the University of Minnesota in 1910, and began practice at Wabasso.

On November 21, 1921, Dr. Brey married Elizabeth K. Daub. His widow and six children, Anna Catherine, Theresa E., Alois, Virginia, Paul and Justine survive him.

Dr. Brey was a member of the Redwood-Brown County Medical Society, the Minnesota State and American Medical Associations. He was an upright citizen, at all times displaying a keen interest in community affairs. During his career he served on the school board, was village health officer and Redwood County coroner, besides being a member of various clubs and societies.

George A. Holdridge

Dr. George A. Holdridge, for nearly forty years leading physician, beloved country doctor of Benton County, was killed in an automobile accident July 3, 1940, as he was returning from a professional call.

Dr. Holdridge was born in Newark Valley, New York, March 31, 1879. He was graduated from Belle-

Pearson, Lawrence Orville Hicks—U. of Minn., M.B. 1940, Saint Paul.

Rosendahl, Frederick Glasoe—U. of Minn., M.B. 1939; M.D. 1940, Saint Paul.

Schmitz, Everett Joseph—U. of Minn., M.B. 1940, Minneapolis.

Shaw, Howard Arthur—U. of Minn., M.B. 1940, Minot, No. Dakota.

Shea, Andrew Whitman—U. of Minn., M.B. 1940, Minneapolis.

Smedal, Harald Aasvald—Harvard U., M.D. 1936, Rochester.

Soucheray, Philip Henry—U. of Minn., M.B. 1940, Jersey City, N. J.

Stark, Frederick Mosier—U. of Minn., M.B. 1940, Saint Paul.

Sutch, Gabriel Charles—U. of Minn., M.B. 1940, Saint Paul.

TREATMENT OF HABITUAL ABORTION WITH VITAMIN E

The Council on Pharmacy and Chemistry authorized publication of a report, prepared for it by one of its referees, on the value of vitamin E in the treatment of various disorders, particularly with reference to its alleged usefulness in habitual abortions. A critical examination of the evidence presented during the last eight years led to the following conclusions:

Claims that vitamin E (wheat germ oil) is of value in the treatment of menstrual disorders, failure of lactation and the vaginal pruitus after the menopause cannot be accepted because of lack of sufficient clinical evidence.

The claim that vitamin E is of value in the prevention of habitual abortion cannot be accepted because of the lack of convincing clinical evidence. The diagnosis of habitual abortion in many of the published reports is open to question; the great variation in dosage of vitamin E and the lack of evidence that the preparations used were active make it difficult to attribute any effects claimed for it to the vitamin. Moreover, the expectancy of spontaneous cure in cases of so-called habitual abortion has not been accurately established.

Although the administration of wheat germ oil probably does not cause the development of neoplasms, unfavorable effects may follow its use in certain cases. These effects are usually not serious.

The published results of the treatment of habitual abortion with vitamin E are sufficiently encouraging to justify further clinical experiment. Such experiments are justified only if preparations of vitamin E of known activity are used and if adequate diagnosis and clinical control can be established. (J.A.M.A., June 1, 1940, p. 2214.)

vue Hospital Medical College in 1900 at the age of twenty-one, the youngest member of his class. Shortly after graduating he came to Foley, Minnesota, where he established a successful practice. In 1907, he moved to Holdingford, Minnesota, where he practiced for two years, returning to Foley in 1909 in response to popular demand.

Dr. Holdridge was a man of sterling character and sound judgment. He took active part in community affairs and quickly became not only physician to every family in the county but trusted friend and wise counselor as well. He will long be remembered as a kind, generous neighbor, never too weary to lend a hand to every worthy cause, never too busy to pause for a cordial word or a cheery greeting as he went about his work. To say that he will be greatly missed in his community conveys but a fraction of the deep sense of loss his friends and co-workers feel at his tragic passing.

Dr. Holdridge served as chairman of the Benton County Health Association for thirty years; he acted as County Coroner for several years. He was a member of the Stearns-Benton County Medical Society, the Minnesota State Medical Association and the American Medical Association. Besides his medical work he served as County Commissioner for eight years, acting as chairman of the Board from 1933 to 1939.

In 1902 Dr. Holdridge married Fannie E. Osborne who, with a son, William, and three daughters, Ida, Katherine, and Helen, survive him. Two sisters and one brother also survive.

Herbert W. Jones

Dr. Herbert W. Jones who had practiced medicine in Minneapolis for thirty-five years, died suddenly while returning from Cottage Grove, Minnesota, on July 9, 1940.

Dr. Jones was born in Berlin, Wisconsin, on October 13, 1873. He was the son of Griffith Franklin Jones of Berlin, a merchant. His grandparents were pioneers in that section of Wisconsin. He obtained his preliminary education in Berlin and later took his medical course at the University of Minnesota. He was captain of the University track team in 1900. He graduated in 1902 and then took a year's internship at St. Luke's Hospital, Saint Paul. After finishing his internship he went to Faulkton, South Dakota, to take over the practice of Dr. Edgerton for a short time. In 1905 he returned to Minneapolis and became associated with the late Dr. W. A. Jones, with whom he practiced for about ten years. In 1906 he went to Vienna where he took a course in neurological and general surgery for a year and then returned to Minneapolis associating himself with Dr. W. A. Jones and Dr. A. S. Hamilton.

In June, 1909, Dr. Jones married Margaret Daniels of Minneapolis.

Dr. Jones was very much interested in the Medical Alumni of the University of Minnesota. He was secretary of the organization for a number of years and at one time its president. It was his desire that the

alumni body should act in an advisory capacity to the teaching faculty and Regents of the University, and he spent much time on committees working to help in the development of the medical department. Much of the success of the medical alumni was due to the indefatigable efforts of Dr. Jones in its incipient stage.

Dr. Jones was a member of the Asbury and Northwestern Hospital staffs, and was president of the Northwestern Hospital staff in 1936 and 1937. He was also an honorary member of the American Neurological Association, a member of the Minnesota Academy of Medicine, American Medical Association, Hennepin County Medical Society and other state and county associations. He was a member of the Nu Sig Nu Fraternity and the M Club at the University of Minnesota. He associated himself with the Westminster Church.

Dr. Jones was held in high esteem by all of his colleagues. He had good judgment which was appreciated by the medical profession. Many of the early operations in neurological surgery in Minneapolis were performed by him.

Dr. Jones, who lived at 2418 W. 22nd Street, is survived by his wife, three sons, Dr. H. W. Jones, Jr., who has occupied offices with his father since his graduation in medicine; Roderick Daniel, and David Griffith, and two sisters, Mrs. R. E. Daniel of Minneapolis and Minnie W. Jones of DeKalb, Illinois.

A. E. BENJAMIN, M.D.

Earl H. Marcum

Dr. Earl H. Marcum, Bemidji, died August 5, 1940, following injuries sustained in an automobile accident three days previous.

Dr. Marcum was born August 14, 1878, in southeastern Iowa, but moved to Crookston, Minnesota, with his parents in 1880. After attending high school in Crookston he attended Hahneman Medical College in Chicago, graduating in 1903. He began practice the same year in Bemidji.

In August, 1917, Dr. Marcum entered the service and was stationed at Fort Riley, Chicago University and Rush Medical College. He later went to France with the Twentieth Evacuation Hospital and had much surgical experience there.

In 1925 Dr. Marcum visited England, Ireland, France and Belgium as a member of the party of 850 in the Inter-State Postgraduate group.

Dr. Marcum was married in 1902 at Crookston to Elizabeth Davies. He is survived by his widow and his brother, Walter F. Marcum, of Bemidji.

Dr. Marcum was a member of the Upper Mississippi Medical Society, the Minnesota State and American Medical Associations. He was active in the civic and fraternal life of Bemidji, being identified with various movements for the betterment of the city. Serving as captain in the medical corps of the army during the World War he was later promoted to major and still later lieutenant colonel in the Medical Corps Reserve. He had passed the examinations for a full colonelcy and had expected to receive that commission shortly.

OF GENERAL INTEREST

Dr. and Mrs. O. J. Campbell of Minneapolis announce the birth of a daughter, August 5.

* * *

Dr. and Mrs. E. V. Strand and children of Bayport recently spent a week motoring on the North Shore.

* * *

A daughter was born July 31 to Dr. and Mrs. Harvey J. Brekke of Minneapolis.

* * *

A son was born to Dr. and Mrs. Philip A. Anderson of Minneapolis, July 23.

* * *

Dr. C. H. Sherman of Bayport has moved his office to Stillwater.

* * *

Dr. C. F. Dixon of Rochester addressed a meeting of the Wyoming State Medical Society in Sheridan last month.

* * *

Dr. Roscoe C. Webb of Minneapolis has been elected secretary-treasurer of the Great Northern Railway Surgeons' Association.

* * *

Dr. and Mrs. D. Kalinoff and Miss Helen Kalinoff returned to Stillwater about the first of June after an extended visit in the South.

* * *

Dr. Siegfried C. G. Oeljen of Waseca has moved into his newly completed office building north of the courthouse. The building, which houses only his offices, is of brick and is 22 x 47 feet.

* * *

Dr. John R. Meade of Saint Paul announces the limitation of his practice to Internal Medicine, and also removal of his offices to 836 Lowry Medical Arts Building, Saint Paul.

* * *

Dr. Hugh W. Hawn has finished a fellowship in ophthalmology in the Mayo Foundation in Rochester and is now a member of the staff of the Fargo Clinic, Fargo, North Dakota.

* * *

Dr. P. E. Kierland of Alexandria made newspaper headlines recently when he rescued two fishermen whose boat upset on Lake Mina. A third man in the boat died of a heart attack.

* * *

Dr. Charles H. Mead of Duluth recently passed the National Board examinations in surgery. It is believed he has the distinction of being the first Duluth surgeon to have passed the examination.

* * *

Dr. William C. Bernstein, who has been practicing in New Richland, has entered the University of Minnesota graduate school to do work in proctology for two years.

* * *

Dr. M. O. Henry addressed the Pierce-St. Croix Counties Medical Society on "Treatment of Fractures of the Upper Extremities" Thursday, August 15, at Baldwin, Wisconsin.

Dr. William M. Moir, Jr., of Minneapolis, who has been a resident physician in internal medicine at the University of Minnesota Hospitals, became associated with Dr. W. R. Humphrey of Stillwater, July 1.

* * *

Dr. Frank F. Wildebush of Minneapolis, Lieutenant Commander, Medical Corps, U. S. Naval Reserve, is taking special work in head and neck surgery at the Naval Medical Center in Washington, D. C.

* * *

Miss Margaret G. Arnstein has resigned as director of public health nursing at the University of Minnesota to rejoin the staff of the New York State Health department. Miss Mellie F. Palmer has been named acting director.

* * *

Dr. George B. Logan, who has been associated with the Department of Pediatrics at the University of Minnesota Medical School since January 1, 1940, has returned to the Mayo Clinic as a first assistant in the Section on Pediatrics.

* * *

The marriage of Dr. William H. Hollinshead, Jr., and Miss Mary Waddell of Saint Paul took place July 16. Dr. James B. Avey of Excelsior was best man. Among the ushers were Dr. Robert Alway and Dr. Charles Naumann McCloud, Jr.

* * *

Dr. Robert Gray, a graduate of Northwestern University Medical School, has located in Marshall and is associated with his father, Dr. F. D. Gray, and Dr. B. C. Ford in the Marshall Hospital and Clinic. He interned in the Swedish Covenant Hospital in Chicago.

* * *

Dr. Marvin J. Stewart has located at Marietta, opening offices there late in July. A graduate of the University of Minnesota Medical School, Dr. Stewart for the past year has been resident physician and surgeon at the Miller Hospital in Minneapolis.

* * *

Dr. R. G. Barnes, Jr., of Duluth is now associated with Dr. R. C. Radabaugh in Hastings. Dr. Barnes, who was graduated from the University of Minnesota Medical School, has been located at Hackensack, New Jersey.

* * *

Dr. Marcus H. Flinter, head of the Cass Lake Indian Hospital at Cass Lake, has been transferred to Arizona where he will be in charge of an Indian tuberculosis sanitarium at Phoenix. His successor in Cass Lake has not yet been named.

* * *

Dr. Richard B. Girvin has been appointed Minneapolis medical examiner for the Civil Aeronautics Authority. This post was formerly held by Dr. Albert J. Herbolshemer who is now in Washington, D. C., with the CAA.

OF GENERAL INTEREST

Dr. C. H. Sherman has located in Stillwater, opening offices at 228 East Chestnut street. For the past year, Dr. Sherman has been associated in practice with Dr. E. V. Strand of Bayport. He previously practiced in Oakes, North Dakota.

* * *

Dr. James A. Johnson of Minneapolis does not shirk his responsibilities as a member of medical associations. He is serving as president of three different groups—the Minneapolis Surgical Society, the Minnesota Academy of Medicine, and the Hennepin County Medical Society.

* * *

Dr. Miland E. Knapp of Minneapolis, third vice president of the American Congress of Physical Therapy, will present a paper at the nineteenth annual meeting of the Congress in Cleveland, September 2-6. His paper will be on the rôle of physical therapy in the treatment of fractures about the elbow joint.

* * *

Construction of a nurses' dormitory and Mother House at the Lutheran Deaconess Home and Hospital in Minneapolis is expected to get under way soon. The new structure, whose cost is estimated at \$75,000, will be ready for occupancy shortly after the first of the year.

* * *

Dr. Robert H. LaBree, a member of the Rood Hospital staff in Chisholm, and Miss Bernardine Brown were married July 20 in Hibbing. Dr. John W. LaBree was his brother's best man. Included among the ushers were Dr. Carlyle Tingdale and Dr. Theodore Schweiger.

* * *

Dr. Charles K. Petter, who was formerly associated with Glen Lake Sanatorium, is medical director and superintendent of the Lake County Tuberculosis Sanatorium in Waukegan, Illinois, which recently completed construction of a new modern building. Dedication exercises were conducted August 18.

* * *

Dr. G. J. Shima of Montgomery opened offices in Sleepy Eye in August. Dr. Shima, who received his B.A. degree from the University of Minnesota, took his medical work at Creighton University in Omaha, receiving his M.D. degree in 1939. He recently completed a year's internship at St. Joseph's Hospital in St. Paul.

* * *

Dr. Milton LeVine, who received his Ph.D. degree in bacteriology from the University of Minnesota in June, 1939, has been appointed instructor in bacteriology, succeeding Dr. M. V. Novak who resigned last spring to take a post as assistant professor at the University of Illinois College of Medicine.

* * *

Dr. Elmer C. Paulson, son of Dr. and Mrs. T. S. Paulson of Fergus Falls, married Miss Ethel Mobraaten of Virginia, August 3. After a wedding trip at Yellowstone Park and the Black Hills, Dr. and Mrs. Paulson are at home at Dalton. Dr. Paulson has been in general practice at Dalton for the past two years.

Dr. John W. Johnson, who has completed a residency at the General Hospital in Wyandotte, Michigan, has become associated in practice with his father, Dr. Hans Johnson at Kerkhoven, Minnesota. Dr. Johnson is a graduate of the University of Minnesota Medical School, '38. The building in which they have their offices has been remodeled, and an addition constructed.

* * *

Dr. Robert D. Evans of Minneapolis, accompanied by his daughter, Betty Jo, and his son, Robert, Jr., motored to California in June. They visited the Bryce and Zion Canyons in Utah enroute and had an interesting experience taking colored movies and Kodachrome "stills." Both of these national parks are a paradise for the amateur color photographer, they report.

* * *

Dr. George T. LeClercq, a graduate of the University of Minnesota Medical School, became affiliated in July with the Massachusetts General Hospital in Boston where he is doing special work in radiology. For six months prior to becoming associated with Massachusetts General Hospital, Dr. LeClercq was a graduate student at Peter Bent Brigham hospital.

* * *

Dr. R. Wynn Kearney has opened offices for the general practice of medicine and surgery in Mankato. Dr. Kearney is a graduate of the Mankato high school and of the Northwestern University Medical School. After receiving his medical degree from Northwestern in 1935, he interned at Ancker Hospital in Saint Paul. Since 1936, he has been a fellow in the Mayo Foundation in Rochester.

* * *

Organization of the Long Prairie Clinic and Hospital at Long Prairie by Drs. M. G. Ericsson, B. L. Gifford and M. E. Mosby is announced. The new arrangement gives Long Prairie one hospital instead of two. The hospital facilities will be available to doctors in the area.

Construction of an addition to the present Long Prairie hospital, which will also be completely remodeled, is now under way.

* * *

For the first time, internes taking duty in Minneapolis hospitals in July automatically become Junior Members of the Hennepin County Medical Society. Their membership continues as long as their status as internes continues. This new membership ruling was voted by the Society last November, and became effective with the new July group of internes. Fellows and Residents make individual application for Junior Membership as previously.

* * *

Among new Diplomates of National Boards through examination are Drs. Abe Bert Baker and Nathaniel Joseph Berkwitz of Minneapolis who have been certified by the American Board of Psychiatry and Neurology; Dr. Reuben Berman of Minneapolis, by the American Board of Internal Medicine; Dr. Lawrence Myrlyn Larson, by the American Board of Surgery, and Dr. Robert Russell Tracht, by the American Board of Ophthalmology.

OF GENERAL INTEREST

Among Minneapolis physicians who have been soldiers and sailors this summer are: Drs. Abe B. Baker, Philip Hallock and Theodore H. Sweetser who gave ear to bugle calls at Fort Snelling; Dr. John A. C. Leland, Jr., who has been at San Diego Naval Base; Drs. Einer C. Andreassen, Harry F. Bayard, Ralph H. Creighton, George F. Schmidt and Frederic F. Wiperman, Camp Ripley; Dr. Donald McCarthy who cruised the Great Lakes aboard the "Paducah."

* * *

Speakers at the summer meeting of the Upper Mississippi Valley Medical Society at Cass Lake, August 9-10, included besides Dr. Michelson, Dr. C. A. Stewart of Minneapolis who spoke on "Infant Feeding"; Dr. F. L. Smith of Rochester whose paper was entitled, "Diagnosis and Treatment of Conditions Associated with Varicose Veins"; and Dr. Macnider Wetherby of Minneapolis who discussed "Rheumatic Conditions."

* * *

Returning to Minneapolis August 11 after speaking before a meeting of the Upper Mississippi Valley Medical Society at Cass Lake, Dr. Henry E. Michelson of Minneapolis was injured when his automobile was struck by another machine being pursued by Brainerd police. Dr. Michelson, who received a fractured patella, several fractured ribs and minor head injuries, has been confined to Northwestern Hospital in Minneapolis since.

* * *

The wife and children of a former fellow in the Mayo Foundation have arrived in Rochester from England to be guests of Dr. and Mrs. V. S. Counsellor for the duration of the war. They are Mrs. A. H. McIndoe and her children, Vanora and Adonia. Dr. McIndoe is chief plastic surgeon to the Royal Air Force.

Also from England have come Mrs. C. Nauton Morgan and her children, Sally and Michael, to be guests of Dr. and Mrs. C. W. Mayo at Rochester during the war.

* * *

The George B. Wright Memorial Hospital of Ferguson Falls dedicated on July 25 a beautiful new community room, furnished by patrons of the hospital. The room is to be used for meetings of the staff and auxiliary, and for health instruction for hospital patients and people of the community.

Speaker at the dedicatory exercises was Dr. W. A. O'Brien of Minneapolis who spoke on "The Place of the Community Hospital and The Care of the Sick." Gabriel A. Skomars is hospital administrator.

* * *

Two Minnesota physicians are scheduled to participate in the Jackson County Health Forum in Kansas City, Missouri, during the 1940-41 season. The forum of lectures given on the third Wednesday of each month is sponsored by auxiliaries of all the accredited hospitals in Jackson County. Dr. Walter C. Alvarez of Rochester is scheduled to give the November 20 lecture. His subject will be "What's the Matter with the Patient Who Is Tired All the Time?" Dr. William A. O'Brien of Minneapolis will give the final lecture, May 21, his topic being "Medicine Meets Middle Age Needs."

Among those who began fellowships in the Mayo Foundation, July 1, are Dr. Eldon W. Erickson of Minneapolis and Dr. Charles W. Fogarty of St. Paul, graduates of the University of Minnesota Medical School; Dr. Charles F. Stroebel of Northfield; Dr. David B. Judd of Rochester, son of the late Dr. E. Starr Judd; Dr. Frank S. Ashburn who was a fellow in medicine at the University of Minnesota on duty in Minneapolis General Hospital from 1939-40; Dr. George A. Hallenbeck of Rochester, son of Dr. D. F. Hallenbeck; Dr. Richardson W. Lyman who interned at the University Hospitals in Minneapolis from July, 1939 to July, 1940; Dr. William J. Ferguson who was interne at Minneapolis General Hospital from January, 1939, to July, 1940; and Dr. Richard E. Reiley who was interne at Fairview Hospital in Minneapolis 1938-39, and teaching fellow in orthopedic surgery at the University of Minnesota from July, 1939 to July, 1940.

* * *

Dr. Orin P. Thorson of Northfield has disposed of his practice and is taking postgraduate work in Chicago and at the University of Minnesota before leaving October 1 to join the Benson Clinic in Bremerton, Washington. Dr. Thorson, a University of Minnesota graduate, has been in Northfield for twelve years. In his new location he will do diagnostic work and assist in surgery.

Dr. Robert F. Mears, recently of the General Hospital in Minneapolis, is taking over Dr. Thorson's practice. Dr. Mears is a graduate of the University of Minnesota Medical School.

* * *

Dr. O. J. Hagen of Moorhead has filed as a candidate for the Republican nomination for the United States Senate. Dr. Hagen is prominent in educational circles, as well as medical activities, having served six years as a member of the University of Minnesota board of regents and eight years on the State Teachers college board.

He was president of the Minnesota Public Health association in 1936; a member of the state board of health for some time; a councilor for Minnesota of the American College of Surgeons for five years; president of the Northern Minnesota Medical Association; and president of the Clay-Becker county sanatorium for seven years.

Another Minnesota physician who may enter the political race is Dr. J. Lawrence McLeod of Grand Rapids, whose friends are urging him to run as a Republican candidate for lieutenant governor.

* * *

When the continuation course in Clinical Allergy was held at the University of Minnesota Center for Continuation Study July 29-August 3, physicians from four states were in attendance.

The registration list follows: Drs. Percival H. Benning of St. Paul, Luther F. Davis of Wadena, J. W. Helland of Spring Grove, Samuel J. Hillis of Minneapolis, Fritz B. Schleinitz of Battle Lake and Thomas Myers of St. Paul; also Dr. Robert W. Currie of Billings, Montana, and Dr. Homer L. Hiles of Pittsburgh, Pennsylvania. From Wisconsin came Drs. Enoch

OF GENERAL INTEREST

B. Brick of Wausau, Harold L. Miller of Milwaukee, Margaret V. Pirsch of Kenosha and Raymond H. Smits of West Allis.

The faculty for the course was made up of: Drs. Walter C. Alvarez, Louis A. Brunsting and Charles K. Maytum of Rochester; Beecher B. Barnum and J. M. Nolte of Minneapolis; and Drs. Lawrence R. Boies, Ralph V. Ellis, Ralph W. Koucky, William A. O'Brien, Elmer M. Rusten, Wallace Sako, Albert V. Stoesser, Horatio B. Sweetser, Jr., and Asher A. White of Minneapolis.

* * *

Medico-Military Inactive Status Training

The twelfth annual inactive status training course for Medical Department Reserve officers of the U. S. Army and Navy will be held at the Mayo Foundation, Rochester, Minnesota, October 6 to 20, 1940. As in former years, special work in clinics and hospitals will be offered during the morning hours for those asking special assignments. Presentations of selected subjects in military medicine are scheduled. There will be appropriate sections or special courses for officers of the Dental and Veterinary Corps. All Medical Department Reserve officers on the active list are eligible for enrollment. Approved applicants will be enrolled on the recommendation of the Surgeon of the Seventh Corps Area or the Surgeon of the Ninth Naval District. Applications should be made at an early date and should be forwarded through the respective Reserve headquarters of the officers concerned.

Physicians Wanted for CCC Duty

Physicians are needed for the medical service of the Civilian Conservation Corps. The initial salary is \$3,200 per annum. No quarters for families are provided, and the physicians are required to pay for their food at camps. Temporary quarters for physicians are provided at the camps for a nominal fee. Physicians selected for this service are required to pay their own travel expenses to the headquarters of the district in which they are to be employed, where they are put on temporary duty for instructional purposes before being sent to camps. Travel expenses incurred in the transfer of physicians from the district headquarters to camps or in transfer from one camp to another are paid by the Government. If the services rendered are satisfactory, the employment is more or less permanent.

The principal duties at camps consist of the medical care of the enrollees and the practice of preventive medicine. To be eligible for this service, the physician must be a citizen of the United States, a graduate of an accredited medical school authorized to confer the degree of doctor of medicine, licensed to practice medicine, and physically able to perform the duties involved. Physicians over sixty years of age are not ordinarily employed.

All physicians interested in this type of service are requested to submit their applications to the Office of

the Surgeon, Headquarters Seventh Corps Area, Federal Building, Omaha, Nebraska, giving date on which available and preference of assignment in the following states: Minnesota, North Dakota, South Dakota, Iowa, Nebraska, Missouri, Kansas, and Arkansas.

It is requested that young physicians not now listed in the American Medical Directory be informed of this service.

Physicians Needed for Army Service

The physician, like every other American, has become actively interested in our national security and stands ready to contribute his services as required for military preparedness.

The immediate problem in this connection is one that concerns the War Department, and primarily the young physician. The War Department must procure sufficient additional personnel from the medical profession to augment the medical services of the Regular Army as the various increases are made in the strength of the Regular Army, as authorized by Congress to meet the partial emergency. The young physician is especially concerned because it is usually advantageous, and is often more convenient for him to serve with the Army.

Present plans of the War Department are designed to make service attractive and instructive for the young physician. If the physician holds a Medical Corps Reserve commission he can be ordered to active duty if he so requests. If he does not hold a commission, but is under 35 years of age and is a comparatively recent graduate of an accredited school, he may secure an appointment in the Medical Corps Reserve for the purpose of obtaining extended active duty for a period of one year or longer. Duty is given at General Hospitals, Station Hospitals, and with Tactical Units, and embraces all fields of general and specialized medicine and surgery. Excellent postgraduate training is obtainable in connection with Aviation Medicine. After serving six months of active duty in the continental United States, a Reserve officer may request duty in Hawaii, Panama, or other United States territories and possessions. The initial period for duty is for one year and yearly extensions are obtainable thereafter until the international situation becomes more clarified and our domestic military program becomes stabilized.

Many young doctors who have served with the Army on extended active duty have taken the competitive examination for entrance into the Medical Corps of the Regular Army. Extended active duty affords an excellent opportunity for the physician to observe modern military medicine and the facilities that exist for a complete and comprehensive medical practice.

Pay is according to rank, and, including subsistence and quarters allowances for an officer with dependents, amounts to an annual sum of \$3,905 for a Captain and \$3,152 for a First Lieutenant; or, without dependents, to an annual sum of \$3,450 for a Captain and \$2,696 for a First Lieutenant. In addition, reimbursement is made for travel to duty station and return.

Further information may be obtained by writing to The Surgeon General, U. S. Army, Washington, D. C.

REPORTS and ANNOUNCEMENTS

MEDICAL BROADCAST FOR SEPTEMBER

The Minnesota State Medical Association broadcasts weekly at 11:00 o'clock every Saturday morning over Station WCCO, Minneapolis; Station WLB, University of Minnesota; and KDAL, Duluth.

Speaker, William A. O'Brien, M.D., Professor of Preventive Medicine and Public Health, Medical School, University of Minnesota.

The program for the month will be as follows:

September 7—Cause of Home Accidents

September 14—Prevention of Home Accidents

September 21—First Aid in the Home

September 28—Injury of the Teeth

AMERICAN PUBLIC HEALTH ASSOCIATION

The sixty-ninth annual meeting of the American Public Health Association will be held in Detroit, Michigan, October 8 to 11, inclusive, at the Book-Cadillac Hotel. Approximately 3,500 health officials are expected to attend. A number of allied associations will meet at the same time and place.

Dr. Reginald M. Atwater is executive secretary. He has offices at 50 West 50th Street in New York City.

INTERNATIONAL ASSEMBLY—INTER-STATE POSTGRADUATE MEDICAL ASSOCIATION OF NORTH AMERICA

This year's assembly will be held in spite of foreign war and the political campaign at home, in the Public Auditorium, Cleveland, Ohio, October 14 to 18.

Members of the Ohio State Association and the Cuyahoga County Medical Society and of the Academy of Medicine of Cleveland are hosts to the Assembly and extend a cordial invitation to all members of the profession in good standing. Physicians are urged to bring their ladies, for whom entertainment is being arranged.

Morning, afternoon and evening sessions for five days will be filled by some eighty outstanding teachers from all over the country. The Saturdays preceding and following the Assembly will be devoted to clinics in the Cleveland hospitals. Excellent scientific and commercial exhibits will contribute an important part of the meeting.

This year, Dr. Chevalier Jackson, Philadelphia, is President; Dr. George W. Crile, Cleveland, Chairman of the Program Committee and Dr. William B. Peck, Freeport, Illinois, continues as Managing Director.

The annual dinner will be held October 16 with Dr. Chevalier Jackson as Master of Ceremonies. Addresses will be given by Dr. Ross T. McIntire, Surgeon-General, United States Navy, and Dr. Nathan B. Van Etten, President of the American Medical Association.

On page xxiii of the advertising section of this issue appears a list of clinicians who will take part in the scientific program, and further information regarding the meeting.

CLASSROOM RADIO HEALTH TALKS

A series of classroom radio health talks to be given by Dr. William A. O'Brien, professor of preventive medicine and public health at the University of Minnesota, is announced.

The talks, to be broadcast over the University station WLB, will be given each Wednesday from 11:05 to 11:20 a. m., beginning September 25 and continuing through January 15. Physicians are urged to call the attention of their school superintendents to these classroom broadcasts designed for pupils of grades six through nine. The program is endorsed by the Minnesota State Medical Association and the Minnesota Public Health Association.

The schedule for the lecture series, known as "Your Health and You," follows:

September 25—Health Ideas and Practices
October 2—Foods We Eat
October 9—Nutrition of Body
October 16—Weight and Health
October 23—Mind and Body
October 30—Rest and Sleep
November 6—Feet and Posture
November 13—Play, The Business of Childhood
November 20—Cleanliness and Godliness
November 27—Air and Sun
December 4—Eyes and Ears
December 11—Mouth, Gateway to Health
December 18—Fads and Fallacies
January 8—Prevention Versus Cure
January 15—Community Health

SCHOOL OF NURSING AT HAMLINE UNIVERSITY

Hamline University and Asbury Hospital of Minneapolis have announced the establishment of a School of Nursing offering a five-year curriculum leading to the degree of Bachelor of Science in Nursing. The first class will be admitted in September, 1940.

The combined resources of Hamline University and Asbury Hospital will be used to provide a course of training that will equip young women of superior qualifications to meet the professional needs of the community and to derive high personal satisfaction from their lives in general and their profession in particular. Preference will be given to those applicants who rank in the upper third of their high school graduating class and whose personality and character traits specially fit them for the field of nursing.

The first three semesters of the course will be taken on the campus of Hamline University. The next five semesters will be taken at Asbury Hospital and affiliated institutions. The last two semesters will be taken at Hamline University. Upon the satisfactory completion of the entire course, students will be awarded the degree of Bachelor of Science in Nursing.

AMERICAN SOCIETY FOR THE CONTROL OF CANCER

The American Society for the Control of Cancer, 350 Madison Avenue, New York City, will furnish without charge copies of the following pamphlets upon request. While these pamphlets have in the past been sold and some appeared several years ago, they contain valuable information and are being given away for the good of the cause.

The pamphlets available are:

- No. 40.—*Cancer of the Breast*, by Arthur H. Estabrook, Ph.D.—an eight page reprint from the "Trained Nurse and Hospital Review," Jan., 1939, with photographs showing steps in the radical surgical operation for breast cancer.
- Re. 1.—*Biopsy in Mammary Cancer*, by James Ewing, M.D.—two page reprint from the *Bulletin of the American Society for the Control of Cancer*, Jan. 1933. A plea for proper methods of biopsy.
- Re. 4.—*The doctor's Practical Relation to the Cancer Problem*, by William Carpenter MacCarty, M.D.—a five page reprint from the *Bulletin of the American Society for the Control of Cancer*, May, 1933. Points on prognosis.
- Re. 6.—*The Responsibility of the Practitioner in Menopausal Bleeding*, by James E. King, M.D.—three page reprint from the *Bulletin of the A.S.C.C.*, July, 1932.
- Re. 7.—*Early Diagnosis of Carcinoma of the Cervix*, by Dr. Henry Schmitz—three page reprint from the *Bulletin of the A.S.C.C.*, June, 1933.
- Re. 8.—*The Family Physician's Place in the Control of Cancer of the Uterus*, by S. W. Cathcart, M.D.—three page reprint from the *Bulletin of the A.S.C.C.*, Nov., 1933.
- 2018.—*Transillumination of the Breast*, by Max Cutler, M.D.—16 page reprint, 1933. On the use of transillumination as a confirmatory aid in diagnosis.

SOUTHERN MINNESOTA MEDICAL ASSOCIATION

The Southern Minnesota Medical Association will hold a one-day meeting in Red Wing, September 23. The day's program of talks will be climaxed with a banquet.

The complete program follows:

Morning Session—9:00 A.M.

- "The Use of Peridural Anesthesia for Office Procedure"—L. I. YOUNGER, M.D., Winona
- "Seminal Vesiculitis"—R. F. HEDIN, M.D., Red Wing
- "Recent Advances in Treatment of Common Skin Diseases"—L. A. BRUNSTING, M.D., Rochester
- "Incisional Hernia and Methods of Repair"—A. E. BENJAMIN, M.D., Minneapolis
- "Brucellosis"—I. FISHER, M.D., Ceylon
- "Diagnosis of Pancreatic Disease"—M. W. COMFORT, M.D., Rochester
- "The Effect of Digitalis on the Coronary Blood Flow"—R. V. SHERMAN, M.D., Red Wing
- "Pathology in the Bronchi and the Esophagus: A Clinical and Endoscopic Study of Recent Cases"—V. J. SCHWARTZ, M.D., Minneapolis

"Diagnosis and Surgical Treatment of Diaphragmatic Hernia" (Motion picture)—S. W. HARRINGTON, M.D., Rochester

Afternoon Session—2:00 P.M.

Case Reports

- "Carcinoma of the Stomach"—J. T. PRIESTLEY, M.D., Rochester
- "The Diagnosis and Treatment of Pneumonia by the General Practitioner in Rural Districts"—R. V. WILLIAMS, M.D., Rushford
- "Evaluation of Sulfathiazole in the Treatment of Human Disease"—WESLEY SPINK, M.D., Minneapolis
- "Practical Suggestions Regarding Use of Protamine Insulin"—E. H. RYNEARSON, M.D., Rochester
- "Fractures of the Tibia"—E. H. JUERS, M.D., Red Wing
- "Organization of the Draft Boards for National Emergency"—LT. COL. H. E. HULLSIEK, M.D., Saint Paul

Evening Session—6:30 P.M.

Banquet

- "Minnesota Medical Association: Its Activities and Aims"—B. S. ADAMS, M.D., Hibbing
- "State Board of Health Problems"—T. B. MAGATH, M.D., Rochester
- Presidential Address—JAMES MORROW, M.D., Austin

MISSISSIPPI VALLEY CONFERENCE ON TUBERCULOSIS and MISSISSIPPI VALLEY SANATORIUM ASSOCIATION

An invitation is extended to all physicians to attend the twenty-seventh annual meeting of the Mississippi Valley Conference on Tuberculosis and the Mississippi Valley Sanatorium Association, which will meet at the Lowry Hotel in Saint Paul, October 2, 3 and 4.

The Mississippi Valley Conference is composed of lay and medical members active in the anti-tuberculosis work of the local and state Christmas Seal organizations in Illinois, Indiana, Kansas, Michigan, Minnesota, Iowa, Missouri, Nebraska, North Dakota, Ohio, South Dakota and Wisconsin. Minnesota is represented on the Conference Council by the following physicians: Drs. Lewis S. Jordan, Granite Falls; Walter J. Marcle, Duluth; E. S. Mariette, Oak Terrace; E. A. Meyerding, Saint Paul; and J. A. Myers, Minneapolis.

Governor Harold E. Stassen will be the principal speaker at the dinner meeting on Thursday, October 3. His subject will be "Social and Economic Problems in the Decade Ahead." Dr. Everett K. Geer, first vice president of the Ramsey County Public Health Association, will give the address of welcome.

The annual meeting of the Minnesota Public Health Association, one of the affiliated organizations, will be held Thursday noon, October 3.

An interesting feature of the scientific exhibits will be the Leitz projector, which enlarges an x-ray film to full motion picture screen size. The projector is the only one of its kind in the United States. A special x-ray conference is scheduled for Friday night under the direction of Dr. John H. Skavlem of Cincinnati, Ohio.

Speakers at a College Hygiene luncheon scheduled for Friday noon will include the following physicians:

REPORTS AND ANNOUNCEMENTS

Dr. Ruth E. Boynton of Minneapolis, president of the American Student Health Association; Dr. J. A. Myers, Professor of Preventive Medicine at the University of Minnesota; Dr. Charles E. Lyght of Northfield, chairman of the Tuberculosis Committee, American Student Health Association.

Dr. Paul A. Teschner of Chicago, Assistant Director of the Bureau of Health Education of the American Medical Association, will preside at a panel Friday afternoon, October 4, on "Nursing Problems in a Sanatorium." Physicians taking part in the panel are: Dr. M. H. Draper, Secretary and Medical Director, Irene Byron Sanatorium, Fort Wayne, Indiana; Dr. J. Vincent Sherwood, Superintendent and Medical Director, South Dakota State Sanatorium, Sanator, South Dakota; and Dr. John W. Towey, Superintendent and Medical Director, Pinecrest Sanatorium, Powers, Michigan.

Joint meetings of the Mississippi Valley Conference on Tuberculosis and the Mississippi Valley Sanatorium Association are scheduled for Thursday, October 3. Separate meetings will be held Friday, October 4. The medical session program are as follows:

JOINT MEETING

Thursday, October 3, 1940

Morning Session

Presiding: THEODORE J. WERLE, Executive Secretary, Michigan Tuberculosis Association

1. "A nation-wide survey on food handlers and infections"
JOHN S. KRUGLICK, M.D., Assistant Medical Director, Tuberculosis Institute of Chicago and Cook County, Chicago, Illinois.
 2. "Silico-Tuberculosis in Missouri"
Under the co-authorship of WILLIAM M. KINNEY, M.D., and JESSE E. DOUGLAS, M.D., Superintendent, Jasper County Tuberculosis Hospital, Webb City, Missouri.
 3. "Industrial clinic examinations (of iron mining employees)"
GEORGE McL. WALDIE, M.D., Director, Department of Industrial Health, the Cleveland Cliffs Iron Company, Ishpeming Hospital, Ishpeming, Michigan.
 4. Industrial Problems
RICHARD D. MUDD, M.D., Medical Director, Chevrolet-Grey Iron Foundry, Division of General Motors Corporation, Saginaw, Michigan.
- Minnesota Public Health Association Annual Meeting
Luncheon, 12:15, Grand Ballroom.

Afternoon Session

Presiding: A. T. LAIRD, M.D., Superintendent, Nopeming Sanatorium, Nopeming, Michigan

1. "Examination of the lungs in recruits"
J. D. ADAMSON, M.D., Winnipeg, Canada
2. "Symposium of choice of x-ray films in tuberculosis work"
"The 4x5 film in Case Finding"—C. C. BIRKELO, M.D., and B. H. DOUGLAS, M.D., Detroit
"The Relative Usefulness of 35 mm. Films in Case Finding"—D. O. N. LINDBERG, M.D., Decatur, Illinois
"The Comparative Value of Chest Roentgenograms made on Films and on Paper"—S. REID WARREN, JR., Moore School of Engineering, Philadelphia
3. General Discussion.

MISSISSIPPI VALLEY CONFERENCE ON TUBERCULOSIS

Friday, October 4, 1940

Morning Session

Presiding: DONALD E. PRATT, Executive Secretary, Missouri Tuberculosis Association, St. Louis, Missouri

1. "Mass testing in rural areas in Manitoba"
EDWARD L. ROSS, M.D., Medical Superintendent, Manitoba Sanatorium Board, Winnipeg, Canada.

2. "Case finding by joint official and non-official cooperation"
C. K. MCCARTHY, M.D., Director, Division of Tuberculosis, Iowa State Department of Health, Director, Co-operative Case-Finding Service, Iowa Tuberculosis Association.
3. "Care of the discharged tuberculosis patient"
W. J. BRYAN, M.D., Superintendent and Medical Director, Rockford Municipal Tuberculosis Sanatorium, Rockford, Illinois.
MISS METTA BEAN, Director, Social Service Department, Wisconsin Anti-Tuberculosis Association, Milwaukee, Wisconsin.
MISS PEARLE J. HELD, Superintendent, Sarahurst Boarding Club, Minneapolis.
4. "Institutional surveys"
5. "A recapitulation of surveys as they affect the local tuberculosis association"
R. G. PATERSON, M.D., Executive Secretary, Ohio Tuberculosis Association, Columbus, Ohio.

MISSISSIPPI VALLEY SANATORIUM ASSOCIATION

Friday, October 4, 1940

Morning Session

Presiding: HAROLD M. CONN, M.D., Superintendent, Wisconsin State Sanatorium, Statesan, Wisconsin

1. "The detection of tubercle bacilli in latent lesions and in normal tissues of the human lung"
WM. H. FELDMAN, D.V.M., and ARCHIE H. BAGGEWSTOSS, M.D., The Mayo Foundation and Clinic, Rochester, Minnesota.
2. "The dissemination of tubercle bacilli in the human spleen and liver."
C. E. WOODRUFF, M.D., and RUBY G. KELLY, Wm. H. Maybury Sanatorium, Northville, Michigan.
3. "Roentgenological-Pathological Conference"
HENRY C. SWEANY, M.D., Medical Director of Research, Municipal Tuberculosis Sanatorium, Chicago, Illinois.

Afternoon Session

Presiding: JOHN B. BARNWELL, M.D., Associate Professor of Medicine, University of Michigan, Ann Arbor, Michigan

1. "The treatment of syphilis in tuberculous patients"
PAUL MURPHY, M.D., and LEON BRAMBURG, M.D., Robert Koch Hospital, St. Louis, Mo.
2. "Pulmonary carcinoma"
EDWIN J. SIMONS, Swansville, Minn.
3. Business meeting
4. "Tuberculosis in public institutions"
H. E. HILLEBOE, M.D., Director of Tuberculosis, Minnesota State Board of Control, Saint Paul, Minn.
5. "Intrapleural pneumonolysis"
Experiences with this Procedure at Nopeming Sanatorium
—G. A. HEDBERG, M.D., Nopeming Sanatorium, Nopeming, Minn.

"SULFATHIAZOLE" AND "SULFAMETHYLTHIAZOLE"

The Council on Pharmacy and Chemistry reports that the terms "sulfathiazole" and "sulfamethylthiazole" are acceptable to Dr. Fosbinder, who is credited as the discoverer of 2-sulfanilamidothiazole and 2-sulfanilamido-4-methylthiazole. Inquiry was also made of Dr. E. J. Crane, chairman of the Committee on Nomenclature of the American Chemical Society, who also informed the Council that, in his opinion, there was no objection to offer to these nonproprietary names. Accordingly, the Council adopted the recommendation of its Committee on Nomenclature that the terms "sulfathiazole" and "sulfamethylthiazole" be accepted as nonproprietary designations for 2-sulfanilamidothiazole and 2-sulfanilamido-4-methylthiazole, respectively. The adoption of these terms does not indicate at this time the acceptance of the substances. (J.A.M.A., June 15, 1940, p. 2387.)

TRANSACTIONS of the MINNEAPOLIS SURGICAL SOCIETY

Stated Meeting, Thursday, January 4, 1940

President, WILLARD D. WHITE, M.D., in the Chair
Secretary, HARVEY NELSON, M.D.

ABDOMINAL PAIN AND ILEUS DUE TO URETERAL CONSTRICTION

Report of Case

CHARLES E. MERKERT, M.D.
Minneapolis

The case that I am presenting is that of a boy who when he first came to me on December 18, 1935, was seven years old.

On his first visit, which was at the office, his mother told me that he had been having attacks of abdominal pain, accompanied by vomiting and fever for the past two years. She said he would have two to three attacks each year, each attack lasting two to four days and then he would be normal again. The present attack had started two days previous and had been accompanied by vomiting. His bowel movements had been normal. There was no urinary burning or frequency. Examination showed normal temperature and pulse. There was moderate rigidity of the abdominal muscles over the whole right side. Maximum tenderness of a moderate amount was just to the right of the navel. There was no abdominal distension. Leukocyte count was 12,000. Urine examination was normal. Three urine examinations over a period of three or four days were all negative. By this time his attack had completely subsided and he was without pain.

Then on June 7, 1936, he had another attack of abdominal pain and vomiting. I saw him early the next day and sent him to Northwestern Hospital. At this time his rigidity and muscle spasm was over the right lower quadrant. Maximum tenderness was just to the right of the navel. Temperature was 99.2; leukocyte count 9,000. A urine specimen examination was normal except for only an occasional pus cell in the centrifuged specimen.

Through a right rectus incision a limited abdominal exploration was done. The appendix was removed and was normal, except for some increase in the amount of lymphoid tissue. No Meckel's diverticulum or evidence of pathology was found.

Within a month following this operation, the patient again had another attack of pain and vomiting, and later that year he had about two more attacks. His mother on my advice, gave him an enema each time which seemed to abort the attacks. I did not see him during this time.

On December 6, 1936, he had an attack of pain all over the abdomen, but more so over the appendectomy scar. This was again accompanied by vomiting. The mother gave him an enema with good results. The next day he still had some pain but felt better in the evening and the vomiting stopped. The day following he had two good bowel movements, but late that night the pain became more severe and he began to vomit again. I saw him the next morning at which time his temperature was 101. His abdomen was doughy in consistency. There was generalized abdominal tenderness of a moderate degree. The patient was listless and looked very sick, which I believed was due to acidosis.

He was sent to the Hospital where on admission Dr. Edward Anderson, pediatrician, was called in consultation. He made a tentative diagnosis, of cyclic vomiting and advised treatment for acidosis by giving glucose and fluids. Hartman's solution was given by hyperdermoclysis. Glucose and saline solutions were

given by vein and by proctoclysis. By the next day, December 10, 1936, he stopped vomiting and felt better.

Next day, December 11, he began to vomit again and a urine specimen revealed some acetone still in the urine. His abdomen became more distended and he had more abdominal pain. His temperature was 102 by rectum and he had a cough. Nasal suction was started and a flat plate of the abdomen was taken showing small bowel obstruction.

The next day the temperature went to 104 by rectum and he was coughing more. There were râles in the left lower chest. Although nasal suction at times seemed to work well, his abdomen remained markedly distended. Enemata of various types including milk and molasses produced some flatus but distension was not relieved. The nasal suction catheter was adjusted, using the x-ray, to determine the position of the tube but still decompression did not result. The patient was delirious at times.

The next morning which was December 13, Dr. Wangenstein was called in consultation and agreed that enterostomy should be done at once. By palpation and auscultation of the abdomen in which he heard borborygmi and tinkling sounds, he stated the obstruction to be of a dynamic rather than a paralytic type.

The patient was taken to the operating room after administration of chloral hydrate by rectum. Under local anesthesia, through a McBurney incision, an enterostomy was done on the first loop of small bowel that presented. This enterostomy was similar to a Witzel gastrostomy, using one catgut stitch to tack the No. 14 French catheter to the bowel wall and interrupted silk sutures to form the bowel peritoneal tunnel.

Bottle suction was applied to the enterostomy tube and this along with nasal suction rapidly decompressed the bowel. Intravenous fluids were increased in amount. A flat plate of the chest at this time revealed some pleural effusion with an atelectasis or pneumonia in the left lower chest. The patient improved and the day after operation passed some flatus. On the second day after operation he had a soft stool. From then on he rapidly improved and left the hospital on January 1, 1937.

On January 19, 1937, a gastro-intestinal x-ray was negative. However, one plate showed an absence of psoas muscle shadow on the right.

On February 11, 1937, an intravenous pyelogram showed a definite right hydronephrosis probably due to ureteral neck obstruction. I recommended cystoscopy followed by operation, but as he was feeling well and had no attacks his parents postponed more surgery at this time.

On July 26, 1938, he had another attack of pain and vomiting. He was immediately brought to the hospital. Dr. Ernest Meland was called in consultation. He inserted a catheter into the right ureter to the pelvis. Retrograde pyelogram showed again the hydronephrosis and also the narrowing of the uretero-pelvic juncture. Removal of the catheter caused recurrence of the pain. It was reinserted and after a few days of drainage, operation was performed.

Under ethylene anesthesia on August 4, 1938, the kidney was exposed. This exposure was difficult due to marked perinephritis. Uretero-pelvic adhesions bound the ureter high upon the pelvis. There was an anomalous artery about 4 mm. in diameter tight across the uretero-pelvic juncture. This artery was very sclerotic and nodular like those of an old man. The artery was clamped and cut. After freeing the ureteral neck

of adhesions it was so narrow that a Y plasty of the Schwyzer-Foley type was done. A few stitches in the kidney capsule were attached to the fascia as nephropexy to place the kidney in a normal position and the wound was closed. A No. 20 catheter had been placed through the kidney, to the pelvis as drainage and a No. 5 ureteral catheter through the kidney, the pelvis and into the ureter to act as a splint.

Except for some urinary infection before and just after leaving the hospital, which responded well to sulfanilamide therapy his recovery was uneventful.

Two months later, on October 28, 1938, intravenous pyelogram showed good function of the kidney but some remaining dilatation of the kidney pelvis.

Last Saturday, December 30, 1939, another intravenous pyelogram again showed good function and the pelvis about the same size.

It is now one year and four months since his operation and during that time has had no pain or vomiting. He has been in excellent health since that time.

The few observations I wish to make are these:

1. With repeated abdominal pain and vomiting in children even in the presence of normal urine, an intravenous pyelogram should be done for diagnosis.
2. Ureteral obstruction in children can produce an ileus either of the paralytic or dynamic type.
3. Y plasty of the uretero-pelvic junction may be necessary even after excision of an obstructing anomalous artery.
4. An anomalous artery under tension may be very sclerotic even in a child.

FRACTURE OF THE SPINE OF THE TIBIA (INTERCONDYLOID EMINENCE)

ERNEST R. ANDERSON, M.D.
Minneapolis

The authors of textbooks on surgery and on fractures are not in agreement as to the treatment and management of fractures of the tibial spine. The condition is dismissed by some as being very simple and others consider it to be a very important fracture because of the possibility of creating a permanent state of disturbed physiology of the knee joint. If an accurate knowledge of the anatomy and a true understanding of the physiology of the knee joint is possessed, an exact diagnosis can be made and rational treatment carried out.

Fracture of the tibial spine was first described by Poncet¹⁹ in 1875. It was a postmortem finding in an individual who died instantly following a fall from a third story window. Dittel,¹⁹ the following year, had a case occurring in a man who had been thrown from a public house. The knee joint became distended with blood and following aspiration became septic. The leg was amputated and the patient died. On postmortem examination, a fractured tibial spine was found.

Goodlee,¹⁹ in 1888, described a case that had occurred in 1873 in the wards of the University College Hospital, London. The specimen was an autopsy finding and had been preserved in the museum of the University College Hospital. Roth,¹⁹ in presenting this subject to the British Orthopedic Association in 1927, demonstrated this specimen.

The condition occurring in a living subject was first described by Pringle¹⁸ in 1907.

The patient, a male aged thirty-six, was injured June 11, 1903, by a severe blow on the outer aspect of the left knee joint. He was knocked down, the left knee being forced inward. He was admitted to the Royal Infirmary, Glasgow, on June 14. The left knee was greatly swollen by the effusion in the joint cavity. The left leg was abnormally abducted at the knee joint. No x-rays were taken of the knee. It was thought that the internal lateral ligament of the left knee was ruptured. No mention was made as to whether extension of the left leg was blocked or not. There was no abnormal anteroposterior movement of the tibia on the femur.

The internal lateral ligament of the knee was exposed on June 26, 1903, and found to be intact. The knee joint was opened and a fracture of the spine of the tibia found. Pringle replaced the fractured tibial spine and sutured it into place.

Following is a report of a case of comminuted fracture of the left tibial spine which was treated in a conservative or non-operative manner producing a very satisfactory result.

A white male, aged twenty-four, while playing basket ball on March 22, 1939, made a sudden stop. He fell forward. In falling the left leg was twisted inward as well as forced medially. He landed with the left leg underneath him. At the time he heard a snap in the left knee. The knee and leg felt numb at first. He was helped to his feet and when he stepped on the left foot the left leg did not support him. He had no pain in the left knee or leg until the knee was moved.

On examination the left knee joint was found to be swollen and fluctuation was present. The left leg was abducted 7 degrees. The leg could passively be completely extended and could be flexed to 90 degrees. There was no abnormal posterior or anterior movement of the tibia on the femur. He had tenderness on the lateral surface of the knee over the interarticular space and over the lateral femoral condyle.

An x-ray of the left knee was taken by Dr. A. G. Allison and a comminuted fracture of both tubercles of the left tibial spine was found. There was a slight displacement of the fragment of the medial tubercle of the tibial spine. X-rays were taken with the knee flexed, these showing the comminuted fracture and an increase in the displacement of the medial tubercle of the tibial spine.

The patient was sent to Asbury Hospital and kept in bed. The knee joint was aspirated daily, 70 c.c., 40 c.c., 23 c.c. and 24 c.c. of bloody fluid were removed on successive days. With the leg completely extended a compression bandage was applied to the knee after each aspiration. On the sixth day following the injury a walking cast was applied from the gluteal fold to the toes on the left leg. The following day he was allowed to walk on the injured leg and discharged from the hospital.

The cast was removed on May 8, 1939. The x-rays taken at that time showed bony union of the lateral tubercle of the tibial spine which was in good position. The fracture line of the medial tubercle of the tibial spine was clearly seen and there was some increase in the density of this fractured fragment with no evidence of union.

The left knee was supported by an Ace bandage and he was instructed to use the left leg. On June 7, 1939, he was walking without support. He had no pain in the left leg or knee and stated that the leg felt strong. The left leg extended at the knee to 180 degrees and flexed so that the posterior surfaces of the leg and thigh came together. There was no relaxation of the ligaments of the knee joint. He returned to work on June 30, 1939.

When he was seen on July 8, 1939, he stated that

he had a sense of confidence in the knee and was able to work his eight-hour shift without having any pain. At this time the motions of the left knee were normal. There was no anterior or posterior movement of the tibia on the femur.

Fracture of the tibial spine does not occur frequently. It is usually associated with other fractures involving the knee joint. The incidence of unassociated fracture of the tibial spine, as reported by different authors, varies.

Swett, McPherson and Pike²² had ten cases of this type included in their study of forty cases of tibial fractures involving the knee joint. Cullovich²² reported three cases occurring in twenty-four fractures of the tibia involving the knee joint. Steuer's²¹ incidence was one case in sixteen. In 5,840 consecutive recent fractures, Clarke³ observed twelve cases in thirty-two tibial fractures involving the knee joint. Kurlander¹⁰ reported three cases in 1,000 fracture cases. In the Massachusetts General Hospital, Barr¹ observed four cases among a total of 4,390 fracture cases.

It is interesting to note that in Swett, McPherson and Pike's²³ study seven of their cases occurred in connection with automobile accidents. They did not mention how many of their fractures were the result of direct blows or twisting injuries. Barr¹ had one case where the fracture was due to a blow in the region of the knee, the remaining three cases being caused by a twisting injury to the knee joint.

To understand this fracture a consideration of the anatomy of the head of the tibia is necessary. The proximal end of the tibia is composed of two articulating surfaces, the medial and lateral condyles. These condyles are separated by a roughened nonarticulating area. The raised portion in the center of this area is the tibial spine or intercondyloid eminence. Situated on the tibial spine are two tubercles: the medial, sometimes referred to as the anterior; and the lateral, which is sometimes called posterior.

Anterior and posterior to the tibial spine there are two flattened surfaces known as the anterior and posterior intercondyloid fossæ. On the anterior intercondyloid fossa are attached the anterior extremities of the medial meniscus, the anterior crucial ligament and the anterior extremity of the lateral meniscus.

The tibial attachment of the anterior crucial ligament is described differently by the various anatomists. Spalteholz's *Atlas*²⁰ states that the attachment is especially on the medial intercondyloid tubercle of the tibial spine, and on the anterior intercondyloid fossa between the anterior points of the fastening of the two menisci.

The anterior crucial ligament is described in Morris' *Human Anatomy*¹⁵ as being attached to the medial half of the fossa in front of the intercondylar eminence of the tibia and to the lateral border of the medial articular facet as far back as the medial intercondyloid tubercle. It is fixed to the tibia behind the anterior extremity of the medial semilunar meniscus. Behind and to the lateral side it has the anterior extremity of the lateral meniscus, a few fibers of

which blend with the lateral edge of the ligament. Its anterior fibers at the tibial end are strongest and longest, being fixed highest on the femur; while the posterior, springing from the intercondyloid eminence, are shorter and more oblique. In Cunningham's *Anatomy*⁴ the anterior cruciate ligament is said to be attached in the rough nonarticulating area in front of the intercondyloid eminence of the tibia. The anterior crucial ligament arises from the depression in front of the spine of the tibia, according to Piersol's *Human Anatomy*.¹¹

Parsons¹⁶ having made a thorough study of the head of the tibia states, "The tibial attachment of the anterior crucial ligament is indicated by a little knob on the outer margin of the internal articular facet. From this the attachment runs transversely outward to about the mid-sagittal line of the tibial head." He describes the medial tubercle of the tibial spine as being free and the anterior crucial ligament as resting against it as it passes backward, upward and laterally from its attachment on the anterior intercondyloid fossa to its attachment on the medial side of the external femoral condyle.

Through the courtesy of Drs. C. M. Jackson and E. A. Boyden of the anatomy department of the University of Minnesota, I dissected and examined sixteen cadaver knee joints. The tibial spine was well defined in all specimens. The medial and lateral tubercles with the intertuberculum sulcus were clearly demarcated.

The tibial attachment of the anterior crucial ligament was found to be a fan shaped area on the anterior intercondyloid fossa along the lateral margin of the medial tibial condyle. The anterior margin of the tibial attachment was consistently about three-fourths of the distance from the tibial spine to the anterior margin of the tibial head. Laterally the margin was usually beyond the mid-sagittal line.

In nine specimens the posterior fibers of the anterior crucial ligament ended on the anterior intercondyloid fossa in front of the base of the medial tubercle. The medial tubercle was free of any attachment. In five specimens the posterior fibers of the anterior crucial ligament fastened to the anterior surface of the medial tubercle. These fibers were not dense and were easily detached. They were not joined firmly with the integral portion of the ligament. In two specimens the posterior fibers of the anterior crucial ligaments were attached along the lateral side of the medial tubercle. The attachment extended backward to the level of the posterior portion of the tubercle. To the anterior intercondyloid fossa were attached the long, dense, strong fibers of the ligament. The fibers that attached to the lateral side of the spine were shorter and angulated from the long axis of the ligament.

In all the specimens dissected the lateral tubercle of the spine was free and had no attachments of any intra-articular structure.

The mechanics for the production of fracture of the tibial spine is one of direct trauma by the condyle or condyles of the femur on the structure. This fracture occurs when the foot is fixed and the femur is forcefully rotated on the tibia, or when the knee is forced medially or laterally, or it could be a combina-

tion of both. In some instances the rotation of the femur on the tibia is the predominant force; while in others the forcing of the femur on the tibia, either in the medial or lateral direction, is the causative force. In forced rotation of the femur the lateral margin of the internal femoral condyle strikes the medial tubercle of the tibial spine and the medial margin of the lateral condyle strikes the lateral tubercle. By the shearing force one or both tubercles of the tibial spine is broken. When a direct force is applied above the interarticular space to the lateral side of the knee, the medial margin of the lateral femoral condyle strikes the lateral tubercle of the tibial spine and fractures it. If the force is sufficient to cause a dislocation of the knee the medial tubercle can also be fractured. With the force directed above the interarticular space against the medial side of the knee, the medial tubercle is struck by the lateral margin of the medial femoral condyle and fractured. The lateral tubercle will be fractured if the force is sufficient to dislocate the knee so that the medial condyle strikes it.

The shearing force as the causative factor in producing tibial spine fractures was recognized by Jones and Smith⁷ as well as an avulsive force produced by the anterior crucial ligament. Webb,²⁴ in describing this fracture in Christopher's Surgery, states that the etiologic factor is the striking of the femoral condyles against the tubercles. Fairbanks,⁵ in discussing this subject before the orthopedic section of the Royal Society of Medicine, differentiated between the true fracture of the tibial spine that resulted from the shearing force, and the fracture caused by the pull of the anterior crucial ligament which produced an avulsion of bone from the tibia in front of the tibial spine in the anterior intercondyloid fossa.

The force that produces this avulsion of bone must be exerted to the tibial attachment of the anterior crucial ligament. The ligament is taut when the knee is extended. The avulsive force is created on hyperextension of the knee. When the knee is in any degree of flexion the anterior crucial ligament relaxes and no avulsive force can be exerted. In view of the fact that the firm tibial attachment of the anterior crucial ligament is not on the tibial spine but on the anterior intercondyloid fossa, the fracture produced on hyperextending the knee is the portion of the fossa in front of the tibial spine. In the case herein reported the fractured medial tubercle of the tibial spine was displaced more when the knee was flexed, that is, when the anterior crucial ligament was relaxed. In extension or hyperextension of the knee the anterior crucial ligament becomes taut and presses down on the medial tubercle exerting a force to replace it. In the case of an avulsive fracture in the tibial attachment of the anterior crucial ligament, extension or hyperextension of the knee causes a pull on the fractured fragment and displaces it from the head of the tibia. Lee²² recognized this fracture and describes his technic for the operative reduction in a paper titled, "Avulsion Fractures of the Tibial Attachments of the Crucial Ligaments."

In knee injuries, a fracture of the tibial spine should be suspected when a rapid distention of the knee joint occurs with the knee held in partial flexion. The distention occurs early and is marked, this being caused by the filling of the joint cavity with blood. Active and passive motions of the knee and weight bearing are painful. The fragments of the fractured tibial spine are in the intercondyloid area and will usually not block the motions of the knee joint. Along with these signs are those resulting from the injury of the collateral ligaments of the knee: namely, tenderness over their attachments; palpation of a depression over the interarticular space if the ligaments are torn; and some degree of abduction of the leg depending on the extent to which collateral ligaments of the knee are injured.

If the tibia can be moved forward on the distal end of the femur while the knee is flexed either at the time of injury or when the knee joint has been aspirated, it speaks for injury involving the anterior crucial ligament. Roentgenographic study will determine if an avulsion fracture of the tibial attachment of the ligament has occurred.

True fractures of the tibial spine are treated conservatively except when the fragments are displaced into the interarticular portion of the joint and cause interference. In that case the fragment acts as a foreign body in the joint and must be removed surgically if manipulation with the knee in flexion does not dislodge the separated portion of the tibial spine. Otherwise, after the knee-joint distention has been controlled by repeated aspirations, the knee is immobilized in complete extension in a plaster-of-Paris cast. With the knee extended, early weight bearing can be employed. The knee should be immobilized for six to eight weeks to allow firm bony union. The injured collateral ligaments of the knee will heal and be solid at the end of the immobilization.

In the case of the avulsion fracture of the tibial attachment of the anterior crucial ligament, reduction should be operative. The fractured tibial fragment should be replaced in the anterior intercondyloid fossa and fixed. This is important because, if the anterior extremity is not anchored, the integrity of the crucial ligament is disturbed and the result is an unstable knee joint. After the operative reduction, the knee joint is immobilized in a plaster-of-Paris cast with the knee partially flexed to relax the anterior crucial ligament. Immobilization should be maintained until firm union of the fracture is obtained.

Summary

1. A case of fracture of the tibial spine is reported.
2. A satisfactory functional and anatomical result was obtained by conservative treatment.
3. The firm tibial attachment of the anterior crucial ligament was found to be in the anterior intercondyloid fossa in sixteen dissected anatomical specimens.
4. Fracture of the tibial spine and avulsion fracture of the tibial attachment of the anterior crucial ligament are separate conditions and should be differentiated.

ENTERIC INTUSSUSCEPTION IN AN ADULT

Report of a Case

RALPH H. CREIGHTON, M.D. and WM. R. JONES, M.D.
Minneapolis

Intussusception is that condition in which a part of the bowel invaginates itself into an adjacent part. It has been recognized for centuries. The first real description of the condition was made by 16th Century anatomists.

The cause in many cases is unknown. Polyps and tumors, both benign and malignant, have set off the process. Acute appendicitis, Meckel's diverticulum, foreign bodies in the intestinal tract and acute inflammation have also been mentioned as causes. A radical change in diet may be responsible as in two cases reported by Moore.⁴ They were observed during the Mohammedan fasting season when the Mohammedans do not eat or drink between sunrise and sunset. These individuals were seized with symptoms of intussusception at the end of the fast, one after drinking a glass of cold water, the other had taken nothing. Both died. At postmortem examination no cause could

be found for the condition. Other cases have been reported in which the etiology could not be explained.

Most cases of intussusception are in infants under two years of age (80 per cent according to Montgomery).⁷ It is more frequently found in boys than girls, especially in healthy robust boys. It is rare in adults, especially the types in which there is no apparent cause such as polyps or tumors. Davis² of Duluth, reviewed the records of St. Luke's and St. Mary's Hospitals of that city and found that in 113,351 patients, intussusception was present only twenty-two times. There was only one adult in this series. At the Beth-El Hospital, Brooklyn, New York, over an eleven-year period, there were six cases of intussusception in 62,682 admissions, and one of those was an adult. (Finkelstein)⁴

McGlannon⁶ classifies intussusception into 3 groups: (1) enteric (10 per cent); (2) entero-colic (80 per cent); and (3) colic (10 per cent). Usually there is a single invagination. Occasionally, however, there may be a double or even a triple process. Very rarely the invagination may be retrograde. As the infolding process progresses the mesentery is pulled in and the venous blood supply is compromised. Swelling occurs and increases, blood extravasates into the bowel lumen, later the arterial blood is cut off and gangrene occurs. Peritonitis develops and if the process has been slow in forming, occasionally it is walled off, and an abscess may form or the invaginated portion of gut may slough off and pass from the rectum, an autoanastomosis taking place. However, by far the most frequent occurrence is a spreading peritonitis and death, unless surgical relief is obtained. Very rarely an intussusception will unfold itself.

The first symptom is sudden, severe pain in the abdomen as in partial intestinal obstruction. This is intermittent and paroxysmal until complete obstruction or peritonitis occurs. The cramps usually last a few minutes and then let up, only to return again in a short time. The pains are severe, causing the patient to double up. He may assume the knee-elbow position or pull the legs up, trying to obtain relief. The face shows a painful, agonized expression. When obstruction becomes complete, gangrene takes place and the pain is both paroxysmal and continuous. Vomiting usually occurs. The higher the lesion is located the earlier and more frequently vomiting is noted.

The bowels move normally early in the attack, but later no fecal material is passed. However, blood and mucus are usually expelled from the rectum in the entero-colic or colic type, or may be found on the examining finger. In the enteric type, blood is a late sign. The abdomen is not distended early but gradually becomes distended as obstruction becomes more pronounced. Auscultation reveals exaggerated peristaltic sounds until complete obstruction or peritonitis occurs; then there is the silent abdomen. The temperature is normal or subnormal early; later it increases. In the beginning of an attack the white blood count is also normal but as time goes on a leukocytosis is present. Palpation of the abdomen usually reveals tenderness and rigidity over the involved area. Under anesthesia

such as chloral hydrate, a tumor mass may be felt, most often sausage shaped and lying transversely across the abdomen. In many cases a mass may be felt on rectal examination which resembles the cervix uteri. The treatment is non-surgical and surgical. Good results are reported by Hipsley⁵ of Australia from rectal injection of water or saline, but in this country, England and Europe, this method of treatment is thought to be dangerous.

If the lesion is less than a day old a barium enema may be given at low pressure and an attempt made to reduce the mass under fluoroscopic control. This is often successful in the colic or entero-colic types but if there is any doubt as to reduction the abdomen should be opened and this point determined. It is practically impossible to reduce the enteric type by rectal injections. Surgical treatment should be instituted as soon as the diagnosis is made in the enteric type and in the colic and entero-colic ones if the barium enema is unsuccessful.

A rectus incision over the point of tenderness should be made. The lesion is located and reduced by pushing the infolded intestine out. Very little if any traction should be put on the proximal intestine. In early cases reduction is usually easily accomplished. Later it may be difficult or impossible to reduce the intussusception. Warm saline compresses should be placed about damaged intestine and if its color and circulation return, it should be put back in the abdomen and the wound securely closed. If the reduction is impossible or the gut dead, we believe that it should be exteriorized as in the Mikulicz procedure.

In the May, 1939, issue of the *Journal-Lancet*, Dr. Philip A. Anderson and I reported a case of enteric intussusception in a boy four and a half years of age, because of its rarity. On November 26, 1939, Dr. Ralph H. Creighton and I¹ operated on a man fifty-two years of age with an enteric intussusception. Dr. Creighton will now report this case.

The patient, a man aged fifty-one, was seen Sunday evening, November 26, 1939, because of severe, periodic paroxysms of pain in the abdomen. The onset had been extremely sudden, about one hour before he was first seen. There had been nothing unusual about his condition or activities during the day, and the cramps started with no premonitory symptoms, shortly after returning home from an automobile ride. The spasms of pain were periodic, occurring every few minutes with complete relief and relaxation in between, and so severe that he would cry out and roll around in agony as soon as they started. He found some relief in assuming the knee-chest position, or sitting up in bed with his legs flexed tightly against his abdomen and his chin on his knees. His facial expression was agonized and apprehensive. His face was pale and beaded with perspiration. His skin was cold and clammy, almost presenting a picture of shock except for the fact that his pulse was not elevated. With each spasm of pain, there would be moderate nausea, and at times he would regurgitate small amounts of vomitus, always with relief. The vomiting was at no time projectile or fecal in character. There was no history, up to the onset of the present illness, of any gastro-intestinal disturbance, and no constipation. He knew of no foods which had ever given him any distress. The bowels had moved normally about eight

hours previously, but since the pain started, there had been no gas passed nor any tenesmus of the rectum, with passage of mucus. The genito-urinary history was negative. He located the severest pain just below the umbilicus and a little to the left of the midline, although the entire abdomen was somewhat tender to palpation. There was no radiation of pain at all.

Physical examination revealed a subnormal temperature and a normal pulse. He was obviously in extreme pain during each paroxysm, and also quite comfortable and relaxed during the intervals. There was no distention of the abdomen. No masses were felt and there was no spasm of the recti muscles. The point of maximum tenderness was located to the left of the midline in the lower abdomen. Auscultation over the abdomen during pain, revealed sounds of active peristalsis, the gas giving a metallic, tinkling sound. Rectal examination revealed nothing, and there was no pain on Murphy percussion.

A tentative diagnosis of intestinal obstruction, due probably to volvulus, was made. At this time, intussusception was considered because the picture suggested that condition in an infant. This thought was discarded, because of the age of the patient, for the more reasonable assumption of volvulus.

On admission to the hospital, the temperature was found to be 96.4, the pulse 74, and respirations 24. Examination of the urine revealed nothing unusual. The leukocyte count was 9,400, with 83 per cent p.m.n.'s. A flat plate of the abdomen failed to show anything suggestive of obstruction, and gave no other leads to suggest a diagnosis.

Dr. William Jones was called in consultation, and the available evidence was considered. An acute inflammatory condition inside the abdomen was ruled out, but renal colic and diverticulitis were thought to be possibilities. It was agreed that we had no direct indication at that time for exploratory laparotomy. The patient was given $\frac{1}{4}$ gr. of morphine and observation was continued.

He passed an extremely uncomfortable night, although the cramps were not as severe, nor as frequent, as before. He had four or five emeses, although he took a fair quantity of fluids. The next morning, the leukocyte count had risen to 15,900, with 89 per cent p.m.n.'s. This brought an inflammatory condition back into the picture. A second flat plate of the abdomen revealed no more than the previous one had shown. The urine examination was again negative. There did not appear to be any change in the abdominal examination, and there was no distention. The barium enema was considered, and discarded because of the possible risk of rupturing an acutely inflamed diverticulum. Hot stupes were used during the day, but were discontinued because their weight caused discomfort. Two enemata were given without success. Little change occurred throughout the day or night.

Tuesday morning, about thirty-eight hours after admission, his condition became as severe as on admission. The bouts of pain came on every few minutes, accompanied by vomiting of small amounts. The vomiting always seemed to bring relief. He again assumed the fetal position to relieve the pain, and now, for the first time, the abdomen began to be distended. No gas or feces had been passed since the onset. There was still no spasticity of the recti muscles, and no mass was felt. The temperature was still normal, but the pulse had risen to 120. The leukocyte count was 14,600, with 87 per cent p.m.n.'s. He looked much more ill than he had on the previous day. Intravenous administration of 5 per cent glucose in normal saline was started, and an immediate barium enema was ordered.

The barium was administered under fluoroscopic control, and passed all the way into the cecum, which was well filled. The colon was found to be entirely normal. Plates, however, showed a marked "laddering" of the small bowel and indicated a definite and marked ob-

struction of the lower ileum, distal to the cecum. Immediate laparotomy was advised and accepted.

A left rectus incision was made. As soon as the peritoneum was opened, a considerable amount of thin, chocolate colored fluid was found free in the peritoneal cavity. As soon as the peritoneal opening was completed, coils of small bowel pushed out of the opening, and an obvious intussusception reduced itself without manipulation. About three feet of mid-ileum was found to have been intussuscepted. The intussuscepiens was edematous, mahogany colored, and covered with petichiae. The intussusceptum was pallid and ribbon flat. There was no evidence of any tumor or other mass in the lumen of the ileum, nor did there appear to be any other pathology present. Warm saline packs were used, and since the bowel appeared viable and no suggestion of mesenteric damage was present, the abdomen was closed.

Intravenous fluids were started on return to his room, and were continued until fluids were tolerated by mouth. He was given a total minimum of 3,000 c.c. in twenty-four hours. There was no postoperative distention at any time, and no vomiting. He started to pass gas by rectal tube the following morning. He needed very little sedation the first twenty-four hours, and none after that. On his second postoperative day he demanded food and cigarettes, it being Thanksgiving Day. An enema was given on the fourth day, with the passage of a large, soft formed stool. The remainder of his stay in the hospital was uneventful, and he was discharged on the eleventh day. There has been no trouble of any kind since.

PADGETT'S DERMATOME AND SPLIT SKIN GRAFTS

H. O. MCPHEETERS, M.D.
Minneapolis

Dr. H. O. McPheeters discussed skin grafts and the use of the Padgett Dermatome. After a discussion of the subject of skin grafts in general and the indications and uses of each particular type and thickness he demonstrated the Padgett Dermatome, an instrument for the taking of grafts of uniform thickness and of any thickness desired.

The Dermatome follows the same principal as the Blair-Brown suction apparatus for the removal of large sheets of skin to cover extensive raw areas. Thin grafts take as a rule better than thick ones. In some places it is desirous to have very thin grafts while in others it is best to have them from the thicker and more tough skin.

The micrometer on the Padgett instrument can be set and adjusted so that one can cut a graft of any

desired thickness and with perfect uniformity even to the full thickness of the skin. The skin will regenerate and develop over the donor area from the deeper layers of the skin, as the base of the papillæ are left in any graft up to the full thickness. In this way no further care is needed for the donor area than the simple first dressing. Dr. McPheeters preferred the perforated cellophane over the donor area sealed along the edges with mastasol to support the tension and avoid pull on the raw area. Pressure over this will help stop the oozing and the serum from the cut surface will come through the perforations. The cellophane is not changed for ten days.

He emphasized that the same precautions should be taken with the area to be grafted as with other methods. It is useless to place a graft over any area not prepared, not sterile, with sloughing tissue still present and with poor or not good granulations present. Following the placing of the graft it is imperative to hold it immobilized and with firm, steady pressure on it for about five days. This can be accomplished by the use of large sea sponges or a firm grade of rubber sponge placed over much fluffed gauze. The dressing and sponges should be moistened with normal saline every four hours.

WAR AND TUBERCULOSIS

War . . . makes pleasant news for the tubercle bacillus. As the deaths from T.N.T. increase, those from tuberculosis lag not far behind. In the World War all countries showed this phenomenon whether under arms or not. What effect on our efforts to eradicate tuberculosis will these grim months ahead bring forth? . . . Unless we find a way to redouble the offensive against our hidden enemy, the sad story of twenty years ago will be told again and we will find ourselves facing a record of lost ground.

—KENDALL EMERSON, M.D.

AN AMERICAN HEALTH PROGRAM*

NATHAN B. VAN ETEN, M.D.
New York City

AWAY back in the era of Babylonian culture, practitioners of healing arts were compelled to organize themselves for the protection of the public from the deceptions of charlatans, quacks and fakirs.

Living under various codes, a cohesive idealism carried them through the centuries—until about two thousand years ago medical organizations were crystalized by the followers of Hippocrates, and the altruistic traditions of the Hippocratic Code have been cherished with rare fidelity. The Hippocratic Code has survived the explosions of successive theories of the science of medicine and still lives as the foundation of medical ethics.

Within a few weeks thousands of young graduates from medical schools in America will listen to a reading of this ancient document and will raise their right hands and swear to uphold it. Very few of them will fail to keep this obligation as their consecration to the service of the sick.

However divergent their ideas concerning the manner of this service, all physicians stand firmly upon this ancient rock.

The evolution of organized medicine in America dates from the founding of the first hospital—by Benjamin Franklin in 1752 in Philadelphia. A group of physicians forming themselves into a hospital staff merged their individualities into an organization which promised to deliver medical care to the sick poor. Soon afterwards medical societies and medical colleges were started and American medical education began to replace European medical education.

All of these establishments represented local efforts working independently. Consequently

there were very uneven standards of quality until the organization of the American Medical Association in 1846, when a federation of medical societies was erected and a serious attempt was made to bring the levels of education and of the practice of medicine up to the highest known standards of the time. The American Medical Association has worked at this job steadily through its councils on Medical Education and Hospitals and on Pharmacy and Chemistry.

Its Judicial Council has jealously guarded the ethics of all practitioners and has been a constant stimulant to an unflinching idealism.

The democratic organization of the American Medical Association gives each one of its one hundred and sixteen thousand members a voice in its affairs. Its House of Delegates, representing every state and territory, originates and strengthens its policies, and elects officers who are obligated to obey its mandates.

As a direct result of ninety-four years of hard work, medical education and medical service in America is the best in the world. Health statistics are unsurpassed and constantly improving. In spite of this undisputed record there are political theorists and imitative philosophers who would substitute European systems of health administration for this American evolution which has such rich vitality and promises still greater attainments through devoted services to the American people.

Contrast the American with the European scene. Germany is no longer the mecca for advanced education. The masters have been driven out by the lash of paganism and medical education has lapsed below mediocrity. The medical course was cut to two years in 1939 and quacks

*Address given before the House of Delegates at the annual meeting of the Minnesota State Medical Association, Rochester, Minnesota, April 21, 1940.

and nature healers were legalized. For more than half a century compulsory health insurance has been destroying initiative, and the high quality of German medicine is a matter of history. Mass medicine is poor medicine—red tape makes a poor surgical dressing.

In spite of more than a half century of poorer and poorer medical care which has been endured by the German people, who have been under the heel of one form of autocracy after another, I do not believe that the German scientific spirit can be crushed. Too long Germans have been good students and have given humanity epoch making discoveries of the greatest magnitude. Even now out of this most depressing European mess has come the unfolding of chemotherapy in the instance of sulfanilamide. Germans discovered it, French students developed it, English and Danes and Americans are perfecting it.

Let us hope that honest scientific effort will restore to the German people the right to be considered human beings instead of herded cattle.

Our present American success is the accomplishment of professionals working in a liberal democracy—physicians and other scientists who work at it every day, but who are neither satisfied nor complacent about it. American physicians want to make American medicine so much better that there can be no justice in stories of neglected people anywhere in this country; that there can be no justice to support claims that thousands of people suffer and die from diseases that are curable and preventable; that thousands of young mothers die from lack of medical care; and that thousands of children fail to grow to strong maturity because of failure of medical social technics.

All American physicians know that large numbers of people live miserably because they lack proper food and shelter and are consequently poor health hazards. They know that thousands of city dwellers are so crowded into vile tenements that they are denied healthy decencies.

Are American physicians sufficiently aroused to enter upon active local crusades against local pestilence? The doctor must take more than a superficial interest in local political machinery if he would improve the health and happiness of his community.

Community units are the foundation stones of this democracy. The doctor can be a potent force in making these stones strong enough to carry a

civilized structure. The general practitioner is one of the most valuable citizens of this republic. His potentialities for leadership must be revitalized. He must regain his old place as counselor and confessor and the people must demand his leadership.

By and large the general practitioner is competent and conscientious, and while his continuing education is necessary, our greatest problem in this country is a continuous campaign of public education to make our citizens so health conscious that they will seek early treatment while cure is possible and while catastrophies may be prevented.

Education has consistently lowered the mortality from tuberculosis. Education has salvaged thousands of children from destruction by diphtheria and other communicable diseases.

Public health education must be furthered in personal hygiene; in values of foods; in values of sanitary housing; in social hygiene, in the prevention of destructive disease through venereal infection, in eugenics (in thoughtful human mating); in serious study of social science with the hope of reducing the number of insane who fill more hospital beds than all sufferers from all other diseases; in study of the whole man by all practitioners of healing arts and study of the individual in his home and diagnosis of his illnesses and treatment of them on the spot. Investigative thinking upon all of these problems by all our citizens would undoubtedly yield incalculably large dividends in the health of the American people.

Medical organizations have been working for years to improve the quality of medical service and I believe that they will continue to carry on their concerted efforts to save our people from quacks and incompetents in spite of accusations of criminal violations of business laws. Physicians are learned professionals giving service regardless of fee. They are not merchants of health selling medicines, or formulæ, or instruments, or cures. They are so earnest in the quest for means to relieve human suffering that they give their discoveries freely to all the world. They have no desire to restrain any one in the pursuit of their ideals, providing they are doing it honestly, in conformity with established ethical standards and in the best interest of the sick. They are the privileged servants of the sick and the fee is not their master. They are not in busi-

ness. They are in a large sense educators of the public conscience. They are valuable leaven in the ferment of social progress.

For twenty centuries their adherence to the Hippocratic tradition has led them to survive the crashings of many civilizations. This spirit will carry them to continued distinguished service long after the legal technicians have strutted their brief moments in the limelight and have been forgotten.

Readjustments will be made of professional activities in order to digest unpalatable and reactionary theories of public service.

The profession of medicine, including dentistry, and the professions of law and the ministry of religion will rise above persecutory technicalities and in their honest pursuits will continue to raise the level of general understanding of moral and physical values in the United States.

These professions will continue to try to serve at all social levels to the best of their ability. They will not refuse to work at night or Saturdays or on Sundays or holidays. Their ears will not be deaf to cries for help before nine in the morning or after five in the afternoon. They will continue to need public support, but they will not relax their efforts even if the public fails them. They will exercise a priestly privilege to try to lead American citizens to a high appreciation of their good fortune in living in an advanced democracy—a democracy created by the genius of George Washington, guided by the scientific genius of Benjamin Franklin and the organization genius of Thomas Jefferson, who must have thought of the health of the people when he advocated life, liberty and the pursuit of happiness.

I hope and believe that the professions will keep that popular demand nailed to the masthead and that it will still be flying there when your children's grandchildren come into their inheritance and that it will inspire them to continue the processes of evolution to the realization of physical, mental and moral health for the American people.

American physicians are justified in a pride of conquest over disease, but they must not rest upon their laurels.

While new low percentages are reported for tuberculosis, for diphtheria, for the casualties of maternity and for all diseases of children, the statistics of degenerative diseases, of insanity and of preventable communicable disease cannot be

taken lightly. Too many hearts are breaking under modern strains—too many people between the ages of thirty-five and sixty-five are limping along with incapacities—too many cases of smallpox, nearly fifteen thousand in the United States last year and increasing at an alarming rate because public health authority is not obeyed.

General paresis and other syphilis of the central nervous system accounts for a very large proportion of the tenants of our state institutions, every one of which is crowded from ten to fourteen per cent beyond normal capacity. These and contributing economic conditions are stirring the medical profession to demand new organization of health services for the American people, and are expressed in the new platform of the American Medical Association.

Every word of that platform is objective. The false accusations that the American Medical Association is static and reactionary are sharply denied in its letter and spirit.

Two thoughts are expressed which may seem sharply contradictory—one is *centralization* of all governmental health activities in one new department, and the other is *decentralization* of all other health activities into local units of administration.

Coördination of governmental health activities is simply a practical move to do away with much overlapping expense and reduction of duplicating machinery.

Developing local health units may be a device to find sickness where it is and treat it on the spot, shorten governmental procedures and keep the government out of medical practice.

Wherever local problems can be solved, they lessen the mass of national responsibility. If we settle minor problems we shall have few major problems.

The platform deals in generalities. Specific provisions for detailed development will have to be studied with care by all who are interested, such as the professions of medicine, public health nursing and welfare organizations. A great deal of laboratory work is needed. Suggestions might well be made by legislative bodies such as yours.

The essentials of this new platform are coördination of government health functions; governmental provision of funds for disease prevention and relief of uncared for sickness on proof of need; development of local responsibility for local demand, and local control of administra-

tion; and encouragement of the private practice of medicine as far as possible in harmony with maintenance of a good quality of medical care.

In 1875 the American Medical Association asked for a secretary of health in the cabinet of the President and has timidly restated its desires at various sessions of the House of Delegates—after which the delegates went home to practice medicine and forgot about it.

Last year in the first session of the present congress on March 6, 1939, Mr. Pfeifer introduced a bill No. H.R. 4791—"To establish a Department of Health." This bill was referred to the Committee on Expenditures in the Executive Department, where it still reposes. It was, however, a first step in the National House of Representatives toward coördinating the health functions of our National Administration, which are now scattered through many separate bureaus and major departments.

If local health departments have proved their value—if state health departments have become indispensable—why has a national health department been so long postponed?

Coördination of all federal health agencies except those of the Army and Navy seems logical. The health of our people should be the honest concern of the chief executive. And the health authority should be a member of his cabinet.

I would like to see a new national department to be known as the Department of Health headed by a secretary who must have had a medical education and be licensed to practice medicine. I would like this new department to include the following bureaus:

1. Public health
2. Infancy and maternal welfare to be transferred from the Labor Department
3. Rehabilitation of veterans
4. Research
5. Licensure
6. Care of indigents
7. And other divisions to care for all other health responsibilities, fusing all departments into one less expensive to operate and eliminating the confusion of overlapping and duplication.

I believe the President should have the benefit of scientific advice in Health and Hygiene within his official family.

Defense against disease is quite as important

as defense against the ideas and domination of foreign enemies.

It seems to me to be timely to drop complicated and slipshod methods and attack the problem courageously and efficiently.

Infancy and maternal welfare developed in the Department of Labor in response to wide outcry against child labor. Its objective has been largely realized and now requires a wider and more general type of direction.

Rehabilitation of veterans, developed with well known administration scandal, under a stimulated emotional campaign, is now well established. Hospitals are widespread and may well have a broader significance with the passing of time under a department of health.

Appropriations for research are now vested in the bureaus of Public Health and in appointed committees. I believe that the value of such work would be greatly enhanced if these studies were coördinated in a Department of Health, where voluntary agencies, such as medical schools, voluntary hospitals and philanthropic foundations could coöperate in directly helpful service for the information of the government.

The National Board of Medical Examiners might fit into a function of a National Health Department.

Medical care of indigency looms as one of the most important functions of government. A concert between local agencies through some new type of local, state and national machinery could well be headed in a National Health Department.

The migrating indigent is one of those for whom no local agency is willing to assume the responsibility. He is pushed from state to state and travels from one seasonal employment to another.

No health insurance scheme can take care of such people who can make no regular contribution to any compulsory or government financing. Their care must be centralized. Would there be a better place for this work than in a National Health Department?

It would seem to be ideal to choose a career man to head this department; some one who has been developed through the present department of Public Health or through service in some of the state administrations.

Examination of the current personnel in the various states shows a real need for competent health officers.

Service in the various fields of public health should be carried on by career persons who should be developed through a special training beyond the ordinary undergraduate course in medicine.

Although it must always be borne in mind that a period of private practice seems to be necessary for understanding intimate personal medical problems, there is reason to feel that those who are to direct public health administration should be specially trained in the science of administration before entering such a field. Too often the health officer is merely a political appointee because he has influential friends rather than because he knows anything about the duties of the office. He should also be made conscious of the fact that he is only an administrator and not a practitioner of medicine.

The public consequence of private practice may need government umpiring, but government participation in private practice must not be tolerated.

I believe that the secretary of health should be a physician who has had enough experience in the practice of medicine to know the viewpoint of the patient as well as that of the physician. He should not be a political theorist who cannot know medical care of the sick because he has never practiced it.

There is evidence of a concerted drive for a general service to the sick, both preventive and curative, supported by taxation and under government control.

There is frequent reiteration of a desire for free medical care, patterned after free public education: all doctors salaried by the state—a complete system for state medicine. There seems to be no limit to the belief that the public purse will be able to pay for it, even in the presence of evidence that state education is already too costly for the public pocket, regardless of the fact that school budgets are now the subject of acrimonious debate and regardless of the mounting national deficit.

In the state of New York last year state education absorbed 43 per cent of the state budget of \$385,000,000. State education takes care of people from the ages of five to twenty-one only, while state medicine would involve the care of people from before birth to interment.

Prohibitive cost means nothing to some political theorists.

A new program must provide something better and simpler than these excursions into Utopia.

I believe that needs for help should be discovered in the smallest political subdivision such as the school district, then referred to the township, to the county, to the state, to the federal authority in that order and that the federal authority should be called upon as infrequently as possible.

I believe that medical service to the economic indigent is the problem of the taxpayer. The economic indigent may be defined as one who is unable to provide the necessities of life for himself and his family.

I believe that medical service to the medical indigent is the problem of the taxpayer. The medical indigent may be defined as one who cannot pay for medical care without sacrificing the necessities of life for himself and his family.

I believe that medical service to these two classes of people should be administered by the medical profession and that the physicians who do this work should be paid by the taxpayer.

I believe that medical service to other people of low income who are able to pay for ordinary but not for catastrophic illnesses should be *shared* by the medical profession and the taxpayer. The medical profession and the taxpayer should provide such needed medical service in tax supported institutions either free or at minimum rates.

I believe that new mechanisms for caring for the health needs of the people involving all political subdivisions from the locality to the federal government should be developed no faster than administrative personnel can be sufficiently trained to be effective.

I believe that preventive medicine, although largely a public health problem involving the control of communicable disease, should be promoted by all practicing physicians, upon whom should be imposed definite civic responsibility.

I believe that every effort should be made to provide for the average man so that he can prepare for emergencies without throwing himself upon the sources of charity.

I believe that budgeting for sickness through insurance providing cash indemnity should be encouraged—as well as insurance against the cost of hospitalization, but that these two forms of insurance should be separate projects.

Compulsory systems of sickness insurance as now operating do not take care of indigents and

are only interested in workers who pay for insurance of this type through payroll deductions.

I believe that the sentiments of groups of religionists who object to compulsory medical care through insurance or otherwise, should be respected so long as their beliefs do not jeopardize the public health through neglect of ordinary health precautions for themselves or the community.

Neither creed nor race nor color should deprive any American of the benefits of the best of clinical medicine, but the manner of its delivery should evolve from simple formulæ. The formulæ should grow from the needs of the people as recognized by the family physician, the public health nurse and local welfare workers. The formulæ should grow into workable being in an orderly way which will require a period of time for short steps before long strides are taken. Much laboratory work must be done, as recognized by the President in his recent proposal to build small hospitals in regions where they are needed. This proposal is in harmony with the new platform of the American Medical Association. It is a sane alternative to the extravagances of the proposed Wagner Health Act. It is a stimulant to local initiative to operate a facility erected by the government for the benefit of the locality. It is also in harmony with the President's private statement on more than one occasion that he is opposed to any extensions of state medicine that can be avoided. It is an immediate forward step toward correcting faulty distribution of medical facilities and may prove as attractive as are many hospitals to young physicians who may be seeking new locations.

The memory of an internship in a hospital furnishing every convenient facility is often disturbing to a young doctor's response to calls to country practices where he must be self dependent.

It is to be hoped that these new hospitals will be placed in response to well established local needs.

At the invitation of the President, a committee from the American Hospital Association, from the Catholic Hospital Association, from the Protestant Hospital Association and the American Medical Association met the President at the White House on January 10.

The committee reports that the President seems to be opposed to the enactment of the Wagner Bill and apparently intends to propose to Con-

gress that a sum approximating \$10,000,000 be appropriated for the purpose of building small hospitals in places where there appears to be great need of hospital facilities. Under the plan proposed by the President, the federal government will build the hospitals, but the community, with or without state aid, will be required to maintain these institutions. The President stated that such hospitals when built will not be placed in undue competition with other hospitals. There was little discussion of details at the conference, though some felt that there should have been more such discussion since the practicalities of the situation seemed to demand it.

Although the medical profession is favorably impressed there has been some expression of fear that the President's proposition is but a stepping stone to the all-inclusive health measure introduced in the Senate last year by Senator Wagner which is still resting in the Committee on Education, where it is supposed to be undergoing revision and is not likely to appear at this session of Congress. In fact, Senator Wagner stated publicly at a meeting in New York on March 28 that revision of the bill was proceeding to harmonize it with the ideas of the American Medical Association. Exactly what is meant by that statement is not known, but it is certain that S-1620 has been sidetracked to allow precedence of the President's program for small hospitals.

It is interesting to note a growing interest in and support of the new program of the American Medical Association. Senator Taft has expressed the hope that the Medical Association or some of its friends would introduce a bill into Congress embodying these basic principles. Other legislators have joined in the opinion that this is desirable. Senator Burke violently opposed the Wagner Health program. From a powerful force within the administration has come the utterance of the Federal Security Administrator, the Honorable Paul McNutt. Speaking before the National Health Council on February 15, 1940, I quote a few paragraphs from his speech which reflect a new line of thought in Washington:

"No program addressed to a few diseases or a few age groups, or a few economic groups can possibly reach our ultimate objective which must be to attain the highest possible level of health for all of our people.

"One important means of reaching this objective is the unification and coördination of health agencies at

the federal, state and local levels. The American Medical Association and the American Public Health Association have recommended the integration of health services at the federal level under one cabinet officer, preferably a secretary of health. A first step has already been made toward functional coordination by the creation of the Federal Security Agency of which it is my privilege to be administrator.

Functionally, the agency is the beginning of a combined department of health, education, and social welfare. There still remain departments of the federal government, although these same activities in the states are administered by a single agency. Our objective must be to attain such integration of health activities that we shall no longer deal with human beings as cases of infectious disease or cancer or pneumonia, as sick babies or sick youths or sick old people, but as whole individuals living in families that make up the 130 million people of the United States of America.

"There has been general agreement as to the objectives of the National Health Bill (S. 1620), but some question as to the sums of money involved and considerable criticism of its administrative provisions. Frankly, as an administrator, I have been seriously disturbed by the dispersion of federal administration proposed in this bill. As you know, the bill gives responsibility to the Children's Bureau for medical care of children, to the Public Health Service for medical care of certain high cost illnesses, and to the Social Security Board for diseases other than those for which the Public Health Service is given responsibility.

"It is my firm belief that the first objective of the bill should be to coordinate the Federal health services. I fail to see how a national health program can be administered adequately with three federal bureaus making grants for the control of different diseases and different groups of the population. Confusion and duplication of effort is bound to result at federal, state and local levels. Not the least confused will be the ultimate beneficiary, whose health problems are artificially segregated according to his age and the nature of his illness."

General activity to stimulate legislation forming a National Health Department under a secretary of health must proceed if the medical profession really desires it. Local work must proceed in our county medical societies to promote local action.

It would be ideal if all county societies would start a study of local needs for medical service. There must be wide divergence of local conditions such as the character of terrain, hilly country, flat country, good or bad roads, bridges over rivers, and general accessibility of doctors and hospitals. Much might be done if there was enough ambulance service at strategic points. I learned very early in my career, from my father who was a railroad surgeon, that patients who were

very sick could endure a good deal of transportation.

When Herman Biggs was health commissioner of the state of New York, he advocated a system of cottage hospitals and laboratories to take care of the rural problem in the state of New York. At a hearing before Governor Smith everybody seemed to favor the project. When the governor said he would like to hear what some country doctor thought about it, finally a doctor from Malone, a town in the northern part of the Adirondacks, arose and said, "Well, Governor, in the summer time the Adirondack region is full of city people and there are plenty of city doctors to take care of them, but in winter very few people are there and the country doctors and country towns have plenty of facilities, all we ask you to do, Governor, is to keep the roads open."

The cottage hospitals were not built. Good roads in the state of New York have largely eliminated the rural problem—there is now a doctor in New York state within thirty minutes of every citizen.

Every county society should be interested to make these studies sincerely. It is important to know whether the county needs hospitals, ambulances, doctors, nurses or welfare workers—whether it can take care of itself or needs state or national financial help.

I presume that doctors in Minnesota are just as much or as little concerned in general health problems, are just as generous or as selfish as doctors in other parts of our country. I presume that in each of your counties a *few* doctors do all the work of your county societies and the others are perfectly willing to let them do it.

Of course, you gentlemen here today are the workers of the Minnesota State Medical Society. I wonder if you take yourselves seriously enough to carry back to every doctor in your counties the real importance for every one of them of cooperation, if we are to bring American medicine to its rightful place in American life.

Every doctor in Minnesota should be a citizen in every sense that citizenship means or implies.

The general practitioner must be revitalized into active leadership of all local political movements concerned with the moral, mental and physical welfare of every citizen of this important state.

We must not take negative positions at a time like this when all sorts of wild theorists are

shouting into the public ear. The public seem to be eager for health education and we must give it to them honestly and freely if we really want America to be a better and happier place in which to live.

The American Health Program has been writing itself for one hundred and eighty-eight years.

The American Medical Association has been

motorizing this program for the last ninety-four years cherishing an ambition not only to conserve all of the verities and values of this medical service evolution, but the projection of them into new objectives for the delivery of better and better medical services to the American people.

If American physicians must have an objective slogan, let it be "Better Medical Care for Every American Citizen."

THE ROENTGENOLOGIC DIAGNOSIS OF INTRASPINAL PROTRUSION OF INTERVERTEBRAL DISKS*

JOHN D. CAMP, M.D.
Rochester, Minnesota

WITHIN the past few years considerable literature concerning intraspinal protrusion of the intervertebral disks has appeared and the condition has been firmly established as a definite clinical and pathologic entity. Studies by Deucher and Love indicate that the protruded fragments are composed of fibrocartilage, portions of the nucleus pulposus and occasionally remnants of the notochord. These structures are not ordinarily opaque to roentgen rays and cannot be demonstrated per se in plain roentgenograms. Bone or calcium in quantities gross enough to be revealed roentgenographically is so rare in these protrusions that it is of little practical diagnostic importance.

It would seem that in any condition such as this, in which trauma is such a common etiologic factor, there should be visible in plain roentgenograms some alteration in the structure of the bone or joint that would denote the site of the lesion. Experience with a large number of cases, however, does not bear out this supposition. Narrowing of the intervertebral space at the site of a protruded disk was present in only 31.9 per cent of a recent series of cases. Since similar narrowing may also result from degeneration and fibrosis of an intervertebral disk without protrusion, this change alone without other evidence is only of suggestive value.

Hypertrophic changes localized about the margins of an intervertebral space at the site of a protruded disk occur in such a small percentage of

cases (10 per cent) that they are of little help in the direct localization of a protruded intervertebral disk. Compression fractures of a vertebral body contiguous to the site of a protruded intervertebral disk are not common.

Since plain roentgenograms offer little aid in the recognition of a protruded intervertebral disk, the roentgenologist is dependent on the use of some contrast agent for the indirect visualization of the protrusion. Several such agents, namely, iodized oil, air, oxygen, skiodan and colloidal thorium dioxide have been employed for visualization of the spinal subarachnoid space. Each of these substances has certain advantages and disadvantages; none of them so far has proved ideal. Increasing familiarity with the history and neurologic examination in cases of protruded intervertebral disks indicates that in a fair proportion of cases the diagnosis and localization of the protrusion can be made clinically without resorting to any contrast agent. With this improvement in clinical diagnostic acumen the necessity for the use of a contrast agent will probably diminish and be reserved for those cases in which the diagnosis is in doubt and those in which it is desirable to know precisely the anatomic level of the lesion for the guidance of the neurosurgeon.

Iodized Oil Myelography

To date, iodized oil has been used more than any other opaque contrast agent for the roentgenologic visualization of the spinal subarachnoid space. When employed under proper circumstances it has resulted in an accuracy of di-

*From the Section on Roentgenology, The Mayo Clinic, Rochester, Minnesota. Read before the meeting of the Minnesota State Medical Association, Rochester, Minnesota, April 22 to 24, 1940.

agnosis that is shared by few other roentgenologic procedures. The chief objections to the use of iodized oil are that it is more or less an irritant to the meninges and is contraindicated in the presence of inflammatory disease. The significance of the irritative action, and the effect of its presence within the subarachnoid space have been discussed pro and con in the literature for some years. Nevertheless, it is the consensus of observers who have used it in a large number of cases, that in properly selected cases the advantages of its use far outweigh any disadvantages that are known. The indiscriminate use of iodized oil in cases of low back pain or sciatic pain is not recommended. No contrast agent should be used unless the clinical and neurologic examination indicates the possible presence of an intraspinal lesion that cannot be localized by ordinary clinical procedures.

The lumbar injection of iodized oil is preferred because it is easier and safer to carry out than cisternal puncture. It is important that the iodized oil be clear, transparent and only faintly yellow before use. Small amounts of iodized oil (0.2 to 2 c.c.) may suffice for the localization of lesions that completely obstruct the canal, but in the interest of early diagnosis and for the localization of lesions before obstruction has occurred, it is necessary to use a quantity of iodized oil sufficient to fill the subarachnoid space at any desired level. In my experience 5 c.c. is the optimal amount for this purpose. Some lesions can be shown with smaller quantities, but on the other hand, a number of surprisingly large lesions, and, in particular, multiple lesions, are easily overlooked if amounts less than 5 c.c. are used.

It is desirable that the roentgenologic study be carried out as soon after the injection as possible, as delayed examination and movements of the patient may lead to separation of the mass and droplet formation. A tilting, fluoroscopic table with appropriate foot and shoulder rests is necessary. If the result of the examination of the lumbar spinal subarachnoid space is negative, it is important to examine the subarachnoid space higher up as recent observations have revealed that 50 per cent of patients with tumors of the spinal cord situated in the thoracic region and 30 per cent of patients with such tumors situated in the cervical region have low back pain, or sciatic pain or both as associated or coincidental symptoms. Quantities of iodized oil less than 5 c.c. are

not practical for this phase of the examination.

The deformity of the iodized oil shadow resulting from a protruded intervertebral disk is influenced by the following factors: (1) the posi-

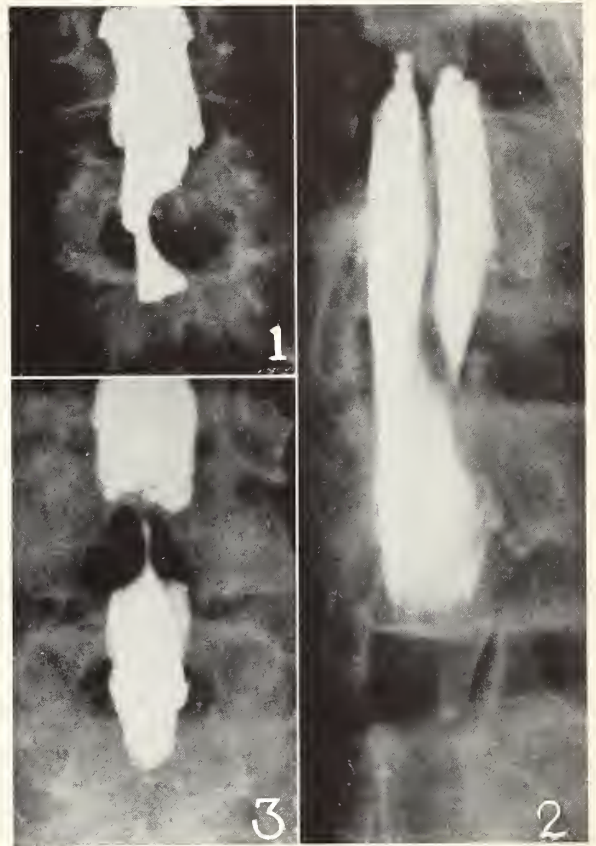

Fig. 1. Intraspinal protrusion of the lumbosacral intervertebral disk. Characteristic unilateral deformity of iodized oil shadow.

Fig. 2. Intraspinal protrusion of the intervertebral disk between the second and third lumbar vertebrae. At the point of obstruction, the shadows of the nerve roots are displaced and compressed by the protrusion. The vertical elongated shadow of diminished density indicates an edematous nerve root, in this case the left second lumbar root.

Fig. 3. Intraspinal protrusion of the intervertebral disk between the fourth and fifth lumbar vertebrae. Bilateral deformity of the iodized oil shadow.

tion of the protrusion, (2) size of the protrusion, (3) associated hypertrophy of the ligamentum flavum, (4) changes in the nerve roots (displacement, edema, nonfilling of affected nerve root sleeve) and (5) anatomic variations of the cul-de-sac.

Position of the Protrusion.—Except in unusual cases the protruded fragment is situated in the anterior portion of the spinal canal and will produce its greatest effect on the column of iodized oil when the patient is lying in a prone or prone-oblique position. The classic defect is a

sharply defined unilateral rounded indentation of the iodized oil shadow opposite an intervertebral disk (Fig. 1). It occurs in about 65 per cent of cases. Midline protrusions when of moderate size may produce only a central defect.

iodized oil posteriorly and laterally. In the lateral view, its presence is characterized by a broad or rounded indentation on the posterior aspect of the shadow of the iodized oil between contiguous laminae. In the prone or supine positions the hy-

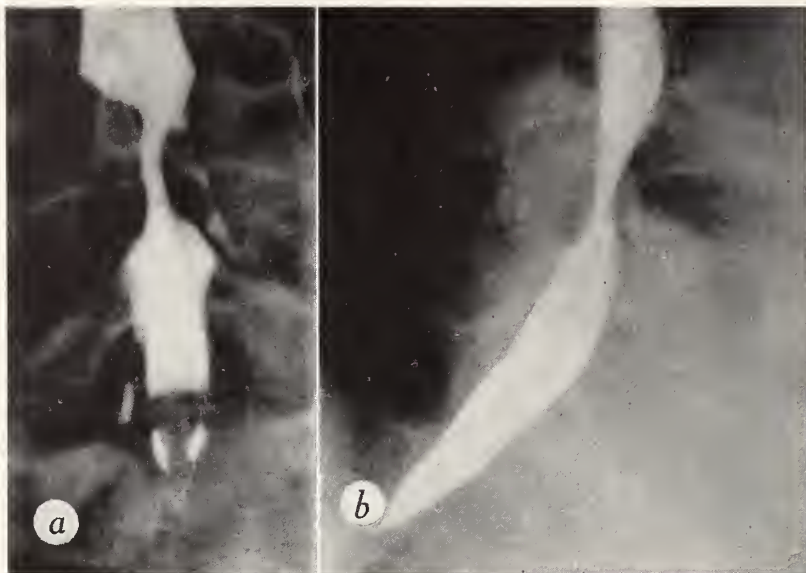

Fig. 4. Intraspinous protrusion of the intervertebral disk between the fourth and fifth lumbar vertebrae and associated hypertrophy of the ligamentum flavum; *a*, anteroposterior view revealing broad bilateral deformity of iodized oil shadow; *b*, lateral view revealing anterior indentation of the shadow due to the protruded disk. The broad indentation on the posterior aspect of the shadow at the same level is due to hypertrophy of the ligamentum flavum.

Size of the Protrusion.—Except as the iodized oil deformity may be influenced by the presence of hypertrophy of the ligamentum flavum, the larger the protrusion the greater the obstruction of the subarachnoid space will be. Partial obstruction occurs in about 11 per cent of cases and complete obstruction in only about 2.5 per cent of cases (Fig. 2). The larger the protrusion the greater the tendency to produce a bilateral deformity, which occurs in about 35 per cent of cases (Fig. 3).

Hypertrophy of the Ligamentum Flavum.—This condition is found frequently in association with a protruded intervertebral disk. It usually occurs at the same level as the protrusion but may occasionally be found at other interspaces. Localized hypertrophy of the ligamentum flavum without coincidental protrusion of a disk is not common. When it does occur it may imitate all the clinical phenomena of a protruded intervertebral disk. Because of the anatomic location of the ligamentum flavum, this structure when it is hypertrophied will compress the column of

protrusion is portrayed by a broad indentation of the column of iodized oil, generally bilaterally but occasionally unilaterally. When considerable hypertrophy of the ligamentum flavum accompanies a large protruded disk, the mass of iodized oil is compressed between the protruded disk anteriorly and the hypertrophied ligamentum flavum posteriorly and laterally. The resultant deformity is characteristic (Fig. 4*a* and *b*).

Changes in the Shadow of Nerve Roots.—In about a third of the cases of protruded intervertebral disk, displacement of shadows of nerve roots will be visible at the site of the protrusion. Abnormal enlargement of a nerve root shadow indicating edema is frequently observed in roentgenograms at or just above the site of a protruded disk (Fig. 2). An early change that results from edema of a nerve root is obliteration of the usual shadow of the nerve sleeve where the root passes through the dura.

Anatomic Variations of the Cul-de-sac.—Two anomalies of the terminal portion of the cul-de-

sac which occur in about 5 per cent of cases may complicate the roentgenologic diagnosis of a protruded lumbosacral intervertebral disk. The first is an anomaly in which the terminal portion of the cul-de-sac is narrower than usual below the level of the fourth lumbar intervertebral space. In such a case a moderate protrusion of the lumbosacral disk may not deform the narrow subarachnoid space and a large protrusion may produce only a minimal defect. The second anomaly is one in which the cul-de-sac terminates one or two segments more cephalad than usual with or without a variation in its diameter. In a few instances, the cul-de-sac will terminate above the level of the lumbosacral interspace. When either condition is present, especially the latter, it is obvious that a lumbosacral protrusion may not be disclosed by means of iodized oil or any other contrast agent.

Air Myelography

The use of air or oxygen for the study of the spinal subarachnoid space has been revived in recent years and this procedure has certain advantages: (1) there are no contraindications, (2) the air is resorbed following examination, (3) there is no irritating effect other than that which temporarily results from the injection and (4) roentgenoscopy is not necessary.

On the other hand, there are certain definite disadvantages: (1) the procedure is unsatisfactory for nonobstructing lesions above the conus, (2) the shadows and defects are less distinct than those caused by iodized oil, their interpretation is more difficult and the likelihood of error is increased, (3) roentgenoscopic verification of the defect is not possible, (4) inconclusive examinations are much more frequent than with iodized oil and (5) experience has shown that the results of air studies, especially when negative, are less accurate than the results obtained with iodized oil.

Experience indicates that if the suspected level of a lesion is at or above the conus, the use of air or oxygen will not help in diagnosis unless obstruction of the subarachnoid space has occurred. This results from the fact that air or oxygen is very difficult to hold in a desired position in the thoracic or cervical portion of the spinal canal and its use in these regions is further complicated by the superimposition of the shadow of air in the trachea, larynx and pharynx which

renders the interpretation of resulting shadows difficult or impossible. Iodized oil therefore is the medium of choice for the demonstration of lesions at or above the conus.

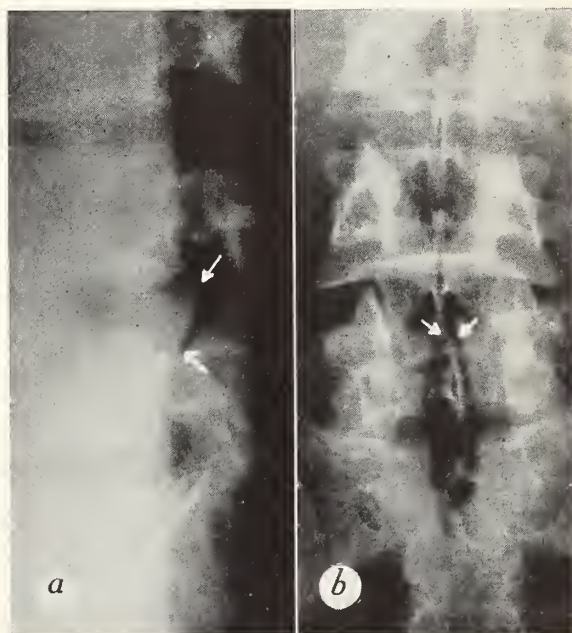

Fig. 5. Intraspinous protrusion of the intervertebral disk between the fourth and fifth lumbar vertebrae. Spinogram (air study): *a*, lateral view showing indentation of anterior aspect of the air shadow by the protruded disk at the site of protrusion; *b*, bilateral narrowing of the air shadow opposite intervertebral space between the fourth and fifth lumbar vertebrae.

Statistics³ indicate that the great majority of protruded intervertebral disks occur in the lumbar and lumbosacral regions where they are accessible to examination by means of either air or iodized oil. Since there is a reasonable chance that the protrusions may be disclosed by means of air or oxygen, it is probably good judgment to attempt their localization by this method before iodized oil is resorted to (Fig. 5). If the results of air studies are positive much has been gained because in 83 per cent of such cases a pathologic lesion has been found by the surgeon at the site of the deformity. If the results of air studies are inconclusive or unsatisfactory, then iodized oil may be used. If the air studies result in negative findings and the history and neurologic examination indicate the probable presence of a protruded disk, the surgeon must then decide whether to check the findings in the spinogram by means of iodized oil or whether to advise laminectomy on the basis of the history and neurologic findings. In my experience, a negative spinogram (air study) has proved com-

paratively unreliable because in a high percentage (77 per cent) of such cases a pathologic lesion has been found at operation. This fact should not be lost sight of by the clinician in appraising the results of such studies with air. When the use of air reveals either a deformity that will not account for the patient's symptoms or a lesion, the level of which is not compatible with the symptoms, the results should be confirmed with iodized oil before laminectomy is advised. Further experience in the interpretation of spinograms (air studies) will undoubtedly re-

sult in improvement of the diagnostic accuracy of the procedure. However, because of certain basic limitations of the method it is not likely that its efficiency will ever equal that attained by iodized oil myelography.

TREATMENT OF PROTRUDED INTERVERTEBRAL DISKS*

J. GRAFTON LOVE, M.D.

Rochester, Minnesota

IT is a distinct pleasure for me to have the privilege of reporting to our State Society again within two years on a subject which has not decreased but has tremendously increased in interest not only in this state but throughout the United States and in many foreign lands.

When I spoke, in Duluth, at the State Meeting two years ago I made the following statement³: "There is only one treatment for protrusion of an intervertebral disk that is producing compression of the spinal cord or of a nerve root. When a definite protrusion is demonstrated and a lesion at the level of the protrusion will explain the patient's symptoms and signs, laminectomy for the express purpose of removing the protruded portion of the disk should be performed."³ Today that statement is just as true as it was then and it needs only to be emphasized. The second sentence, which reads as follows, "When a definite protrusion is demonstrated and a lesion at the level of the protrusion will explain the patient's symptoms and signs, laminectomy for the express purpose of removing the protruded portion of the disk should be performed," should, in the light of our increased knowledge of the lesion and our increased technical ability, be changed to, "When a definite protrusion is demonstrated and a lesion at the level of the protrusion will explain the patient's symptoms and signs, it

should be removed." This change is necessitated by the fact that since December, 1938, it has been possible in a large percentage of cases to remove protruded intervertebral disks without removing any bone from the spinal column.

In order to perform such operations it is essential that the operator know which disk is protruded, have special instruments and a large experience dealing with small intraspinal lesions. It is therefore essential in the great majority of cases to have the lesion visualized by a contrast medium. The use of a contrast medium serves not only to demonstrate the protrusion but also to exclude or demonstrate other lesions. Since not infrequently protrusions are multiple it is necessary to know the condition of the other disks. At times also the history and findings on examination seem to indicate definitely that the difficulty experienced by the patient is the result of a disk protrusion, whereas in reality the true pathology is an intraspinal neoplasm. This may be recognized at the time of diagnostic lumbar puncture, at the time of visualization of the spinal canal or only when the lesion is uncovered at operation. When operating, therefore, for a protruded intervertebral disk, the surgeon should be prepared to handle any intraspinal lesion that might be encountered. The electrosurgical unit, suction apparatus and other special apparatus that is standard equipment in a modern neurosurgical amphitheater should be at hand and

*From the Section on Neurosurgery, The Mayo Clinic, Rochester, Minnesota. Read before the meeting of the Minnesota State Medical Association, Rochester, Minnesota, April 22, 1940.

ready for use. Well-trained assistants and surgical nursing staff are essential.

All patients who come to The Mayo Clinic complaining of pain low in the back or sciatic pain or both are not operated on for protruded intervertebral disk. In fact, all patients with such a complaint are not fully investigated for such a lesion. Only those patients who have definite evidence of pressure on the spinal cord or on a nerve root and those who are unable to carry on their normal activities are thoroughly investigated (that is, by studies of the spinal fluid with or without visualization of the spinal subarachnoid space). These patients who have had distress for a short time and who show no impairment of nerve function and those who are able to keep up with their usual work with the aid of some physical therapy plus the wearing of a support are not urged to undergo extensive investigation with the idea of undergoing operation. We see many patients whose history and physical examination suggest the probability of protrusion of a disk and we advise conservative therapy for them. They are told what we suspect as the underlying pathologic lesion and are told that if the symptoms increase in severity or become incapacitating, then they should submit to a thorough investigation and possibly to operation.

In order to accomplish most for the large group of patients who have backache and sciatic pain, team work and coöperation on the part of the patient, the family physician and those in special fields is essential. The general condition of the patient must be evaluated not alone from the standpoint of physical health but also from the economic point of view. His home life should be considered, the type of work to which he is accustomed and whether or not there is an insurance or compensation angle.

When it is agreed that the patient is incapacitated as far as his usual activities are concerned and that relief must be offered, the close coöperation of the clinician, orthopedist, neurologist, roentgenologist and neurosurgeon will result in the best possible care. Today it is impossible for any one doctor to know all branches of medicine well and only through close coöperation can we expect to obtain the best results from our therapeutic endeavors.

When an operation for protruded intervertebral disk is to be undertaken, all pertinent factors relative to the diagnosis, the patient's general

physical condition, the presence of complications, orthopedic or otherwise and the surgeon's experience plus the question of insurance or compensation liability should be thoroughly considered. There are many things other than the presence of a protruded portion of fibrocartilage within the spinal canal which influence the result of therapy.

The mere presence of a history of backache and sciatic pain or of both, even with positive roentgenologic evidence, is not sufficient indication for a surgical attack on the lesion if these are any other factors of greater weight which contraindicate a major surgical procedure. The operative removal of a protruded disk is a major surgical procedure and it should not be attempted by anyone not familiar with intraspinal surgery. Although the history, findings and roentgenograms may indicate the protrusion of a disk, at operation a primary tumor of the spinal cord or of the nerve roots may be encountered. This is true even in spite of the onset of symptoms after a specific injury. I recall a young girl who related what we could call a typical history of protrusion of a lumbar disk and the findings on physical examination likewise were typical. At operation, however, she was found to have an ependymoma of the filum terminale. An extensive intradural operation that required the use of the electrosurgical unit and all of the special neurosurgical equipment had to be performed. Before undertaking an operation for a protruded disk, it is extremely important to know whether or not there is an insurance or compensation angle. This is important not alone for studies of final results but also for carrying out the pre-operative examinations, evaluating symptoms and following the patient's postoperative period of hospital convalescence. Patients who think that compensation may be had for the most part make poor witnesses for themselves in the examining room. Their symptoms are likely to be bizarre, more numerous and much more marked than those of an individual who is interested only in getting relief from his distress. Patients who have compensation in view seem to feel that they must impress the examiner with their terrific plight. One must be very careful in examining such patients lest he be misled into placing too much emphasis on inconsequential symptoms and signs, or lest he overlook pathognomonic signs hidden by functional states.

In order to check up on our diagnostic ability and to evaluate the progress of the neurosurgical attack on intractable backache and sciatica, I asked Dr. Patton, neurosurgical first assistant, The Mayo Foundation, to analyze the last 100 records of cases previous to January 1, 1940, in which operation was performed because of a diagnosis of protruded intervertebral disk. Out of this study came some very interesting facts. These cases represent 100 consecutive spinal operations performed by Adson, Craig, Baker and me. Of the 100 patients, ninety-one were found to have a protrusion of a single disk, whereas each of three patients had two protruded disks. The remaining six patients were found to have thickening and fibrosis² (so-called hypertrophy) of one or more ligamenta flava without protrusion of a disk. Four of these six cases had two abnormal ligamenta flava whereas the other two had only one thickened ligament.

In the period covered by these 100 cases, radiopaque oil* was injected in eight cases to confirm our clinical diagnosis and to locate more accurately the level of the lesion. In seven of the eight cases, the roentgenologic findings were positive for protruded disk; in the eighth case the findings were reported by the roentgenologist as negative. In view of this patient's history and clinical findings, the neurologist, neurosurgeon, and orthopedist all felt that radical treatment was indicated. He had had all the conservative measures without relief. His story was suggestive of a protruded disk. The patient's fourth and fifth lumbar disks were explored by the neurosurgeon without detecting any abnormality. There was definite thickening and fibrosis of the ligamentum flavum which was resected. The orthopedist who was present transplanted a graft from the flat internal surface of the patient's tibia to the lumbosacral region for the purpose of fusing the last two lumbar vertebrae and the first two sacral vertebrae. This procedure had been explained to the patient prior to his decision to have an operation.

At times, because of the coexistence of an orthopedic condition, a bone graft is applied by the orthopedic surgeon after the neurosurgeon has removed a typical protruded disk.

It is the opinion of orthopedists and neurosurgeons at the clinic that bone grafting or fusion is necessary in only a small percentage of cases in which a protruded disk is found and is removed.

Results of Operative Treatment of Protruded Intervertebral Disks

When a patient is operated on and a classical protrusion of a lumbar disk is removed because of its production of pain low in the back or sciatic pain or both, that patient should obtain immediate relief of his symptoms. In a small percentage of such cases, several days will elapse before complete relief ensues. In a very small percentage of cases the patient will experience immediate relief but will have some distress when up and around for as long as two or three months after operation. The patient whose convalescence is not complicated by other organic lesions or medico-legal problems is usually back at his occupation three months after dismissal. In any compensation case or insurance case, at least twice as long a period of convalescence is likely to be required. Such individuals must be convinced that they are relieved and are able to carry on normally. If compensation is pending and there is a dispute regarding liability, and particularly if there is going to be a trial in open court, the patient is prone to have a neurosis develop and to present many symptoms which cannot be explained on an organic basis. The most careful examination may fail to reveal any signs indicative of organic disease and those signs which were present prior to operation may be gone but the patient will insist that he is incapacitated and unable to do any work. If the question of insurance and compensation could be settled prior to operation, I feel sure this group of patients would obtain a much more satisfactory final result.

That the surgical removal of protruded intervertebral disks is based on sound anatomic, pathologic and surgical grounds is clear to all who have had much experience with the lesion. That all patients are not relieved of their complaints following operation likewise is apparent and is again admitted.

When we stop to consider, however, that this group of patients is suffering from intractable pain which has been present on the average for several years and which has not responded to any type of conservative treatment or to many

*Although radiopaque oil is by far the best contrast medium for the visualization of the spinal canal we have tried to avoid its use whenever possible because of its slow absorbability. This is particularly true in the handling of medico-legal cases. It is so easy for the patient who has an opaque substance in the spinal canal to try to capitalize on its presence. We are now using air almost entirely for visualization of the lumbar region of the spinal canal.¹

types of radical operations, such as manipulation under anesthesia, open operation and stretching of the sciatic nerve, fasciotomy and bone grafting, we can still speak optimistically about the results of surgical removal of the protruded portion of intervertebral disks even though this operation does not relieve all patients.

At the present time we are undertaking a follow-up study of all patients operated on at The Mayo Clinic for protruded intervertebral disk. This study will require a great deal of time and effort and when it is completed the results will be published. At present, although we cannot yet give accurate statistics on our cases, there are certain observations which have been made which seem worthy of record.

The mortality rate associated with operations for protruded intervertebral disks in our hands has been about 0.5 per cent. About 3 to 5 per cent of the patients who come to operation for a protruded disk require bone grafting or fusion because of a coexisting orthopedic condition. The fusions are performed at the time of the intraspinal operation by one of our orthopedic colleagues who, of course, has seen and examined the patient prior to operation. About 1 per cent of the patients will return, usually after unusual stress or strain to the back, for the removal of another protruded disk. About 1 or 2 per cent of the patients who have been operated on for a protruded disk will require fusion subsequently because of a static type of backache or because of failure to obtain complete relief following the removal of the protruded disk.

In spite of the most careful selection of patients for operation and the most painstaking care in the performance of these operations, there will be a group of patients who are not completely relieved. Some of these will fail to obtain relief because of the coexistence of other diseases which may produce or contribute to the production of the same symptoms, such as spondylitis, endarteritis obliterans, diabetes and old vertebral fractures (rare with protruded disks). Patients with a low threshold to pain may continue to complain of distress in the back and may focus their minds on the site of operation. There are others, who, often for reasons best known to themselves and at times when discovered by the physician adequate enough, have an overpowering desire for sympathy and continue to enjoy "poor" health. In some cases, it is obvious

at the time of operation that the compressed cord or nerve root has sustained irreparable damage and even though the pressure is removed the patient is likely to have residual symptoms or signs. In other cases, the nature of the lesion must be that of an interstitial neuritis (from pressure) with marked fibrosis. At times it can be seen that some of the fibers of the compressed nerve root have been interrupted by the protruded disk.

By far the most troublesome group and the hardest to appraise satisfactorily consists of those cases in which there is litigation pending. This group demands the utmost consideration not alone because of the difficulties involved but also because of the great tendency for people to sue one another and particularly to sue corporations in an attempt to obtain compensation for their misfortunes regardless of whether or not the suit is justified. In this connection careful attention should be paid to the taking of the history in these cases and dates of alleged injuries should be recorded. The question of compensation and insurance problems should be noted, if it is possible to get the information, while the history is recorded. Any physician who has seen many industrial, automobile or railroad accident cases knows how difficult it is to obtain an excellent result in such cases. Likewise, if a patient is carrying disability insurance that will pay him more than his declining income, it is easy to see that it might be difficult to cure him by means of any type of therapy. The insurance companies, of course, realize this, and the larger companies are very careful about writing policies with clauses which would entitle the insured to collect as much as or more than his income in case of disability.

We, as physicians, must continue, of course, to do everything that we can to alleviate suffering and we must strive to restore all injured persons to their former activities, but at times there are factors over which we have little or no control and these factors militate against the success we so sincerely desire from our therapeutic efforts.

INTRACRANIAL TUMORS*

A Study of 467 Histologically Verified Cases

A. B. BAKER, M.D.

Minneapolis, Minnesota

SINCE the appearance of the various studies on the classification of the glioma group of brain tumors (Roussy, L hermitte and Cornil,²⁸ Roussy and Oberling,²⁹ Bailey and Cushing,⁹ and Bailey^{4,5}) a great impetus has been provided for the investigation of all intracranial tumors. Many investigators have reviewed those brain tumors that have been available in their laboratories, in an attempt to reclassify these neoplasms in the light of these more recent advances. An attempt has also been made by some to correlate the various individual histological types with the age of the patient, the location within the brain or intracranial cavity, the rapidity of growth and finally the amenability to surgery or the response of the tumor to deep x-ray therapy. Such reports have been published by Davidoff and Ferraro,¹⁶ Cushing,¹⁴ Bailey,⁴ and Gogel.²⁰

In keeping with these advances in our knowledge regarding the intracranial neoplasms, an attempt was made to collect, study and reclassify all such tumors that were available from the Department of Pathology and the Division of Nervous and Mental Diseases of the University of Minnesota. Only those cases were selected in which sufficient material or sections were available to allow for a careful histological study. Much of the older material was unsatisfactory while in many cases no material had been preserved. After due selection there remained a total of 467 tumors that were used in the present investigation. For our statistical studies we also included twelve pituitary adenomas which had been unmistakably diagnosed by x-ray, thus bringing the total tumors to 479. Because of the infrequency of operation upon pituitary adenomas and also because of their prolonged course, they are infrequently obtained for histological study. It is for this reason that these 12 clinically diagnosed cases were included, in order to make this present series as representative as possible. In all cases fairly complete records were available. This material appeared to us to offer a fairly accurate picture of the frequency of the

various types of tumors, inasmuch as the cases were obtained without selection throughout the state. Since the greatest portion of the material was obtained at autopsy, (406 out of 479 cases or 85 per cent), a study of the whole tumor was usually possible as well as a careful investigation of the varying histology in different portions of the tumor.

The intracranial tumors in this study were divided into the following nine groups described and used by Bailey: tumors of the nerves, tumors of the meninges, gliomas, vascular tumors, tumors of mixed tissue, hypophyseal tumors, granulomas, miscellaneous group, and metastatic tumors. The relative frequency of each is listed in Table I.

A comparison of our figures with those of other investigators is shown in Table II. All figures have been corrected to coincide with the classification presented in this study.

A brief statement concerning our experience with these groups of intracranial tumors can now appropriately be undertaken.

Tumors of Nerves

This group of intracranial neoplasms includes the acoustic neuromas, the optic nerve gliomas, and the cerebral type of neurofibromatosis. It comprised but 1.5 per cent of our cases. This is in direct contrast to the series of Bailey⁴ and Cushing,¹⁴ where 176, or 9.1 per cent, of their tumors were acoustic neuromas alone. The latter tumor, which was by far the most common one in this group, arises from the nerve sheath, although there is still some question as to whether they are Schwannian or connective tissue in origin. Most investigators feel that they probably arise from the endo-perineurium and are collagenous in origin. The nerve fibers usually passed around this tumor and were never found within it.

A von Recklinghausen's disease in which the predominant involvement is intracranial is of rather unusual occurrence; only one such case appeared in the present series.

Optic nerve gliomas are also extremely uncommon. Verhoeff,³⁰ at the Massachusetts Eye and

Total	1938	73	443	479

Ear Infirmary, encountered four out of a total 669,857 patients, while Martin and Cushing²⁵ recorded seven chiasmal tumors out of a total 826 intracranial neoplasms. These tumors are usually gliomas, our case being a fairly typical slow growing astrocytoma. The patient, five years after a partial removal, is still living and well. It appears that these new growths either take origin and remain confined to the intraorbital portion of the nerve or that their growth is slow enough to allow for a long span of life in spite of non-complete removal.

Tumors of Meninges—Meningiomas

These are, as a rule, benign encapsulated masses that rarely invade the brain but compress it and may, because of their slow growth, reach huge dimensions. As is well known they frequently invade the skull, producing increased vascularization, hyperostosis or even direct erosion. The current name for these tumors has been adopted as meningiomas, although Mallory²⁴ and Penfield²⁷ have felt that on histological grounds the cells of the leptomeninges belong to the fibroblastic series and that these neoplasms should be called arachnoidal fibroblastomas. It is recognized today that they are derived from some embryonal rests in the meninges, but beyond this there is little agreement. Since the probable origin of these tumors is still a moot question, it

seems best to adopt the non-committal term of meningioma until further information is acquired concerning their origin.

In the present study there was a total of eighty-eight meningiomas, which comprised 18.4 per cent of all intracranial tumors. This compares fairly closely to most other series (Bailey and Cushing, 14 per cent; Gogel, 18.7 per cent). Sixty-five per cent of these tumors occurred between the fifth to the seventh decade, while 6 per cent occurred within the first decade. As could be expected from such a slow growing tumor, over one-third of the cases gave histories dating back over a period of at least three years.

The location of the meningiomas was of great interest. The greatest number arose from the region of the sagittal sinus, fourteen being situated anteriorly and four posteriorly. The next most common location was the sphenoid ridge, where ten of the tumors were situated. Next, in order of frequency, these tumors occurred in the cerebellopontine angle, eight; tuberculum sellae, 7; cribriform plate, seven; dura over temporo-parietal region, six; foramen magnum, five; clivus, three; torcula, three; dura over temporal region, two; corpus callosum, pineal and dura over the parietal and occipital regions, one each.

Histologically they presented a great variability in tissue structure. For this reason they were reclassified according to the most prominent

type of tissue present (Table III). This type of classification was used by Bailey and Bucy⁸ in their publication on meningiomas.

TABLE III. HISTOLOGIC TYPES OF MENINGIOMAS
(18.5 per cent of all intracranial tumors)

Tumors of Meninges	Number	Per Cent
1. Fibroblastic	36	40.9
2. Psammomatous	19	21.6
3. Meningotheliomatous	12	13.6
4. Mesenchymal	3	3.4
5. Angioblastic	3	3.4
6. Melanoblastic	3	3.4
7. Lipomatous	3	3.4
8. Osteoblastic	2	2.3
9. Sarcomatous	1	1.1
10. Undetermined	6	6.8
Total	88	100.0

It is seen from this division that the most common type of meningioma was composed of fibroblasts with the tumor cells forming fibroglia and laying down collagen. It was to this group of meningiomas that Mallory's term of arachnoidal fibroblastomas was applied. Although some fibroglia and collagen fibers were found in many of the other histological types, still the predominant tissue was of another nature and hence warranted a different classification. The next most frequent and probably better known types of meningiomas were the meningotheliomatous and psammomatous varieties, which comprised almost 35 per cent of the meningiomas. The meningotheliomatous variety consists of sheets of cells in which the cell boundaries are hard to distinguish. When the cells tend to assume whorl formation within the center of which are frequently found concretions, the cell type is spoken of as psammoma. In many respects these two varieties are very similar histologically. The rest of the histological varieties of meningiomas were fairly uncommon.

It was apparent from a comparison of the case histories and the histological types, that the fibrous, psammomatous and meningotheliomatous varieties were relatively slow growing tumors. The most rapidly growing meningiomas were the mesenchymal and sarcomatous varieties with an average duration of symptoms of only 2 and 3.5 months, respectively. The slowest growing type was the osteoblastic with an average history of twelve and nineteen years in each of our cases.

Gliomas

This group has received a great deal of attention during the past number of years due to the most enlightening contributions of Bailey on their histological structure and classification. Bailey's classification of the gliomas was first published in 1926. In spite of the numerous alterations and additions (Penfield,²⁶ Bergstrand,¹¹ Carmichael¹²) the classification as presented by Bailey has appeared to be the most practical and has been adopted for use in our laboratory. The percentages of each type of glioma in our studies as compared with other investigators are presented in Table IV.

It will be seen that the relative frequency of the various gliomas in most studies is fairly consistent with the exception of the astrocytomas which were somewhat more numerous in our series. This difference may easily be accounted for in the individual variation in the histological interpretations of cell type. It is very likely that some of the tumors which we were inclined to classify as rapidly growing astrocytomas have been considered by other investigators as glioblastomas.

The usual location of our gliomas have been tabulated in Table V. The greatest number occurred in the frontal, temporal, and parietal regions. The medulloblastomas were almost exclusively cerebellar tumors, while the ependymomas seemed to have the widest distribution and appeared in almost any region of the brain. Many of the tumors were so extensive as to involve more than one region and hence were included under more than one location.

The relative age distribution and age incidence of these tumors are summarized in Tables VI and VII. The age incidence was determined by calculating the frequency of the total number of gliomas in each decade compared to the total number of autopsies performed. We were forced to omit the first decade since the many stillbirths included in this age group prevented an accurate determination.

When gliomas of all types were considered they appeared with almost equal frequency during the first six decades of life. The cerebellar tumors (astrocytoma and medulloblastoma) and the ependymomas tended to occur most frequently during the earlier decades, although cerebral astrocytomas and glioblastomas were by no means uncommon during this period. If the former group of tumors were excluded, then the

gliomas appeared most commonly during the fourth to the sixth decades.

With these general remarks, it would seem appropriate to briefly summarize some of the characteristics of the individual gliomas. De-

tailed histological descriptions will be avoided, since such excellent reports on this subject have already been published (Bailey,^{1,3,2} Bailey and Bucy,^{7,6} Kwan and Alpers,²² Globus and Silber¹⁹).

The astrocytoma was the most common type of intracranial neoplasm comprising almost half of the gliomas and one-fourth the total intracranial tumors. It was a slow growing infiltrating tumor with a tendency to degenerate with cyst formation. The longest duration of symptoms in our series was twenty-two years, while twenty-three of the cases gave a history of three years or longer. In adults it was most commonly situated in the frontal, temporal and parietal lobes, and appeared usually during the fifth and sixth decades. In children it occurred with about equal frequency within the cerebellum and cerebral hemispheres. About 30 per cent of these tumors were cystic or associated with a cyst.

The glioblastoma multiforme was usually a rapidly infiltrating tumor arising within the white substance of the cerebral hemispheres. It presented an extreme multiformity in the size and shape of its cells and a great variation of appearance due to associated hemorrhages and necroses. It comprised about one-fourth of the gliomas and involved primarily the frontal and parietal regions of the brain. It occurred most frequently between the fourth to the sixth decades of life. The longest duration of symptoms was twelve years, while only six gave a history extending over three years. In most cases the tumor was rapidly growing and offered a life expectancy of less than one year after the onset of symptoms.

The medulloblastoma was primarily a cerebellar tumor of children. It comprised about 7.5 per cent of the gliomas. Fourteen of our twenty-one cases occurred during the first two decades of life, only one occurring as late as the fifth decade. This tumor was very rapidly growing and involved primarily the midline of the cerebellum, in which cases the life expectancy after the appearance of symptoms was less than eight months. Only 3 per cent of these tumors were cystic, the rest being fairly solid but somewhat soft and reddish.

The spongioblastoma polare was a relatively uncommon tumor. It is reported to be most common in the region of the brain stem, although in our series it occurred in widely scattered regions of the brain (Table V). This tumor occurred with equal frequency during the first and fifth decades. When occurring in the region of the base of the brain or within the posterior fossa it was usually a slow growing, fairly solid mass, one of our cases giving a definite history of involve-

ment for over twenty-three years. Those tumors appearing within the cerebral hemispheres were somewhat more active and offered a shorter life expectancy. Because of the general growth characteristics of this tumor one often wonders whether it is really composed of bipolar spongioblasts, or whether it could perhaps be an astrocytoma, which, because of some peculiarity of growth, has developed a bipolar appearance to its cells.

The ependymoma comprised 7.1 per cent of the gliomas. It appeared predominately in the younger age groups, thirteen of the twenty cases occurring during the first two decades of life. Most of the tumors were situated in the vicinity of the walls of the lateral ventricles chiefly in the region of the frontal and occipital horns. Only six occurred in the region of the fourth ventricle. In Bailey's original series, by far the greatest number were found in the posterior fossa in the vicinity of the fourth ventricle. Finckler and Coon¹⁸ reported eight cases, of which five occurred in the region of the lateral ventricles. Because of their location near the ventricular system, with early production of a block in the fluid flow, the duration of symptoms was usually short. Only one case presented a history extending over five years; the remaining all lived less than eight months after the onset of symptoms. Since these tumors pathologically are usually slow growing encapsulated masses one would suspect from the rather acute clinical course that they lay dormant for a long time without producing symptoms. Because of their inaccessibility to surgery, removal is usually difficult.

The oligodendrogliomas were all slow growing tumors of the cerebral hemisphere of adults. Our cases were too few to warrant any general conclusions. A few were calcified and hence allowed for x-ray diagnosis.

The remaining glioma types occurred too infrequently in our series to warrant any general comment.

Vascular Tumors

In these studies the classification of Cushing and Bailey¹⁵ was again followed fairly closely. These authors classified the vascular tumors of the nervous system into angiomas and angioblastomas.

The angiomas are usually considered as developmental anomalies capable of subsequent alteration in size and character. These are frequently

subdivided into venous and arteriovenous types. Because of the abnormal development and structure of the vessel walls, it is often difficult even histologically to tell whether one is dealing with arteries or veins. Since these tumors are malformations, they usually are very slow in their clinical course and appearance. One would, therefore, expect symptoms to be present over a long period of time. This was true in our cases. Of the thirteen angiomas, even though accurate histories were not obtained in all, eight presented symptoms for more than two years and three of these had symptoms for over ten years. The angiomas comprised 2.7 per cent of all the intracranial tumors. They occurred chiefly between the fourth to the seventh decades and all but three cases were found in the cerebral hemispheres. A more detailed study of these tumors will form the material for a later publication.

The angioblastomas are considered as true neoplastic growths. They were usually associated with large cysts, the tumor itself being small, reddish and solid and embedded in the cyst wall. These tumors were most frequently situated in the cerebellum (seven of our twelve cases) and produced clinical symptoms of a rapidly increasing intracranial pressure associated with some cerebellar involvement. The duration of symptoms before death or operation was surprisingly short. Lindau²³ in 1926 discussed the association of these cerebellar tumors with angiomas of the retina and cysts of the pancreas. He believed that angiomas of the cerebellum occurred in 20 per cent of the cases of retinal angiomas. This association of cerebellar and retinal angiomas has come to be known as von Hippel-Lindau's disease. In none of our cases was there an associated retinal angioma. The cerebral angioblastomas produced symptoms over a longer period of time than did those in the cerebellum. The angioblastomas appeared chiefly during the third and fourth decades, only one case occurring before the third decade.

Tumors of Mixed Tissue

These tumors are now accepted as arising from embryonic rests. If they contain tissues from all three germ layers, they are referred to as true teratomas. Only one such case occurred in our series. When tissues of mesodermal as well as epithelial origin are represented, they are called dermoid cysts. These are usually large cystic masses containing hair, teeth, bone and cartilage.

Only one such tumor was available for study and has been reported in detail (Gray²¹). The most common and simplest type of mixed tissue tumor is the epidermoid (pearly tumor, cholesteatoma). These are sharply circumscribed, irregular, firm and have the external appearance of mother-of-pearl. Histologically but one germ layer is represented, namely the ectoderm. These tumors are composed of a firm fibrous wall whose inner surface is lined by a layer of stratified epithelium, the innermost layer of cells often containing keratohylin granules. Often many flattened structureless cells are seen lining the innermost surface of the capsule. The interior of the epidermoids is composed of a broken down mass of debris consisting of cholesterol crystals and fatty material. Two cases occurred in our series. Both were slow growing and presented symptoms for many years. Since this compilation three more epidermoids have become available and will be incorporated in a detailed study in a separate report.

Hypophyseal Tumors

Both the pituitary adenomas and the craniopharyngiomas have been placed in this group of neoplasms. The latter have frequently been classified with the congenital tumors, but since no separate group of congenital tumors has been included in this study and because of the location and origin of the craniopharyngiomas it was deemed somewhat simpler to consider them with the tumors of the pituitary gland.

The pituitary adenomas, as is well known, may be of three varieties, depending upon the three types of cells found within the anterior lobe of the pituitary, namely, chromophobe, acidophil and basophil adenomas. The latter two are usually small in size and often escape postmortem detection, while the chromophobe adenomas are usually large and distort the chiasm as well as produce numerous clinical symptoms and signs. All are very slow growing, hence, the course in the patient is a long and chronic one with the patient usually drifting away from the original source of observation. For this reason there has been a great scarcity of postmortem tissues available for study. Since the location of these tumors does not lend itself for satisfactory surgery, operative procedures have been avoided unless the rapidly progressive loss of vision or the profound incapacitating headaches have forced such a procedure. Of late fragments of considerable number

of pituitary adenomas have been removed through operative procedures and reported by various authors. In our series the actual number of histologically verified adenomas has been very few (ten of twenty-two cases). In order, however, to balance our statistical studies we have checked our clinical case histories of intracranial tumors and have included twelve cases in which x-ray investigations have definitely substantiated the presence of an adenoma of the pituitary. This produces a total of twenty-two pituitary adenomas or 4.6 per cent of the total intracranial neoplasms, as compared to 17.8 per cent in Cushing's series where operation was more frequent and where no doubt as regards this type of tumor, the material was somewhat selective. In most other series, the percentage follows fairly closely those quoted in this study.

The craniopharyngiomas or pharyngeal duct tumors are usually large irregular growths situated at the base of the brain, often extending upward into the third ventricle. They are usually firm tumors with a well defined capsule. Many are calcified, as well as cystic, containing a viscid yellow fluid. These tumors by their growth compress and destroy the pituitary as well as the optic chiasm and floor of the third ventricle. For purposes of description the craniopharyngiomas have been divided into the adamantinoma and the Rathke Pouch tumors.

The adamantinomas are composed of epithelial columns and are said to resemble the embryonic enamel organ. Twelve such tumors occurred in our series. The duration of symptoms was extremely short as judged from the histories. All but two presented symptoms for six months or less prior to death or operation, while the remaining two presented symptoms for one year and five months respectively. It is generally stated that these tumors occur in the younger age group. This was not entirely substantiated in our studies in which eight of the twelve cases occurred during or after the fourth decade. The majority of cases occurred in the fourth and fifth decades. Our youngest case was six years of age with symptoms having appeared one year previously.

Granulomata

In this group are placed the tuberculomas and the gummas. In our series, these comprised 6.3 per cent of all the intracranial neoplasms. This figure is a little higher than is found in most

other series (Bailey and Cushing, 2.3 per cent; Gogel, 1.4 per cent).

The tuberculomas were four times as frequent as the syphilomas, comprising 80 per cent of all the granulomas. Tuberculomas are uncommonly observed in a general hospital. In most studies the greatest incidence of tuberculomas have been in children. This does not seem to follow in our studies where fifteen of the twenty-four cases occurred during or after the third decade, only seven cases appearing during the first nine years of life. The highest incidence of occurrence was during the third decade in which eight cases appeared. It has been frequently stated that one of the most common locations of a solitary tuberculoma is in the cerebellum. Only eight of our total cases occurred in this organ. Thirteen were found in different regions of the cerebral hemispheres excluding the basal nuclei which alone contained four. Treatment was limited because most of these tumors were either inaccessible or multiple. Surgical removal even in accessible tumors is often inadvisable because it is frequently followed by a meningitis which is invariably fatal. Only four of our cases contained multiple lesions.

Gummas are extremely rare occurrences. Our series contained six cases, all of which were found in the cerebral hemispheres. In recent years due to the intensive antiluetic therapy, this type of lesion has become a medical and pathological curiosity.

Miscellaneous Tumors

Such tumors as colloid cysts of the third ventricle, true cysts usually cerebral in origin, fibroblastomas and chordomas were included in this group. The number of such tumors in our series were too few to warrant discussion. We have studied two fibroblastomas of the brain, both of which have been reported in detail (Baker and Adams,¹⁰ Cottrell¹²).

The metastatic brain tumors are not included in the present statistical analysis, but will form the subject of a future report.

Summary

1. A statistical study of 467 histologically verified intracranial tumors is presented.
2. Eighty-five per cent of the neoplasms were obtained at autopsy, hence, allowing for a careful investigation of the varying histology in the different portions of the tumor.

3. An attempt is made to correlate the various histological types of tumors with the age of the patient, the location within the brain or intracranial cavity and the rapidity of growth.

SMALL CARCINOMATOUS GASTRIC LESIONS SIMULATING CHRONIC BENIGN ULCER: PRESENT STATUS OF DIFFERENTIAL DIAGNOSIS AND TREATMENT*

GEORGE B. EUSTERMAN, M.D.

Rochester, Minnesota

EVEN in this unprecedented era of scientific progress the medical profession cannot view with complacency the fact that 75 per cent of the patients with gastric carcinoma come to the surgeon too late for successful operation. Increased ability to diagnose early gastric carcinoma can be obtained only by more respectful consideration of the accepted precursors of this disease namely, gastric polyps, ulcers and chronic inflammatory changes in the gastric mucosa, and prompt recourse to roentgenoscopic and endoscopic examination of each patient more than thirty-five years of age who suffers from digestive disturbances, however mild, or has lost weight for some unexplainable reason. It is apparent that the rank and file of the medical profession are becoming increasingly conscious of the fact that small or circumscribed, innocent looking ulcerous gastric lesions may be actually or potentially ma-

lignant. Progress in our knowledge in this respect so far is due largely to the disclosures of the fluoroscopic room and the unexpected results of histologic examination of presumably benign excised lesions or lesions in resected portions of the stomach.

If a physician is confronted by a patient harboring a small ulcerating gastric lesion which the roentgenologist has been able to visualize, how may he best determine its possible natures that he may carry out that procedure which will serve the patient's best interests? Obviously, in the absence of a specific biologic test for carcinoma, certain symptoms and signs, or what is more to the point, a grouping of certain symptoms and signs, must be depended on to point the way.

Although it seems logical at the outset to consider the significant features elicited by the anamnesis and gastric analysis, it is really more practical to evaluate the objective evidence presented by the roentgen film. If the patient's phy-

*From the Division of Medicine, The Mayo Clinic, Rochester, Minnesota. Read before the eighty-seventh annual session of the Minnesota State Medical Association, Rochester, Minnesota, April 22, 1940.

sician is fortunate enough to have the coöperation of an experienced roentgenologist his opinion should be considered first because he may have made significant observations during the fluoroscopic examination that cannot always be depicted on the ordinary film. He may or may not have a positive opinion regarding the nature of the process.

Significance of Roentgenologic Examination

Two types of malignant gastric lesions may masquerade as chronic benign ulcer, namely, the small ulcerating carcinoma and the less frequent carcinomatous ulcer. The latter is an ulcer without evident tumefaction but which on microscopic examination proves to be carcinoma. In ulcerating carcinoma the cavity produced by the ulceration is usually situated well within the normal confines of the gastric lumen. If the meniscus complex described by Carman and Kirklin, which consists of a meniscal form of crater encircled by a transradial zone representing the approximated overhanging border, can be demonstrated, the lesion almost invariably proves to be malignant. The crater of a carcinomatous ulcer, like that of a benign ulcer, is sculptured as a niche in the gastric wall and invariably projects beyond the normal outline of the lumen. If this niche is large, that is, in excess of 2.5 cm. in diameter, if there is an absence of gastrosplasm and of tenderness on pressure, and if the adjacent rugæ are obliterated or if the margin of the niche is sharply conical or has an irregular profile, then the roentgenologist usually regards the ulcer as carcinomatous. A large niche without these associated features would even be looked on with some suspicion. My roentgenologic colleagues, in the interest of the patient's welfare, lean over backward to regard large size or any irregularity of the lesion as signifying its actual or probable malignant nature. This is evidenced by the latest statistical study, indicating that in 26 per cent of cases in which the lesion was diagnosed by the roentgenologists as questionably malignant the condition was actually benign.

Unfortunately a small carcinomatous ulcer with a small niche may have all the other roentgenologic characteristics of benign ulcer. In the review of a large series of cases, 7 per cent of the lesions unequivocally diagnosed in recent years as benign ulcer by my roentgenologic colleagues were actually carcinomatous.

Significance of Situation and Size of the Lesion

The situation of the lesion is of relative significance in differential diagnosis because lesions that are near the pylorus, on the greater curvature, or well up on the posterior wall of the stomach, have a greater tendency to be carcinomatous than those on the lesser curvature. In our experience at The Mayo Clinic the size of the lesion has a definite bearing on diagnosis, although I realize that this aspect of our problem is still controversial. According to MacCarty,^{11,12} the average diameter of carcinomas of the stomach excised at The Mayo Clinic up to 1931 was 6.1 cm. From 1918 to 1937, inclusive, out of 1,978 carcinomas removed at operation, according to this observer, 128, or 6.5 per cent, of these were small carcinomas (2.5 cm., or smaller, in diameter). By way of comparison, 3,358 cases in which a diagnosis of gastric ulcer was verified either by roentgenologic examination or operation, came under our observation during the same period. In 2,324, or 69 per cent, the ulcer was removed at operation and histologically verified. Alvarez and MacCarty (1928) showed that although the excised benign ulcer is comparatively small, 79 per cent of them being smaller than a dime (1.8 cm. in diameter) and 92.3 per cent smaller than a quarter (2.4 cm. in diameter), 23 per cent of the carcinomas removed were within the size range of benign ulcer (4 cm. or less in diameter). On the basis of the observations of Alvarez and MacCarty my roentgenologic colleagues consider any lesion more than 2.5 cm. in diameter as carcinomatous until proved otherwise. There are, of course, frequent exceptions to the rule. It is apparent that the great majority of benign lesions and thus far a minority of carcinomas are of small size.

From a study of 135 carcinomas and 513 benign ulcers, in which the upper limit for the diameter of the lesions was 4.4 cm., Comfort and Butsch found that on the basis of incidence alone a resectable lesion had approximately four chances out of five of being benign.

Significance of Symptoms

To what extent does a case history contribute to differential diagnosis? The majority of benign gastric ulcers are accompanied by the classic syndrome of ulcer, although not to the same degree or with the same frequency that characterized

duodenal ulcer. A typical history of ulcer favors benign ulcer but does not exclude the possibility of a malignant lesion; contrariwise, an irregular or nonulcer type of history does not exclude the possibility of a benign lesion being present. A change in symptoms in the absence of demonstrable complications, such as pyloric obstruction, penetration, or perigastric involvement, implies, but does not necessarily signify, carcinomatous transformation. Thus, it will be seen that the symptoms per se are only of secondary value in the differential diagnosis. Naturally, in scrutinizing and appraising symptoms, the age of the patient, duration of symptoms and the findings on gastric analysis are considered. Here the observations of Comfort and Butsch are again enlightening. They showed that whatever the duration of the symptoms, the type of history, or the concentration of free hydrochloric acid, and whether or not a change in symptoms has occurred, or gastric retention, or occult blood is present in the gastric contents, a gastric lesion within the size range of most benign ulcers is benign more frequently than it is malignant. "This is especially true when the patient is less than thirty years of age (odds 20:1), when the symptoms are of the ulcer type (odds 5.6:1), when the symptoms are of ten years' duration or longer (odds 12:1), and when the concentration of free hydrochloric acid is greater than 60 clinical units (odds 51:1)."

Further observations with reference to sex, age at time of onset, gastric secretory and motor status and results of examinations of the stool are of interest. Gastric carcinoma and peptic ulcer are three times more frequent among men than among women forty years of age or older; in spite of this fact studies at the clinic have demonstrated that sex does not aid materially in determining whether the lesion is benign or malignant. The difference in the average age of patients with small carcinomas (52.9 years) and with ulcers (48.5 years) is too small to be of any value. We have found, however, that although the incidence of ulcer is greater than that of carcinoma in all decades, ulcer is twenty times more prevalent than carcinoma in the third decade of life. Advanced age and recent onset of symptoms characterize many cases of carcinoma of all types and sizes. One significant combination of circumstances, advanced age, recent onset, reduced acid titer, especially histamine refractory

achlorhydria, irrespective of the size of the lesion, favors a diagnosis of malignancy. The added feature of pyloric obstruction and achlorhydria almost invariably point to malignancy.

Systematic examination of the feces for occult blood under controlled conditions should be a routine procedure, especially when the patient is undergoing treatment in the hospital. Gutmann and his associates, in their recently published volume devoted exclusively to early gastric carcinoma, regarded this procedure as next in importance to the roentgenologic examination. The continuous presence of occult blood after two to three weeks of treatment makes necessary the exclusion of carcinoma; persistent absence of occult blood from the stools is a strong indication of a benign lesion, although it does not entirely exclude carcinoma.

Significance of Gastrosopic Findings

From our experience at the clinic it is not yet clear to what extent gastrosopic examination is helpful in distinguishing between small ulcerous types of carcinoma and chronic benign ulcer. Schindler has maintained that this examination is a valuable procedure and he has described differential aspects of carcinoma and benign ulcer. He stated that the gastrosopic appearance of a lesion may at times be more informative than the observations of the surgeon or pathologist concerning the gross specimen, and second in importance only to the microscopic examination. He has attributed this advantage to the high relief pattern and the brilliantly colored appearance of the living tissue in the gastrosopic picture due to the presence of circulating blood. Palmer, with whom Schindler recently has been associated closely, has expressed the belief that the gastrosopic examination is of great differential value in experienced hands but that it is by no means infallible. It is the better part of wisdom to submit to gastrosopic examination all patients who harbor lesions in which malignancy cannot be excluded, especially if such patients are not going to be promptly submitted to operation.

Significance of Results of Medical Treatment

Regardless of opinions to the contrary, the results of adequate medical treatment are only less decisive in distinguishing a benign from a circumscribed malignant process than surgical removal and histologic examination of the lesion.

I say this with full cognizance of the fact that the physician may be lulled into a false sense of security as the result of such treatment. In the first place, relief from symptoms, even though complete for the time being, is no criterion of

three days later. The gastroscopic appearance was that of a small benign lesion on the lesser curvature and anterior wall distal to the incisura angularis.

The patient was hospitalized and underwent intensive treatment for more than a month. Roentgenologic examination was repeated April 18, 1938, but this failed

Fig. 1. Appearance of stomach: *a*, March 28, 1938, shallow crater on lesser curvature slightly below angle of stomach; *b*, April 18, 1938, crater of ulcer not visible, but area of induration at site of former crater; same picture June 2, 1938; *c*, January 17, 1939, small filling defect of recurrent ulcerating lesion just below angle of stomach; malignancy cannot be excluded.

benignancy. Neither is progressive diminution of the niche, and in *rare* instances, neither is its complete disappearance even when confirmed by roentgenologic and gastroscopic examination, as illustrated by the following case.

Case 1.—A man, aged sixty-eight years, came to The Mayo Clinic on March 21, 1938, because of stomach trouble. In 1923 and 1928 he had experienced brief periods of gastric distress coincident with unusual nervous and physical strain. This distress, which was characterized as gas, and hunger pain, was situated in the epigastrium and appeared about two hours after each meal. On relief from occupational stress the symptoms promptly disappeared. The present illness began about three months prior to his admission to the Clinic, during the Christmas holiday (December, 1937). Epigastric distress appeared about one hour after each meal and persisted for several hours. Alkalis or milk afforded relief. There was no impairment of weight, appetite or strength. In February, 1938, a gastric ulcer was diagnosed after a roentgenologic examination. Ambulant treatment for ulcer was promptly instituted and the symptoms disappeared. Because there was not a proportionate improvement in the roentgenologic appearance of the lesion, the patient was referred to the clinic for an opinion.

The general physical examination gave satisfactory results. The patient was short, stocky and well nourished. Gastric analysis following an Ewald meal revealed a total acidity of 32 clinical units and free hydrochloric acid, 20. The total contents removed measured 125 c.c. Roentgenoscopic examination on March 28, 1938, revealed a shallow ulcer on the lesser curvature just below the incisura angularis (Fig. 1*a*). Its presence was confirmed by gastroscopic examination

to disclose any sign of the ulcer (Fig. 1*b*). On gastroscopic examination on July 7, 1938, the original ulcer had disappeared completely. Roentgenologic examination on September 14, 1938, again revealed normal conditions. The patient had experienced none of his previous distress in the meantime. He was, however, asked to return periodically for reexamination on account of his advanced age and the recent onset of the symptoms. On January 17, 1939, there was roentgenologic evidence of a recurrence of the ulcerating lesion (Fig. 1*c*). Two days later gastroscopic examination revealed the lesion as depicted on the film. It was situated at the original site and appeared to be fairly well circumscribed, somewhat indurated, and 2 cm. in diameter. On June 25, 1939, partial gastrectomy was performed.

The pathologic findings were as follows: An ulcerating colloid carcinoma grade 3, measuring 2 by 2 by 1 cm. situated on the anterior wall and lesser curvature of the stomach, 3 cm. above the pyloric ring. The serosal surface of the stomach immediately underlying the ulcer showed carcinomatous lymphangitis. No lymphatic involvement was found (Fig. 2).

The patient was examined again on February 13, 1940, and appeared to be in excellent health. He had no disturbances of any kind and the examination failed to reveal any evidence of recurrence.

Templeton and Schindler recently reported that in five of a series of eighteen cases which had been carefully observed during medical management, and in which from a roentgenologic standpoint the lesion apparently had healed, shallow craters were still present on gastroscopic examination. It seems, therefore, that gastroscopic confirmation of roentgenologic evidence of complete healing is essential. However, with few ex-

ceptions, the complete and permanent disappearance of all symptoms and signs that can reasonably be attributed to the ulcer is usually reliable evidence of its benignancy. On the other hand, some sclerosed, indurated or perforated benign lesions will not heal, and the niche may persist in whole or in part. Even an uncomplicated ulcer may undergo complete healing, with persistence of the niche, as demonstrated by Unger and Poppel. That this should not occur oftener has frequently intrigued me when one considers the fact that the bulbar deformity caused by most duodenal ulcers will persist after such ulcers are healed. Small ulcerating carcinomas usually undergo few morphologic changes as a result of treatment. In some the crater actually enlarges. In rare instances, as pointed out by Rigler, the niche may disappear roentgenologically because the carcinoma has grown into the base of the ulcer. Occasionally the crater of lesions eventually proved malignant decreases in size, but as a rule the other signs, occult bleeding for example, or the symptoms, or both, may persist or recur within a short period.

The necessity for periodic reëxamination of patients who have had medical treatment only is important at all times and especially when such patients are past middle life. The possibility should be kept in mind that patients with chronic ulcers may undergo treatment at a time when the carcinomatous changes in the ulcer are microscopic and therefore an apparent cure may be secured temporarily. In MacCarty's experience the smallest carcinomas involve only the mucosal borders of the ulcer. This observer is also of the opinion that approximately 10 to 15 per cent of all chronic gastric ulcers undergo early and late changes which cannot be detected by any procedure other than microscopic examination. The necessity for further adequate supervision of patients treated medically is indicated by the fact that even these small lesions may be highly malignant and therefore their true nature should be determined without unnecessary delay. This fact was strikingly exemplified in the case reported by Rivers and Dry, of a young man aged twenty-seven years, who had two gastric lesions, the smaller one being carcinomatous. Balfour stated that the five-year survival of patients who had large malignant lesions of the stomach (60 sq. cm.) after operation was 10 per cent more than that of patients who had small malignant lesions

(20 sq. cm.). In explanation of this he concluded that the smaller lesions are more likely to be of a penetrating character and of a higher degree of malignancy than the larger ones. Among sixty-eight patients with small carcinomas or carcino-

Fig. 2. Ulcerating colloid carcinoma measuring 2 by 2 by 1 cm.

matous ulcers observed by Alvarez and MacCarty, thirty-six, or about 53 per cent, were dead within one and a half years following operation, presumably of recurrences.

It seems appropriate to revert to the moot subject of the relation of ulcer to carcinoma. That chronic ulcers, like adenomatous polyps, and chronic gastritis are the precursors of carcinoma is generally accepted today. There is considerable difference of opinion as to the incidence of carcinoma in ulcers. A minority of investigators, such as Palmer and Klein, take the extreme viewpoint that an ulcer rarely, if ever, undergoes carcinomatous transformation. With such an irreconcilable viewpoint we at the clinic cannot agree, on the basis of our own clinical and pathologic evidence. In a critical study of the histories of eighty patients who had undergone gastric resection for small ulcerous malignant lesions, Eusterman and Bueermann noted that 52 per cent of the patients had presented symptoms characteristic of benign ulcer with an average duration of such symptoms of eleven years. Eighty-two per cent of these had free hydro-

chloric acid in the gastric content. To ascribe such antecedent symptoms to nervous indigestion or other unlikely causes is, to my mind, begging the question. To what extent such symptoms could be ascribed to gastritis remains to be proved. In this connection, Konjetzny's well known observations in this field lead him to believe that carcinoma may develop in the edge of a benign ulcer or adjacent to the ulcer, but independent of it, related not to the ulcer, but to the gastritis, to which this authority attributes both the ulcer and the carcinoma.

A reasonable question is why not operate at once in every instance? In the first place, the great majority of small gastric lesions are benign, and many of the uncomplicated gastric ulcers heal readily. It is reasonable to presume that complete healing forestalls eventual carcinomatous changes. In the second place, as emphasized by Bloomfield and many other internists before him, gastric resection in the hands of the average surgeon is attended by a mortality sufficiently high so that the outlook for the patient will not be improved unless the menace of carcinoma exceeds the operative risk.

Summary and Conclusions

Carcinoma in its earlier stages is still diagnosed too infrequently. Circumscribed innocent looking ulcerous gastric lesions may be actually or potentially malignant. Satisfactory differential diagnosis, in the absence of a specific biologic test for carcinoma, is frequently impossible without recourse to microscopic examination of the lesion. On the basis of repeated clinical and pathologic observations, certain diagnostic criteria of relative or absolute value in differential diagnosis have been evolved.

The typical benign ulcer is small, usually not exceeding 2.5 cm. in diameter, and has certain familiar roentgenologic characteristics. When the patient is thirty years of age or less, a small ulcerous lesion associated with 40 units of free hydrochloric acid in the gastric contents after the Ewald meal is usually benign. A concentration of free hydrochloric acid of 60 or more clinical units (Ewald) also strongly favors benignancy. The benign nature of the lesion is also characterized by the permanent disappearance of all symptoms and signs following adequate medical treatment, irrespective of age, nature or duration of symptoms, or size or location of the lesion.

Although about a fifth of all malignant gastric lesions may be within the size range of benign ulcer (4 cm. or less in diameter) only 6.5 per cent of carcinomas are small ones (2.5 cm. or less). At least 5 per cent of lesions unequivocally diagnosed in recent years by our roentgenologists as benign ulcer were actually carcinomatous. The meniscus complex for all practical considerations is pathognomonic of ulcerating carcinomas, irrespective of size. The roentgenologic characteristics of carcinomatous ulcer are less definitive than the meniscus complex. Large niches are regarded with suspicion, but a large ulcer is not necessarily malignant. Other features suggestive of the possible malignant nature of the lesion are an elderly patient with late onset of symptoms, the combination of histamine refractory achlorhydria and pyloric obstruction, persistent occult blood in the stool during and after treatment, incomplete response to adequate treatment, and situation of the lesion near the pylorus, on the greater curvature or posterior wall, as well as certain features elicited by the gastroscopic examination.

The presence of a gastric lesion, however small, makes imperative adequate medical treatment and observation, if exploratory operation is not undertaken. This applies in particular to the middle-aged or elderly individual. Treatment is justifiable when the lesion is not frankly malignant as the majority of uncomplicated gastric ulcers heal readily under favorable conditions, and gastric resection, under average conditions, still carries a much higher mortality than the risk of death from carcinoma. The nature and degree of response to treatment are also important factors in differential diagnosis.

THE SURGICAL TREATMENT OF GASTRIC CANCER MASQUERADING AS BENIGN DISEASE*

WALTMAN WALTERS, M.D., Sc.D., and WILLIAM H. CLEVELAND, M.D.
Rochester, Minnesota

THE frequency of malignant lesions in the stomach in contrast to their rarity in the duodenum brings to gastric ulcer a special significance. Only constant recollection of this fact leads to rational treatment of such lesions. Though the gastric ulcer is less commonly encountered in clinical practice than duodenal ulcer—according to Eusterman and Balfour¹ one-twelfth as often at The Mayo Clinic—its presence is sufficiently common to deserve careful attention. In 1938¹⁰ at The Mayo Clinic a diagnosis of gastric ulcer was made in 178 cases and operation was performed in eighty-four, or 47.2 per cent. In the same year a diagnosis of duodenal ulcer was made in 2,215 cases and operation performed in 328, or 14.8 per cent. In 1939 there were 207 patients for whom a diagnosis of gastric ulcer was made and 109 were operated on, an incidence of 52.6 per cent. In 1939 a diagnosis of duodenal ulcer was made in 2,729 cases and operation carried out in 467, or 17.1 per cent. Unfortunately, too often gastric and duodenal ulcers are grouped under the misleading title of “peptic ulcer” and their inherent dissimilarities are neglected. They are thus not recognized as occurring in individual types of tissue in which there is a difference both in pathologic reaction and in response to medical and surgical treatment.

A large, chronic gastric ulcer (more than 2.5 cm. in diameter) in a patient more than forty years of age, especially if the complications of perforation, obstruction or hemorrhage have

been present, or one on the greater curvature or near the pylorus usually should be removed surgically without delay, as few of these lesions respond to nonsurgical treatment and many of them may be carcinomatous. The small gastric ulcer which has failed to heal or has recurred under adequate medical management should be removed surgically, for, if the lesion is malignant, it is frequently of high degree.

The incidence of malignant changes in gastric ulcers has been estimated to be from 10 to 20 per cent. Katsch found an incidence of 20 per cent, and Walton stated that the figures of Stewart are generally accepted, namely, that 9.5 per cent of chronic gastric ulcers became carcinomatous and that 17 per cent of cases of carcinoma of the stomach originated in chronic ulcer. Walton called attention, however, to a probable higher incidence in view of the fact that many of the carcinomas, when removed, are found to be so large that it is impossible to tell whether they might have originated in an ulcer or not. In a recent study⁹ at The Mayo Clinic of 100 consecutive cases in which small, presumably benign gastric lesions were removed, the lesions in nineteen were found to be carcinomatous on pathologic examination.

There are several satisfactory procedures that may be employed in the surgical treatment of gastric ulcer. The procedure of choice is partial gastrectomy with removal of the lesion. The advantages of this procedure are the removal of the lesion with its possible hemorrhage, perforation or malignant degeneration, riddance of associated pylorospasm and induction of a high incidence of relative achlorhydria with almost total

*From the Division of Surgery, The Mayo Clinic (Walters) and The Mayo Foundation (Cleveland), Rochester, Minnesota. Read before the meeting of the Minnesota State Medical Association, Rochester, Minnesota, April 22 to 24, 1940.

absence of gastrojejunal ulceration. The Polya type of end-to-side anastomosis posterior to the colon is utilized most frequently. If the lesion should prove, on microscopic examination, to be malignant, its removal by partial gastrectomy gives the patient the best chance of cure, for it removes the lymphatic regions in the wall of the portion of the stomach removed and in the adjacent gastroduodenal and gastrohepatic omenta, which might harbor malignant cells which extended from the original lesion.

The Billroth I type of anastomosis after partial gastrectomy is a satisfactory treatment of gastric ulcer and carcinoma in selected cases. It is particularly useful in instances in which the duodenum is mobile and the lesion is in the pyloric one-third of the stomach, for, under these circumstances, the end-to-end anastomosis can be made without tension on the suture line. The risk of performing this operation in the experience of some surgeons has been somewhat greater than that of the Polya type of resection unless the cases are carefully chosen. It was noted by one of us (Walters) and Clagett in a study of 272 consecutive operations for gastric ulcer performed at The Mayo Clinic that this procedure was used but twenty-two times in contrast to the Polya operation, which was used 131 times. It should be emphasized that the satisfactory results from the Billroth I procedure for gastric ulcer are not duplicated in as high a percentage of cases as in operations of similar type for duodenal ulcer. This is probably due to the fact that the Billroth I operation produces a relatively high incidence of postoperative achlorhydria in gastric ulcer and does not in duodenal ulcer.

When partial gastrectomy cannot be safely utilized, on account of the poor general condition of the patient or the nature of the lesion itself, surprisingly good results may be obtained by less radical methods, such as excision of the ulcer with gastro-enterostomy or occasionally by excising the ulcer alone. It is to be repeatedly emphasized that, when possible, removal of the lesion in some manner should be done. Finsterer, in a study of 532 consecutive resections for gastric ulcer, found 141 lesions to be carcinomatous. Of these 141 carcinomatous lesions he found forty-one which he could not macroscopically distinguish from benign ulcer, and only by pathologic study was the sinister na-

ture of the lesion brought to light. By local excision of the ulcer with knife or cautery and gastro-enterostomy, pathologic study of the lesion to tell its exact nature is possible, and protection against further ulceration is accomplished by reduction of acidity by the gastro-enterostomy. This was done fifty times with very good results in the series of 272 cases studied by one of us (Walters) and Clagett.

Excision with knife or cautery may occasionally be done without gastro-enterostomy but it is not recommended because it does not offer an alteration in gastric physiology to prevent recurrence.* In the occasional case it has been utilized with rather surprisingly good results. It does enable microscopic study of the lesion. Similarly, segmental or sleeve resection may be done to remove the lesion, but disturbance in gastric peristalsis may follow in its wake, in addition to the fact that little change in gastric physiology results. It has been used with some success in selected cases, however.

When the condition of the patient is such that removal of the lesion is impossible without too great risk, then as safe a procedure as possible should be done which sufficiently alters the conditions that healing of ulceration may be anticipated. No one by choice desires to leave behind a gastric ulcer with the menace of malignancy in it, but if survival of the patient is deemed impossible with its removal, some less satisfactory procedure must be done. In this predicament, providing the lesion is benign, experience at the clinic has shown that gastro-enterostomy may be satisfactory. With the relative achlorhydria which frequently follows, a recalcitrant gastric ulcer¹ may heal with this alone. Eusterman and Balfour showed that 79 per cent of 100 patients on whom gastro-enterostomy had been performed for gastric ulcer were well after five years. This procedure of low risk, 3.9 per cent for 540 cases according to Eusterman and Balfour,² is thus worthy of consideration when conditions make removal impossible. The palliative resection of Madlener, in which the ulcer is also left behind, has not been utilized at the clinic. Lewisohn says the results of the Madlener operation, when viewed in a large series, are unsatisfactory. Jejunostomy is not utilized because of the necessity of prolonged treatment and fre-

*Reduction of gastric acidity and relief of pylorospasm.

quency of recurrence of the ulcer following discontinuance of the jejunal feedings.

Results of Operation

The results from well-chosen surgical treatment of gastric ulcers are among the best in surgery. In forty-three of sixty-two patients with benign gastric ulcer, or approximately 70 per cent, operated on at The Mayo Clinic in 1938, partial gastrectomy was performed with one death, or a mortality of 2.3 per cent.¹⁰ Most of these procedures were of the posterior Polya type. One of us (Walters) and Clagett in a study of 272 patients with gastric ulcers operated on between January 1, 1933, and January 1, 1937, found that 131 patients with gastric ulcer had the posterior Polya type of resection. Of the 131, eighty of eighty-five patients who responded to the questionnaire and had this type of operation were in excellent health without distress, while five were in good health with only slight occasional distress.

The high location of a gastric ulcer should not prejudice against surgical treatment, when surgical management is indicated. We have shown that many of the benign cardial gastric ulcers can be removed with a risk of less than 4 per cent, in other words, not appreciably greater than for removal of ulcers in the body of the stomach. For example, thirty-five benign cardial gastric ulcers were treated surgically with one death at The Mayo Clinic in 1938 and 1939 (mortality 2.8 per cent). The cardial gastric carcinomas, of which there were thirty-four in 1938 and 1939 with five deaths (14.7 per cent mortality) were removed by partial gastrectomy with a risk comparable to that of resection for carcinoma of the stomach in general. For comparison, 126 partial gastrectomies were performed for carcinoma of the stomach at The Mayo Clinic in 1938 with a mortality of 13.4 per cent. Often the ulcerating gastric lesion appears to be located higher in the roentgenogram than it actually is, because perforation of the ulcer onto the capsule of the pancreas or gastrohepatic omentum may foreshorten the stomach proximal to the lesion. In such cases high ligation of the gastric artery, division of the gastrohepatic omentum above the lesion and mobilization of the perforating lesion usually demonstrate an adequate amount of stomach available for safe resection. Thus, any patient

with gastric ulcer for which surgical intervention is thought best should not be deprived of the benefits of operation because the lesion seems to be high, on roentgenographic or gastroscopic examination.

Summary

Gastric resection is the surgical procedure of choice in the management of gastric ulcer and the best results follow the posterior Polya type of partial gastrectomy. Removal of the lesion should be accomplished wherever possible; a simple excision, combined with gastro-enterostomy, gives very satisfactory results when the lesion is benign but cannot be safely removed by partial gastrectomy. When the lesion seemingly cannot be removed with safety, gastro-enterostomy is favored over the Madlener palliative resection or jejunostomy. The results of a properly performed, well-chosen surgical procedure for chronic gastric ulcer are among the best in surgery today, and no patient should be deprived of surgical treatment because of the large size of the lesion or its apparent inaccessibility when viewed radiographically, for such lesions may be more accessible than the roentgenologic examination would indicate. The preoperative differential diagnosis between a benign and a malignant ulcer is difficult and the roentgenologic report that a gastric ulcer is present does not exclude the possibility that it may be malignant. In fact, in 100 consecutive cases of reported "gastric ulcer" the lesion was found to be carcinomatous in nineteen.

INDICATIONS FOR USE OF IRON IN TREATMENT OF THE ANEMIAS*

PHILIP F. ECKMAN, M.D.

Duluth, Minnesota

THE work of Whipple, Castle, Rhoads and a host of others has given clinicians a great deal of light on much that pertains to normal and abnormal erythropoiesis. There is still a place, however, for clinicians to introduce into practice an orderliness in applying these gifts of researchers. Obsolete and confusing nomenclatures must be gradually displaced. The terms "primary" and "secondary" as applied to anemias should be used with greater discrimination. Addison's anemia is no longer "pernicious" but has been established as a deficiency disease in a conditioned individual. When an accurate diagnosis is followed up with adequate and persistent fortification of the diet with the deficient factor as represented by gastric or liver extract, the patient will remain well. A variety of other conditioning and nutritional interruptions account for a series of anemias of nearly identical type.

In a similar manner the investigations of Whipple and Robschey-Robbins^{13,14,15} on the diet and iron requirements of their "standard anemic" dogs have illuminated to a remarkable extent the problem of the large group of anemias associated with hypochromia and iron deficiency. Such terms as "primary" or "idiopathic hypochromic" anemia are likewise doomed to become obsolete since the circumstances attendant upon iron metabolism, bodily storage, availability, and sources of iron loss have become so thoroughly understood.

A combination of these types of anemia, representing both maturing and iron deficiency factors, occurs uncommonly. Thus we may say that the therapeutic indications on the one hand to stimulate red cell maturation and on the other to adequately stock the body with sufficient iron for hemoglobin production, are so definite as to make the various combinations of liver extract and iron as illogical as they are expensive. An individual in whom liver therapy is indicated will need continuous and persistent treatment during life. This situation does not obtain in the iron deficiency group for once the reserve has been replenished and causal factors eliminated, the ne-

cessity of further treatment ceases. Furthermore, the use of such combinations greatly increases the probability of inadequate dosage of whichever factor chances to be the required one.

I propose to hold this discussion to the several circumstances which lead to depletion of the iron stores in the body. This will involve consideration of dietary deficiencies, of disturbed absorptive facilities, of liver inadequacy in its relation to hemoglobin protein metabolism, and finally of the channels through which body iron is lost. Where such circumstances obtain, the most common of all blood conditions—hemoglobin deficiency anemia—results.

The hemoglobin molecule is large and consists of two component parts. Hematin, the smaller of these, carries all the hemoglobin iron combined with its protein. It has been shown that the body is able to synthesize all material necessary in the formation of new hemoglobin except iron. Some highly significant investigations have recently been reported by Whipple¹² demonstrating that certain relationships exist between hemoglobin proteins and the plasma and fixed tissue cell proteins. By starvation experiments with his standard anemic dogs, he was able to show that during such stress an important exchange of proteins would occur from the tissue cells to the hemoglobin and that this reaction was not reversible. The rôle played by the liver in this exchange of protein from tissue cells and plasma to hemoglobin, appears to be that of an important assembling and distributing station. He demonstrated, furthermore, that the plasma and hemoglobin proteins in these dogs were controllable by diet and that certain foods have a specific effectiveness in stimulating the production of new hemoglobin. In view of such observations one may emphasize the therapeutic importance of a quantitatively as well as qualitatively adequate protein intake.

Although minute traces of iron are known to be present in all tissue cells, the bulk of this element is contained in the circulating hemoglobin. It has been estimated that the normal adult human body contains an approximate total of four and one-half or five grams of functioning iron.

*Read at the annual meeting of the Minnesota State Medical Association, Rochester, Minnesota, April 24, 1940.

Of this total, approximately ten per cent is tissue cell iron and sixty per cent is combined in hemoglobin. The remaining thirty per cent, about one and one-half gram in amount, is stored in available depots as the liver, marrow, and spleen, to be used in the production of new hemoglobin as need arises. This then represents the so-called normal iron reserve. Other iron deposits may be found in body tissues and organs in an entirely non-functioning capacity. In conditions as hematochromatosis and in hemosiderosis, these foreign-body-like deposits may be very extensive, but do not under any known circumstances become available for use.

The iron conserving mechanism of the body is equally remarkable in that none of this iron reserve is lost in any appreciable degree through excretion. When hemoglobin disintegrates to form bilirubin and the other bile pigments, the iron bearing hematin is split off early in the process to be conserved within the body and apparently reutilized in the formation of new hemoglobin. What, then, are the sources of loss of iron from the body, and through what channels may this reserve be depleted? We may say specifically that this may occur only through the processes of bleeding, of pregnancy and lactation, and of growth.

To lose hemoglobin through blood loss is to lose iron. By simple calculation one can assume, theoretically at least, that a normal individual, having lost one-half of the blood in the body through acute hemorrhage, may restore the blood level to normal without receiving any iron from extraneous sources. This would be accomplished, of course, at the expense of the entire iron reserve; and the replenishment of the same would become the immediate physiological problem. More insidious depletion ensues as a result of chronic and recurring blood loss. The anemia-producing effect of daily bleeding from hemorrhoids and from gastro-intestinal malignancies is generally known. The commonest instance, however, is menstrual bleeding with its almost universal depression of hemoglobin values during this period of life. Minot^{7,8} states that the iron requirement in women during their menstrual life is four times that of men. It seems entirely consistent, therefore, that the severe types of hemoglobin deficiency, chlorosis and so-called idiopathic hypochromic anemia, occur almost exclusively in females.

The hemoglobin deficiency in chlorosis, which in its severe form was relatively common three or four decades ago, undoubtedly results from the additional strain of menstrual blood loss in girls in whom the iron reserve has been seriously lowered by recent rapid growth plus inadequacies in diet and absorption facilities. Most investigators and clinicians feel that mild cases of chlorosis are not altogether uncommon even at present and advocate the routine prophylactic administration of iron to adolescent girls.

The appearance of severe hemoglobin deficiency anemia in women nearing the end of their menstrual life produces a characteristic clinical picture. These patients, by virtue of anacidity or some other factors inhibiting absorption of iron from the gastro-intestinal tract, have been unable to maintain a positive iron balance against the inroads made by years of menstruation and, frequently, numerous pregnancies. This condition occurring in men invariably means chronic blood loss, and painstaking investigation must be resorted to until the bleeding source has been identified. Serious hidden pathology may be the answer to such investigations. After elimination of the bleeding source and adequate administration of inorganic iron, it has been common experience that further treatment may be discontinued without fear of recurrence.

Pregnancy is invariably associated with some decrease in hemoglobin level. This occurs in part as a result of the physiologic increase of blood volume during the latter part of pregnancy with hydremia accounting for ten or twenty per cent dilution of the blood solids. However, the developing fetus requires its blood building pabulum and takes its apportionment of iron from the mother. In the case of a normal full term fetus, born with an average hemoglobin complement of 120 per cent (regardless of the status of its mother's iron store), this would represent a loss to the maternal supply of approximately 500 milligrams of iron, or the equivalent of one liter of blood. Strauss and Castle,^{9,10,11} from extensive observations on anemias of pregnancy, concluded that the essential causal factors were dietary deficiencies, mal-absorption from the gastro-intestinal tract usually in association with diminished gastric acidity during the third trimester, and the demands made by the growing fetus on the mother's iron supply. Thus we see the reason why iron becomes such an important adjuvant in

the dietary care and safeguarding of the pregnant woman.

From the standpoint of the infant, the iron reserve may be deficient if the maternal supply is low. This may be gathered from observations indicating that after the first year of life the hemoglobin level of an infant born of an anemic and untreated mother will usually fall to approximately 40 per cent. In contrast to this are the hemoglobin values of 80 per cent plus usually noted in one-year-old infants whose mothers' blood counts, if not normal during pregnancy, had been sufficiently bolstered by iron therapy during this period. Obviously, the hemoglobin values of prematurely born infants and of multiple pregnancy babies need special attention because of the probability of a subnormal iron endowment at birth.

Depletion of the iron store through growth occurs as the result of the sharp demand for new red blood cells to satisfy the rapidly enlarging and spreading blood volume. This becomes most apparent during the periods of greatest change in growth ratios, as during infancy and adolescence. During childhood, with enhanced dietary intake and a slowing of the growth ratio, anemia is not usually evidenced unless faulty iron absorption ensues due to circumstances as infections, gastric anacidity, or capriciousness of eating habits. Heath^{1,2} has expressed as his opinion that iron should be administered routinely to all infants after the age of three months, to adolescent girls and to pregnant women.

Having considered these three sources of loss of bodily iron, and the depleting effect on the iron reserves, attention must be given to the mechanism of restitution. The faculty of absorbing and making available for use sufficient iron is influenced by numerous adverse circumstances, many of which have been referred to in the preceding discussion. The dietary intake must be adequate in all respects, in protein, in vitamins as well as in iron containing foodstuffs. Besides this there must be the will to eat and a properly attuned gastro-intestinal tract to insure normal absorption. This implies an availability in the digestive processes of hydrochloric acid and of bile and an absence of such deterrant factors as hepatic inadequacy, chronic diarrheal states, intestinal fistulæ, hypothyroidism, and avitaminosis. Under favorable circumstances the rate of absorption of iron is controlled largely by the demand. In severe

depletion, Heath^{3,4,5} has shown that injected iron can be recovered quantitatively as hemoglobin, thus indicating the avidity with which the body may take up iron if available.

Under normal circumstances the body is able to replenish a depleted iron store from dietary source alone but at a relatively slow rate. Approximately 25 milligrams of absorbed iron is required to synthesize enough hemoglobin to raise the level one per cent. When one considers that only about 5 milligrams daily are absorbed from an adequate food intake, simple calculation would indicate that some fifty days would elapse before a rise of ten per cent in hemoglobin level could be expected. When by common experience this absorption rate is accelerated ten or fifteen times by the addition of an excess of inorganic iron to the diet, the indication for gross iron therapy becomes obvious.

It is of greater concern in iron therapy that adequately large doses of inorganic iron be given than that any particular form or combination be used. The more soluble iron compounds have come into favor because the effective dose is smaller. The necessity of giving infants and children relatively larger dosage per kilo has been emphasized by Meulengracht,⁶ who incidentally was one of the first to point out the fallacy, so prevalent in the first quarter of our century, of treating low hemoglobin anemia with small, supposedly stimulating doses of iron, frequently in the form of ineffective organic combinations. The technic of iron therapy in very weak infants and prematures seems to be beset with danger of serious gastro-intestinal irritation. Minot⁷ points out the ineffectiveness of administering iron solutions in milk owing to the formation of insoluble phosphates which are not readily absorbed. The fallacy of using combinations of liver extract and iron in routine treatment of anemia has been previously pointed out. Although Hart and Steenbock have demonstrated that minute amounts of copper are essential in the utilization of iron, therapeutic attention to this combination is in all probability unnecessary because of the almost universal contamination of foods and commercial iron preparations by sufficiently large traces of this element. The parenteral use of iron should be mentioned merely to discourage it. Heath has stated that injected iron may be very toxic in doses approaching therapeutic value. The parenteral administration of

25 milligrams which, if entirely utilized, will elevate the hemoglobin level only about one per cent, may cause severe local reactions, as well as nausea and vomiting. If necessary to employ this method, a ten per cent solution of ferric ammonium citrate may be injected intramuscularly in doses not exceeding one cubic centimeter.

I have attempted to outline the fascinating, yet quite simple, principles dealing with bodily iron, its physiology and the mechanism of restoration therapy. The three great sources of iron loss to the body are found incidental to the growth factor in infancy and adolescence, to the apportionment of the mother's iron to the infant during pregnancy and lactation, and to the loss incidental to bleeding. Persistent consideration of these factors opens up for us the main indications for iron therapy. Appreciation of the principles underlying iron deficiency anemia is as stimulating to diagnostic acumen as it is to effectiveness of preventive and curative therapy.

TOXIC EFFECTS OF CARBON TETRACHLORIDE

Report of Case

WAYNE S. HAGEN, M.D., H. A. ALEXANDER, M.D., and T. A. PEPPARD, M.D.
Minneapolis, Minnesota

CARBON TETRACHLORIDE is a chemical used in industry and also used for therapeutic purposes. Physically it is a colorless, transparent fluid, derived from methane, having the formula: CCl_4 . It is similar to chloroform but is more toxic. It is volatile at ordinary room temperature and is about five times as heavy as air. Its volatility makes it accessible for inhalation and its density makes ventilation of buildings difficult. The chemical is readily absorbed through the lungs, integument and gastro-intestinal tract. There are numerous occupations in which the workers may be exposed to vapor from carbontetrachloride: in dry cleaning, shoe dye establishments, in the manufacture of certain paints, in the vulcanizing industry.¹² Numerous cases of toxic effects have been reported from the industries.^{4,11}

Oral administration⁴ of carbon tetrachloride has been used in hookworm therapy since 1921^{2,3} and Lambert⁵ reported in 1933 over 100,000 consecutive treatments without a death and with few un-

toward symptoms. However, toxic effects were reported by Lamson, Minot and Robbins⁶ in alcoholics or in those who ingested alcohol soon after treatment. They also found that the taking of fatty foods hastened the appearance of toxic symptoms. It was also observed that animals on a diet low in calcium were more susceptible to carbon tetrachloride poisoning and that animals on diets to which calcium carbonate or calcium lactate had been added showed a tolerance to the drug.

The inhalation of fumes of carbon tetrachloride causes acute symptoms which are chiefly narcotic similar to the anesthetic effects of related drugs. However, the toxic effects to the liver and kidneys may become manifest at a later time, from twenty-four to thirty-six hours after exposure.^{7,9} One hundred parts of carbon tetrachloride per million parts of air is generally considered the maximal, allowable concentration for any prolonged exposure.¹ Madding and Butt⁸ have reported a case of hepatitis from inhalation of

fumes. Hans Smetana¹⁰ has called attention to the renal symptoms of poisoning by this drug, which soon overshadow the symptoms of hepatic damage and presents a characteristic clinical picture which is so typical that one may be led to the correct diagnosis merely from observation of the symptoms and interpretation of the laboratory findings, even in the absence of the history of carbon tetrachloride poisoning. The laboratory findings indicate a severe hepatitis and an accompanying or subsequent kidney damage, which have been confirmed by autopsy material. The gross anatomical findings were central necrosis of the liver and microscopic studies showed marked renal nephrosis. Smetana has suggested that an analysis of the cases of carbon tetrachloride poisoning reported in the literature indicates a greater percentage of renal symptoms in those cases of poisoning due to inhalation.

A brief description of the clinical symptoms of the immediate and late effects of poisoning by carbon tetrachloride will be presented in outline form along with the usual laboratory findings considered of value in arriving at a diagnosis.

Clinical Effects of Carbon Tetrachloride Poisoning

Immediate effects: (three to twenty minutes)

1. General: Headache, dizziness, general malaise, loss of consciousness (narcotic) or death by paralysis of vital centers.
2. Local: Irritation of oral, nasal and conjunctival mucous surfaces.

Delayed effects: (twelve to thirty-six hours)

1. General: Headache, muscle pains, general malaise.
2. Local: Inflammation of mucous membranes noted above.
3. Visceral: Nausea, vomiting, hematemesis, diarrhea.
4. Hepatic: Abdominal pain, tenderness in abdomen, jaundice (icteric index 12 to 30).

Late effects: (two to eight days)

1. General: Headache, vertigo, general malaise.
2. Local: Sub-conjunctival hemorrhages, hemorrhagic diathesis, inflammation of mucous membranes.
3. Visceral: Nausea, vomiting, diarrhea, colicky pains in abdomen, bloody stools or hematemesis.
4. Hepatic: Signs of hepatitis (liver enlarged and tender). Jaundice increases (icteric index 30 to 90).
5. Renal: Oliguria, anuria, generalized edema, uremic coma (suppression of renal function).
6. Central Nervous System: Epileptiform convulsions, increased blood pressure, increased muscle tonus, hiccough and stupor.
7. Other effects: Pulmonary edema (Variable).

Laboratory Findings in Carbon Tetrachloride Poisoning

Blood cytology:

1. Red blood cells: Polycythemia early.
Anemia later
2. White blood cells: leukocytosis up to 35,000 cu. mm.
Later returns to normal.

Blood chemistry:

1. Non-protein nitrogen: increased to 200 mg.
2. Urea content: increased to 200 mg.
3. Creatinine content: increased to 12 mg.
4. Carbon dioxide combining power: lowered.

Icteric Index:

1. Early—12 to 30.
2. Late—30 to 90.

Urine:

1. Specific gravity: no significant change.
2. Sugar: negative.
3. Albumin: two to four plus.
4. Microscopic: Red blood cells, 10 to 200 per high power field.
White blood cells: 20 to 100 per high power field.
Casts: many with predominance of hyaline forms.

Blood pressure:

1. Early, very little change.
2. Late, readings of 200 to 300 mm. Hg. systolic and readings of 90 to 120 mm. Hg. diastolic.

Case Report

A thirty-one-year-old white man, a salesman, was admitted to the hospital on December 6, 1938, because of general malaise, nausea, vomiting, diarrhea and numbness of the extremities. Three days previously he had used a "Pyrene" fire extinguisher to put out a small fire in the upholstering of his automobile and had inhaled considerable smoke and fumes with no immediate deleterious effects except a burning sensation in the nose, throat and of the conjunctivæ. These latter symptoms had persisted to the time of his admission to the hospital.

Present Illness.—Immediately after exposure to the fumes of the smoke and fomite from the fire extinguisher, to which he was exposed for about one-half hour, he took one or two alcoholic drinks and states that he felt well that night. On awakening the following morning he had some general malaise and later developed a severe headache. He then noted some abdominal discomfort and became nauseated and vomited several times. That evening he noted a looseness of the bowels with several watery stools. He slept poorly that night and on the second day had persistence of the malaise, nausea, vomiting, diarrhea and headache. He then noted that the conjunctivæ were injected and sore and that he had some numbness of the extremities. He was coughing and expectorating a greyish sputum. On this day he took some "Alka-Seltzer" and some Peppermint Water (2 per cent) and states that he did not

retain these nor any food or liquids taken during that day. He further stated that his urine was cloudy but seemed to be normal in amount. He consulted his physician on December 5 and was sent to the hospital the following day, which was the fourth day after exposure and the third days of his illness.

Physical Examination.—The patient, well nourished and well developed, appears to be acutely ill, but is intelligent and coöperative. The conjunctivæ are injected and an ecchymosis is present in both sclera and conjunctiva. The skin has a bronzed color and is dry. The temperature was 98.6 F., the pulse rate 90 and the respiratory rate 20. The blood pressure was 120 mm. Hg. systolic and 70 mm. Hg. diastolic. Pupils responded to light and accommodation. Oral mucous membranes were dark and deeply cyanotic. There was no dullness over the lung fields and breath sounds over the chest were normal. The heart tones were of good quality and no murmurs or arrhythmia were noted. The abdomen was slightly distended and was tympanitic to percussion. The liver margin was down about 4 cm. below the costal margin and was tender to deep palpation. The extremities showed a slight edema. All the reflexes were found to be hyperactive. The Babinski was negative. Knee jerks were four plus.

Laboratory Findings.—Examination of the blood showed: hemoglobin 83 per cent (Sahli); red blood cells 4,110,000 cu. mm.; white blood cells 10,000 per cu. mm.; differential count, polymorphonuclears 87 per cent, lymphocytes 10 per cent, eosinophiles 2 per cent, basophiles 1 per cent. A subsequent white blood count on December 13 showed 13,800 cells per cu. mm. with 94 per cent polymorphonuclears. On this same date the hemoglobin was 75 per cent and the red blood cells were 3,780,000 cells per cu. mm. On the day of admission no urine could be obtained and on the specimen obtained the following day the quantity was not sufficient to determine the specific gravity. This specimen showed a 1 plus reaction for albumin and was negative for sugar; microscopic examination showed 30 to 40 pus cells per high powered field; urobilinogen was negative, bilirubin was negative and urobilin a trace. Later urine specimens on subsequent days showed a 1 to 2 plus albumin, sugar negative to a trace, pus cells 20 to 80 per high powered field and 10 to 40 red blood cells per. high powered field; also the presence of occasional granular casts was noted. The blood serum at the time of admission showed: urea nitrogen 47.5 mg. per hundred cubic centimeters; icteric index 22. Later readings showed an increase in these values which are given below.

Course.—There was an almost complete shutdown of the function of the kidneys for a period lasting several days in spite of a satisfactory intake of fluids including daily intravenous administration of 5 per cent glucose in normal saline solution. The urinary output was zero the first twenty-four hours with succeeding measured outputs per twenty-four hours of 100 c.c., 180 c.c., 145 c.c., 150 c.c., 20 c.c., 765 c.c., 650 c.c.,

775 c.c., 1,750 c.c., and 2,125 c.c. from the period December 8 to 17, inclusive. During this period the albuminuria and pyuria persisted and there was hematuria on several occasions. It was during this period that the nitrogenous waste products accumulated, as evidenced by chemical studies on the serum: non-protein nitrogen readings of 99.04 mg., 77.85 mg. and 97.17 mg. on December 11, 12 and 13, respectively; creatinine value of 3.77 mg. on December 12. Sputum typing on December 13 showed no reaction with Neufeld serums. However, chest radiograph on December 12 showed evidence of pulmonary edema. Short wave diathermy was instituted on December 12 over both lumbar areas and was continued for two days. From December 13 to 26 the output of urine increased, reaching a normal value on about December 18 or 19 and this was accompanied by marked clinical improvement. The jaundice receded, the urine became negative for albumin and there was a reduction in the number of white blood cells, red blood cells and casts in the urine specimens. The blood pressure had been elevated during the period of oliguria to 180 mm. Hg. systolic and 110 mm. Hg. diastolic, but returned to normal readings as the urinary excretion became nearer to normal in amount. Chest radiograph on December 15 showed regression of the signs of pulmonary congestion (edema). During the period of oliguria (December 6 to 16) the patient suffered from hiccough, mild convulsive seizures, restlessness, insomnia and numbness of the face, hands and extremities. During this same period he had repeated emesis and did not retain food or liquids. He received daily intravenous injections of glucose (5 to 10 per cent) in normal saline and on December 13 and 14 he was given intravenous injections of 50 per cent dextrose, 50 and 65 c.c., respectively. He received parenteral fluids until December 18, at which time he was able to eat and retain food and liquids.

The patient was ambulatory at the time of his discharge from the hospital on December 28, 1938, and has returned to his former occupation. Subsequent blood examinations have revealed no evidence of damage to the hematopoietic system.

The final clinical diagnosis was acute poisoning due to inhalation of fumes of carbon tetrachloride. On the basis of clinical symptoms and laboratory findings the clinico-pathological diagnosis was: Toxic hepatitis and acute nephrosis, secondary to poisoning by carbon tetrachloride.

Comment

1. This case report illustrates the delayed effects of inhalation of fumes of carbon tetrachloride.
2. Special attention is invited to the effects on the central nervous system, which were evidenced by hiccough, mild convulsive seizures, increased muscle tonus, hyperactive reflexes and numbness of the face and extremities.
3. Another effect observed was the prolonged bleeding time and the hemorrhagic diathesis as

manifested by the ecchymoses and bleeding into the sclera and conjunctival membranes.

4. The use of physiotherapy in the form of short wave diathermy over the kidney regions was thought to have favorably influenced the return of normal kidney function.

Report of a case of carbon tetrachloride poisoning from inhalation of fumes of a fire extinguisher is made from the personal observation of the authors.

ANNUAL MEETING OF THE COUNCIL ON PHARMACY AND CHEMISTRY

The following were among the subjects considered at the annual meeting of the Council on Pharmacy and Chemistry:

The Council voted that a special committee be appointed to consider in extenso the digitalis unit and report back to the Council. It was emphasized that digitalis, or anything that purports to be digitalis, is an official drug and must be standardized according to the methods laid down by the U. S. Pharmacopeia; that if there is a demand for another standard, that standard may appear on the label in addition to the U.S.P. standard, provided the labeling of the second standard is not misleading.

The Council's Committee on Contraceptives made a progress report concerning certain articles that have been authorized for publication.

The Council voted to adopt the pharmacopeial term "thiamine hydrochloride" to replace the term suggested by the discoverer, i.e., "thiamin chloride."

The Council authorized the Secretary's office to approach certain persons with the request that they contribute to the new series of articles on glandular physiology and therapy.

The Council discussed the present status of pneumonia therapy. It was the general consensus that there is not sufficient information yet available to determine the value of combined serum and sulfapyridine compared with adequate serum therapy alone or with adequate sulfapyridine therapy alone. The Council members felt that the practice of typing should be continued for information, both in relation to treatment and for statistical purposes. The Council also voted to accept type III rabbit antipneumococcic serum for a period of one year only. Furthermore, the Council will consider with the view to acceptance the carbohydrate material for skin testing and treatment in conjunction with antipneumococcic serums (Francis test).

The Council concluded that a statement should be prepared announcing recognition of solution of zinc insulin crystals for inclusion in New and Nonofficial Remedies. The referee was authorized to formulate a report regarding the problems relating to antiseptics, bacteriostatic agents, preservatives and disinfectants, for the consideration of the Council and, if possible, to consult with the federal authorities concerned with these questions. A progress report was made concerning the further investigation of catgut sutures.

The Council discussed the question of the increasing number of large size brochures dealing with proprietary drugs. In this form of advertising the commercial houses take on themselves the task of educating the physician in the fields to which their products pertain. It was voted that a special committee be appointed to inquire into the matter of advertising brochures and report to the Council, especially in regard to the abuses.

The Council voted to revise and rearrange the New and Nonofficial Remedies chapter on serums and vaccines. The Council authorized a review to be made of the lipid pneumonia problem, on the basis of which the Council might again consider what action to take in the case of nasal sprays in which liquid petrolatum is the vehicle.

The Council ordered that revisions be made in the permissible claims for riboflavin, nicotinic acid and pyridoxine (vitamin B₆), these alterations to be passed on by the Cooperative Committee on Vitamins with the view of later publishing a revised edition of the pamphlet entitled "The Status of Certain Questions Concerning Vitamins," and concordant revision of the statements in New and Nonofficial Remedies. The Council voted to accept the terms "pyridoxine" and "pyridoxine hydrochloride" for the substances known as vitamin B₆ and vitamin B₆ hydrochloride, provided the nomenclature met with the approval of the American Society of Biological Chemists and the American Institute of Nutrition (an official announcement of the Council on these names was published in *The Journal*, June 15, 1940, p. 2387).

The Council also discussed the term "halibut liver oil with viosterol" for a product containing halibut liver oil with viosterol and other fish liver oils. The addition of cod and other fish liver oils to a product sold under the labeled name "halibut liver oil with viosterol" will make the product subject to action under the misbranding provisions of the Federal Food, Drugs and Cosmetic Act even though the presence of the added ingredients is declared elsewhere on the label. The Council therefore voted that the present New and Nonofficial Remedies' definition for halibut liver oil with viosterol be revised to read: Halibut liver oil-N.N.R. to which has been added sufficient viosterol (activated ergosterol) to assure a potency of not less than 10,000 U.S.P. units of vitamin D per gram. (*Jour. A.M.A.*, July 139, 1940, p. 132.)

HISTORY OF MEDICINE IN MINNESOTA

HISTORY OF WINONA COUNTY

(Concluded from September issue)

Biographies

Francis J. Tourtellotte was born on December 26, 1835, in Windham County, Connecticut. He graduated from the normal school at Bridgewater, Massachusetts, then began the reading of medicine under Dr. John McGregor, of Thompson, Connecticut. He later graduated from the College of Physicians and Surgeons of New York. In 1863 he entered the medical service of the U. S. Navy, where he served as surgeon until 1868. Coming to Winona in 1869, he engaged in the business of loaning money. Dr. Keyes of Winona said of him (September, 1930) that he never practiced, but was a capitalist. Dr. Tourtellotte and his wife did much traveling during their residence in Winona.

George Townsend was listed as a Winona County physician in 1865.

J. H. Travis was a Winona County doctor about 1864.

Oscar Trenkler, M.D., came to Winona to practice in July, 1861, and at that time published the following notice:

O. TRENKLER AND CO.
German Homeopathic
Physicians and Surgeons
Office—over Orrin Smith & Co.'s Bank
Dr. O. Trenkler Dr. A. Putsch

This partnership dissolved before Dr. Trenkler's service in the Civil War. He returned to Winona and again started the practice of his profession in August, 1866.

T. S. Troyer was a Minnesota City doctor who came to practice there in 1881 or 1882.

J. Q. A. Vale came to Minnesota as early as 1857. In 1868 he was practicing at Homer. In that year he was a member of the lower house of the State Legislature, representing the 11th district. He served as town clerk of Homer in 1869 and again in 1876. Dr. Vale was a very active Republican, and in 1875 was chairman of the Republican county convention in Winona. He had served on a committee for the permanent organization of the Republican county convention in October, 1869. In that year the Winona County Medical Society was organized and Dr. Vale was one of the charter members. He was elected to membership in the Minnesota State Medical Society in 1870. In 1876 he moved to Winona in order that his children might have the advantage of the excellent schools of that city.

Aside from the practice of his profession and his political interests, Dr. Vale had an interest in a sugar mill in Homer, and owned the mill in 1881. At that time he may have returned to live at Homer.

L. Viall was a Winona doctor in 1857.

Peter Von Lackum was a botanic physician and surgeon in Winona in 1872 and remained four years or more.

H. S. Wahl, physician, settled in Minnesota City in 1884. In the same year he had graduated from the Chicago Medical College. Later he became a member of the Winona County Medical Society. Before his coming to Winona County he had been a resident of London, Canada. He became involved in domestic difficulties and left Winona under a cloud.

J. B. Walton was a physician at Homer about 1873 to 1880.

H. S. Walrath, M.D., came to Winona County from New York in 1869 and settled at Stockton as a partner of Dr. S. B. Sheardown. Dr. Sheardown was to be absent for a time and he recommended his new partner to his friends and patrons. In August of that year, Dr. Walrath married Miss Belle M. Collins, also of Stockton, who later took up the practice of medicine. In 1876 or before, he moved to Minnesota City and practiced there until September, 1882. At that time he sold his residence and office to Dr. Newberry and moved to Saint Paul. Both Dr. Walrath and his wife practiced in Saint Paul. In 1885 he was elected to membership in the State Medical Society.

Belle M. Walrath, M.D., the wife of Dr. H. S. Walrath, graduated from the Woman's Medical College in Chicago in 1882, after a two-year course. In April, 1882, her husband was accidentally poisoned, but was saved by her prompt administration of antidotes. She may have practiced in Minnesota City for a few months before their moving to Saint Paul in September, 1882. In 1883 she became a member of the Minnesota State Medical Society. At that time she was practicing medicine in Saint Paul.

H. D. L. Webster came to Winona about 1860 or 1862. His card read as follows:

Homeopathy

DR. H. D. L. WEBSTER

having added largely to his stock of medicines, will, in addition to his professional duties, furnish country practitioners and families with Homeopathic Tinctures, Triturations, and medicated pellets by the case or single bottle, in any attenuation desired. Particular attention paid to chronic Diseases, such as Dyspepsia, Scrofula, Female Complaints and Consumption.

Office—with Dr. Welch, over People's Store, Hubbard's block

Residence—In the yellow house on Third st. near J. H. Jacoby's.

Dr. Webster left Winona but returned in May, 1867, and again engaged in the practice of medicine.

Baker Webster was a doctor in Winona County in 1857.

Henry R. Wedel, M.D., graduated with distinction from the medical department of the University of Pennsylvania in the spring of 1862. He came to Winona early in that year and opened an office for the practice of medicine and surgery over Wienand and Company's drug store. He had been an assistant druggist with Wienand in 1857.

In September, 1862, he received the appointment of first assistant surgeon in the Fourth Minnesota Regiment, taking that commission in preference to an appointment of surgeon in one of the new regiments. During his term of service he became surgeon of the Fourth Regiment. He returned from service in June, 1865, and again took up the practice of his profession. Later in the same year he married Miss Anna Hibert of Winona.

In July, 1866, he associated himself with Mr. William Netter in the drug and medicine business, relinquishing his practice.

In March, 1878, he again took up the practice of medicine and surgery. During that year he became a member of the Minnesota State Medical Society, and about the same time was elected to membership in the Winona County Medical Society. He held the office of president of the latter organization in 1879. He sold his drug store in 1881, wishing to give his attention exclusively to medical practice. During his stay in Winona, he was at one time examining physician of the Saint Joseph's Benevolent Society, which was probably in connection with Saint Joseph Hospital referred to by Curtiss Wedge in his "History of Winona County" as the first adequately equipped hospital in Winona.

Dr. Wedel was an active Democrat during the seventies. He was a charter member of the Winona Council of the Order of the Royal Arcanum.

In 1883 Dr. Wedel decided to locate in Saint Paul, where he practiced for some time. He was very well liked by the Winona people, and occasionally returned for a visit.

Alfred Welch, physician, surgeon, and druggist, settled in Winona in 1856. In that year he advertised a wholesale and retail drug and prescription store. He had been for a long time connected with a large house in Philadelphia, in the sale, compounding, and dispensing of drugs and medicines. He pledged himself to sell drugs as low as they could be bought in Chicago or Cincinnati, and also advertised correct and prompt service.

Dr. Welch lived in Winona as a physician and druggist thirty years or more.

Frederick Welch was a Winona doctor in 1867. He died in New Jersey in 1883.

George Welch was a Winona physician during the seventies. He left Winona in 1878.

Charles E. Wentworth was a Winona County physician in 1864.

William A. Whippy, M.D., came to Winona in 1866 from New York State "bearing high recommendations as a practitioner." He was the partner of Dr. Pierce, and their card, published in 1866, read as follows:

HISTORY OF MEDICINE IN MINNESOTA

DRS. PIERCE—WHIPPY
Homeopathic physicians surgeons
Office in Hubbard's Block—2nd Street
Winona, Minn.

Dr. Whippy married in 1868, and lived in Winona for a time. In 1883 he and his wife and child were residents of Goshen, Indiana.

Lawrence G. Wilbertson, M.D., was born in Hornellsville, New York, on April 18, 1852. After completing his preparatory studies, he entered Cornell University, where he studied for some time. Then he taught school a year in the Lima Seminary, at Lima, New York. Early in life he had determined to be a physician, so he began reading medicine at the office of Dr. T. C. White at Rochester, New York. In 1880 he graduated from the Hahnemann College at Philadelphia, and at once came to Winona. Not long after his arrival he became a member of the Winona Academy of Homeopathy. Later he was elected to membership in the Minnesota State Homeopathic Association, and also the American Institute of Homeopathy. He supplemented his medical education by extensive reading and by study abroad in 1901-1903. He practiced in Winona for more than fifty years.

B. A. Wilder was a Winona County physician in 1864.

Adelaide Williams was a homeopathic physician in Saint Charles about 1870, or earlier. She remained there for ten years or more. In 1877, Dr. Williams was elected to membership in the State Homeopathic Institute.

J. E. Wright was a physician and surgeon in Saint Charles in 1869 or 1870.

William J. Youmans graduated from the medical department of the University of New York, taking special instruction under Professor Draper, and soon afterward went to England to pursue physiological studies in the laboratory of Professor Huxley. While there, in connection with Professor Huxley, they jointly published "The Elements of Physiology and Hygiene," the section on hygiene being Professor Youmans' work. This work was simultaneously published in England and in the United States. Returning to America, Dr. Youmans came to Winona (1869), and for about two years engaged in the practice of medicine and surgery. On the establishment of the *Popular Science Monthly* he was called to New York to assume the post of assistant editor. In June, 1871, he was the scientific editor of the *Galaxy*. He was editor of the *Scientific Monthly* for many years.

Arthur B. Young, M.D., came to Winona in July, 1876, from Minneapolis. He purchased the residence of Dr. A. B. Stuart and took up his residence in Winona as the partner of Dr. J. B. McGaughey. In the year of his arrival, Dr. Young became a member of the Winona County Medical Society. In 1875-1876 he taught in the Winona Preparatory Medical School. The date of his departure from Winona is unavailable, but in March, 1884, he was a resident of Prescott, Wisconsin.

THE MISSIONARY AS PRACTITIONER: DR. THOMAS SMITH WILLIAMSON

By ARTHUR S. HAMILTON, M.D.

MAJOR Purcell was succeeded as physician at Fort Snelling by Dr. B. F. Harney, who had as his assistant Dr. Robert C. Wood. The latter became Surgeon in 1829. During the Civil War he was appointed Assistant Surgeon General. Among the names of other medical men stationed at Fort Snelling, the following may be noted: Nathan S. Jarvis, who entered the army in 1813 from New York and died in 1862; Dr. Fitch, 1837; George F. Turner, 1843, who entered the army from Virginia in 1825 and died in 1854; Joel Martin; Adam N. McLaren, who entered the army in 1833, became post surgeon in 1849 and died in 1874; and John Emerson. These men were not particularly noted physicians. Emerson derives his chief claim to be remembered from his ownership of the Negro Dred Scott. Dr. Turner's name is of interest because of his report on an epidemic of scarlet fever at the fort, which was the first contribution to a medical periodical to be written by a Minnesota physician. As has been suggested, the first responsibility of the post surgeons was the health of the soldiers stationed at Fort Snelling. They also offered remedies and surgical services to Indians living around the fort. However, as the line of settlement, moving steadily westward, caught up with the army, and the civil population around the fort became increasingly numerous, the services of the military physicians assumed a wider significance. Not infrequently they were called on errands of mercy outside the limits of the reservation, and ministered to the needs of the residents of Saint Paul's. In this they were aided, or rather their efforts were supplemented during the decade of the forties by the work of Dr. Christopher Carli and Dr. Thomas Smith Williamson. Dr. Carli lived at Stillwater, and was the first resident physician to build up a regular practice in Minnesota. His work will be noted in further detail in another place. Dr. Williamson represents the missionary as practitioner.

Born in the year 1800 in South Carolina, Williamson lived there for only a few years; his family moved to Ohio when he was four years of age. He first chose the medical profession for his life work and after his graduation from Jefferson College in Cannonsburg, Pennsylvania, read medicine with his brother-in-law, attended a course of lectures at Cincinnati, and studied at the medical school at Yale University, completing his course there in 1824. There followed eight years of general practice at Ripley, Ohio. During that period he became interested in missionary work among the Indians of the Northwest, but hesitated to go out to the field because of the hardships that his wife and three young children would be required to endure. While the question remained still undecided in his mind, "the three little ones were gathered into the arms of their Savior." Accepting this as the will of God, Dr. Williamson at once gave up his practice, and entered Lane Theological Seminary in Cincinnati. In April, 1834, he was licensed to preach and, in the summer of the same year, he visited the Indians of the Upper Mississippi, going as far as Fort Snelling. The following year, in May, 1835, the Reverend Thomas Smith Williamson, M.D., a regular appointee of the American Board, arrived at Fort Snelling with a missionary band of five adults and three children—his wife and child, his wife's sister, Miss Sarah Poage, and Mr. and Mrs. Huggins with their two children. Mr. Huggins came to teach the Indians improved methods of agriculture.

From the time of his arrival in 1835 until his death in 1879, Dr. Williamson devoted himself unsparingly to the needs of others. For several years the scene of his labors was the mission that he established near Joseph Renville's trading

station at Lac qui Parle. During this period his chief concern was the Christianizing of the Sioux Indians. His efforts toward that end were largely evangelical and educational. Within two years he had mastered the Dakota language sufficiently to preach to the Indians in their own dialect. Soon he was engaged in the writing of hymns, the compilation of a dictionary, and the translation of the scriptures into the Dakota language. In the latter task he was assisted by Joseph Renville and Gideon Pond. In November, 1846, he moved with his family to Little Crow's village, seven miles below Saint Paul, where for six years he ministered to the needs of his white neighbors as well as of the Indians. After the Treaty of Traverse des Sioux in 1851 he followed the Indians to their new reservation at Yellow Medicine in the western part of the present state. There he continued to work until the Indian massacre of 1862. In later years he served as a member of the Board of Visitors to the Chippewa Indians in the vicinity of Cass, Leech and Winnibigoshish lakes. The years preceding his death were spent in St. Peter.

Although he was primarily interested in spreading the gospel, the medical work that Dr. Williamson did among the Indians assures him of his place in the present volume. He carried on an active practice, and established a medical mission years before such units were recognized by missionary boards. Possibly this activity had much to do with the wave of unpopularity which manifested itself eight or nine years after his coming to the post at Lac qui Parle.† The Indians did not want the white man's religion and were frankly suspicious of his motives for coming amongst them, but they were not, at first, aggressively opposed to the missionaries, and it was possible, by means of a feast, for example, to bring together a fair congregation, even of men. As time went on, however, the Indian medicine men began to see that the white men's medicine was superior to theirs and that their power would necessarily decline. Then began an organized opposition to the white man. A failure in crops and other misfortunes were charged to the missionaries. Then the mission oxen began to disappear, then the horses, and finally the family cow was all that was left to haul the firewood. The Indians were directed to remain away from the church, school, and mission house, and those who disobeyed the injunction were subjected to various petty persecutions. These were the conditions that induced Dr. Williamson to remove to Kaposia.

While living at Kaposia, the missionary doctor assumed the duties of Dr. Turner at the fort during the latter's absence from the garrison. An account book has been preserved which carries the following items of interest, dated 1843:

"For attending on the Garrison and Indians for Dr. Turner, three months and eight days, \$229.00. For private practice while living near Fort Snelling, \$110.06."

The items do not show whether he was paid by Dr. Turner or by the government. The six cents must have come in some way through the price charged for drugs. In his private practice he was moderate in his charges, and seldom received money in payment. Usually he received his compensation in beef, potatoes, and grain.

Dr. Williamson's long period of service among the Sioux Indians enabled him to study their diseases, and their medical practices much more closely than was ordinarily possible for a white man. He improved his opportunities, and in later years wrote several papers which have their place in the literature of Minnesota

†*"A Brother to the Sioux,"* by Winifred W. Barton, p. 22.

medicine. Two of these articles have been selected to be reprinted in the present volume. The first, entitled "Diseases of the Dakota Indians," first appeared in the *Northwestern Medical and Surgical Journal*, 4:411, 1873-74. The second, on "Dakota Medicine," is reproduced from Stephen R. Riggs, *Tah-Koo Wah-Kan; or, The Gospel Among the Dakotas*, 1869, page 435.

DISEASES OF THE DAKOTA INDIANS*

By THOMAS S. WILLIAMSON, M.D.

MY acquaintance with the Indians of Minnesota dates from the time of my arrival with my family at Fort Snelling, May 16, 1835. After residing there a little more than a month, I proceeded to Lac qui Parle, where I arrived on the 9th of July; and made my home there from that time until November, 1846; though in that time I was absent two winters, and most years at least one month in summer, getting supplies for my family.

There were about 400 Indians estimated as residing there at the time of my arrival, though a large portion, considerably more than half, were absent a month or two every fall and spring, and sometimes most of the winter; but in the winter the places of the absentees were more than filled by the aged, diseased and infirm from other villages, who were brought and left there by their relatives, who could not carry them along in their wanderings in search of food or furs in winter; and trusted to the hospitality of the residents to keep them from starving in their absence.

I had practiced medicine ten years in Southern Ohio, Adams and Brown Counties, had become familiar with the malarious paludal diseases; at that time very prevalent in those localities, and I here used my knowledge of medicine as a means of getting a hearing for that which I came to teach.

Though the medicine men bitterly opposed me because I refused to give medicine to those over whom they performed their incantations, and by my success deprived them of half their fees, I was called to see nearly every fatal case of disease which occurred among the Indians residing there; many also came, or were brought to me from other villages to get medicine, and for the last ten years of my residence there I heard of nearly all the deaths occurring in a population of about 1,000. It was not possible, however, to get such statistics as you ask for. The Government at one time asked for a census of the population there, and the traders and myself attempted to take it, but as soon as this was known by the principal men they positively forbade our completing it, and any attempt to proceed would have endangered our lives, for the reason that *their* lives would be endangered, they thought, by any such step.

About the time of leaving I remember having made an estimate that fully one-half of the deaths among the Indians with whom I was acquainted while there were violent deaths. Eleven were killed at one time by the Chippewas, and almost every year one or two were killed; there was, I suppose an average of one or two murders a year from drunkenness, jealousy, envy, et cetera, and also one or two suicides during the time.

Of those over ten years old who died of disease, I think fully half died of con-

*Published in *Northwestern Medical and Surgical Journal*, Vol. iv, July, 1873-June, 1874, inclusive, p. 411.

sumption (phthisis pulmonalis), nor does this seem strange to me as from your letter it appears to you; for I do not think it was much more prevalent among the Indians than among our white population; while from the fact that they were all tainted with scrofula, their mode of life, et cetera, it might be expected that it would be very much more so.

Notwithstanding the many deaths from violence while I was at Lac qui Parle the number of births very much exceeded the number of deaths. The great proportion of phthisis was chiefly owing to so few dying of other diseases. I had lived among the Indians above twenty years before I ever saw one of them suffering from typhus or typhoid fever. Smallpox was in the country several times and was very fatal among the Indians on the Missouri and at Winona, but only one death occurred from it among the Indians at Lac qui Parle; and perhaps not more than a dozen among all the Indians on the Minnesota River, as they were generally protected by vaccination.

The measles, in an aggravated form, prevailed among the Indians once while I was there, and a number of them, several far advanced in years, died from it and the dysentery, which generally accompanies or follows it among Indians.

The above are all the cases of death from what are called zymotic diseases. I do not remember of ever having seen a well marked case of scarlatina among the Indians. There were some severe cases of sore throat, but none fatal of which I remember to have seen or known. From their phlegmatic temperament they are less subject to nervous diseases than whites, yet I have seen a number of severe cases of spasms among them, none of which, however, proved fatal, if I remember correctly. I recall one case of cancer, and only one. It was on the top of the foot, and fatal after four or five years. Several killed themselves by overeating, but I was not called to see them. As at that time they used little or no salt with their food, which was for the most part poor in quality, and often scant in quantity, plethora and the many inflammations which originate therefrom were unknown among them.

I remember of one old conjurer who died of pneumonia, brought on by exposing himself naked for hours out of doors to a chilly wind in October when it was alternately spitting snow and drizzling rain, performing religious rites to secure the assistance of their gods in favor of a war party against the Ojibways.

There were some several cases of suffering from disorders of the urinary organs, but none that came to my knowledge at Lac qui Parle proved fatal. Children often suffered severely from teething and owing to lack of suitable food. In such cases, some of them died from diarrhea or dysentery, and others from hydrocephalus; but not a greater proportion than among our white population. But among the women and children who remained in the neighborhood during the winter, scrofula was almost universal; caused by their subsisting entirely on corn, for weeks, and some years for months. Enormous swellings formed about their necks and armpits, and occasionally on other parts of the body, forming abscesses which sometimes so exhausted the system as to prove directly fatal, but more frequently by inducing phthisis or mesenteric diarrhea. In the spring when the ducks returned so that they could get animal food most of them got better and some entirely recovered.

(To be continued in November issue)

President's Letter

MEDICAL TESTIMONY

FOR a long time both our Medical Association and the Bar Association have felt that changes in court procedure in cases requiring expert medical testimony were needed. One of the chief reasons cited being the frequency in which medical testimony is biased in favor of the side employing the medical witness; this happens so often that it is hard for the Court to obtain impartial information. Another criticism is that of perjured testimony by the physician; this in turn at least implies a dishonest attorney. Another objection is testimony that is garbled and inconclusive, given by physicians who are not qualified by experience or training to act as experts.

Expert medical testimony should be intelligent, scientific, and dependable. Any physician chosen as an expert witness should by special training and broad experience be qualified to give reliable authoritative information. We realize that consultants often differ and the best of men may have honest differences of opinion; but too often these experts give opinions and draw conclusions so diametrically opposed and so conflicting that bias and partisanship are self-evident, and the expert testimony thus becomes worthless to the Court and jury.

Both the State Bar Association and the State Medical Association are agreed that improvements in court procedures involving medical testimony can and should be made. A number of changes have been suggested, some of which sound plausible. It would seem sensible that the testimony of the attending physician should be limited to the condition of his patient, the progress of the case, and the results obtained; he should have a definite idea as to the amount of recovery made, and be able to justify his opinion. But he should not be called upon as an expert witness. Various plans have been suggested for choosing expert medical witnesses: One plan is for the plaintiff and defendant each to choose a physician, and the court to choose a third to act as referee. Another suggestion is to have the County Medical Society choose the expert medical witnesses. Legislation will be required to make any such changes, however, and this will be difficult, requiring a long period of time.

In an endeavor to start some improvements in medical testimony, a new committee of our State Medical Society has been formed. Recently, and without our knowledge, the Minnesota State Bar Association also appointed a committee to work on the same problem. On July 11, 1940, during the annual meeting of the State Bar Association, we had the privilege of meeting with that committee. Among those present was Justice Royal A. Stone of the Supreme Court of Minnesota. Justice Stone is chairman of the Judicial Council created by the Minnesota Legislature in 1937, to make a "continuous study of the organization, rules and methods of procedure and practice of the judicial system of the state, and of all matters relating to the administration of said system and its several departments." Justice Stone told us it was his firm belief that when the various courts of the State are informed of the creation of our committee, we shall receive the enthusiastic support and cooperation of the courts in dealing with flagrant violators in the medical profession in matters concerning medical testimony. Reprimanding a few physicians should be an effective deterrent to such practices; more serious cases, and those involving perjury can be referred to the Minnesota State Board of Medical Examiners for action leading to suspension, or revocation of the license of the physician involved. This may seem like drastic action, but we cannot afford to allow the dishonesty of a few to continue to bring reproach on our profession. Our code of ethics not only does not condone such practices, but it is strongly opposed to them, and the courts of justice certainly cannot, and will not, uphold such violations of trust and honesty. This kind of misconduct must be stopped and it is the duty of every self-respecting physician to see that it is stopped.

B. S. ADAMS, M.D., President
Minnesota State Medical Association.

Volume 23 OCTOBER 1940 Number 10

NEW PLAN ADOPTED TO CONTROL MEDICAL TESTIMONY

A new plan for control of dishonest medical
testimony, source of scandal for many
years, both to the medical profession and the
public, was officially adopted by the Council
of the Minnesota State Medical Association
at its regular fall meeting held Sunday, Sep-
tember 22, at the St. Paul Hotel.

This plan is the result of several confer-
ences between a special committee appointed
to study the question by President B. S. Ad-
ams of Hibbing and representatives of the
Minnesota State Bar Association, who have
also interested themselves in the problem.
The conferees had the benefit, also, of advice
from Justice Royal A. Stone of the Supreme

Court of Minnesota, who is himself Chairman
of a Judicial Council appointed by the Min-
nesota State Legislature in 1937 to study
rules and regulations and procedures of the
judicial system of the state.

No change in legislation is contemplated in
the plan submitted by Chairman E. M. Ham-
mes of St. Paul and approved by the Council.
Instead, a permanent Committee on Medi-
cal Testimony of the Minnesota State Med-
ical Association will be formed. Services of
this Committee will be put at the disposal of
any judge in the state who has reason to be-
lieve that medical testimony in any case de-
cided in his court has deliberately deviated
from the truth.

Judges will be invited to submit such cases
to the Committee for investigation and study.
If, upon close investigation, it appears to the
Committee that the testimony of the physi-
cian was indeed dishonest, the case will be
turned over, together with all findings, to the
State Board of Medical Examiners for disci-
plinary action.

Offenders who are thus reported to the
State Board will be subject to censure and
warning or to suspension or revocation of
their license to practice medicine, according to
the judgment of the Board.

The seriousness of the problem of dishonest
expert testimony has been recognized by rep-
resentatives of organized medicine for many
years. Many proposals have emanated both
from physicians and lawyers for changes in
the law which would eliminate entirely the
hiring by litigants of medical experts. Legal
authorities who conferred with the Commit-
tee on the new plan of attack did not, how-
ever, favor any movement to change the law
at the present time. All of them felt that
the existence of the new Committee would,
if its functions and objectives were well
known, achieve a great deal to control the
situation in Minnesota.

The importance of the new Committee and
its work was therefore emphasized by the
Council and instructions were issued to inform

every judge on the Minnesota bench of its existence and its availability for investigation of suspicious cases.

"Honest differences of opinion exist, of course," Dr. Hammes pointed out in his report. "Every allowance should be made for such differences wherever the point at issue admits of honest disagreement on the part of medical witnesses called.

"The plan is not designed to eliminate differences of opinion but to control the occasional 'shyster' physician who, like the 'shyster' lawyer, makes a farce out of justice and casts discredit upon his entire profession.

President Adams immediately appointed the members of the temporary committee who studied the question with the Bar Association, to the permanent committee. They are:

Dr. E. M. Hammes, St. Paul, *Chairman*
 Dr. H. B. Annis, Minneapolis
 Dr. L. A. Barney, Duluth
 Dr. J. F. Norman, Crookston
 Dr. W. G. Workman, Tracy.

A similar committee is being appointed by the Minnesota State Bar Association and plans are already under way for an early meeting of the two committees.

In the meantime, immediate steps will be taken by order of the Council to apprise all Minnesota judges, members of the Bar Association, and physicians of this action.

STATE LICENSURE OF LABORATORY TECHNICIANS

OLDER physicians may recall the days, not so long ago, when clinical laboratory service consisted mainly of simple routine procedures which any young woman of average intelligence could easily learn and carry out. No essential educational background or systematic instruction and training was deemed necessary to qualify her for the task. At best, her training embraced a short period of apprenticeship. Known as laboratory technician, she was able to adequately meet the needs of her days and was often considered competent or even indispensable.

However, with the rapidly widening scope and increasing complexity of the present day practice of laboratory medicine which intimately evolves

around the practical application of the principles of all fundamental sciences, it had become increasingly apparent that the laboratory technician of those days with her limited preparation could no longer satisfy the demand of the modern clinical laboratory.

In order, therefore, to adequately insure the aid of properly trained technical workers and thus safeguard the practice of clinical pathology, the American Society of Clinical Pathologists, in 1928, created a Board of Registry of Medical Technologists whose function was to clearly define the qualifications of laboratory workers and to issue certificates of registration to those who came within that definition, and voluntarily submit to the examination. The present requirement consists of two years at least of college work with the necessary credits in chemistry, biology and bacteriology and a year of practical instruction and training in a clinical laboratory approved for such training by the American Medical Association and the American Society of Clinical Pathologists.

The American Medical Association, the American College of Surgeons and other medical organizations have wholeheartedly endorsed the Registry's program and encouraged all approved hospitals to employ registered medical technologists in their clinical laboratories in preference to those who do not possess the minimum qualifications required by the Registry.

In the past decade, the services of the qualified medical technologist have become increasingly indispensable to the practice of clinical pathology. She has gradually supplanted the old time laboratory technician of yesterday.

Thus, in the twelve years that have elapsed since the establishment of the Registry and solely through its efforts, the laboratory worker has been transformed from a non-descript lay-helper to a scientifically trained professional who plays an important rôle in every day practice of medicine. This has clearly demonstrated not only the wisdom of the American Society of Clinical Pathologists in having initiated the system of voluntary registration of qualified laboratory workers but also the value, professionally and economically, of such registration to the registrants themselves.

Today, the Registry of Medical Technologists of the American Society of Clinical Pathologists, with its six thousand registered members, is an

established institution of national importance enjoying the confidence and support of representative medical organizations.

Unfortunately, there are a large number of laboratory workers who by reason of their inadequate education and training are unable to qualify for registration. These and other disgruntled elements are making organized effort to discredit the work of the Registry, whose alleged "dictation" they resent, by banding themselves together, ostensibly for the purpose of obtaining state legislation to license all laboratory workers in every state in the Union but actually to nullify the already well established nation-wide voluntary system of registration sponsored by the Registry.

The American Society of Clinical Pathologists, after careful investigation, has come to the conclusion that the present system of universal voluntary registration of qualified laboratory workers by a responsible national agency, no matter who may conduct it, is more effective in maintaining their scientific and ethical standards than any method of individual state licensing.

Such a law, if enacted, will inevitably lead to several undesirable consequences. The chief among these, which vitally concerns the practice of clinical pathology, would be the lowering of the standard of qualifications of the eligibles in order to allow the advocates of this legislation to qualify, the majority of whom can not meet the minimum requirements of the Registry. This would naturally bring down their professional standard, which in turn would defeat the very objective of the proponents of the legislation, namely, to bring about a better economic status for the average laboratory worker.

Another undesirable feature of legal licensing would be the substitution of the present universal voluntary system with its twelve-year record of successful operation, by untried, compulsory state laws necessitating forty-eight or more separate and unequal standards of qualifications and regulations which would be the source of unending confusion. On this point, Doctor W. D. Cutter, Secretary of the Council on Medical Education and Hospitals of the American Medical Association, made the following statement: "It was determined that the Council was in no position to feel that a state board of examiners in medical technology would represent any advance over present methods of control in this field. The ex-

perience of the Council in the licensure of physicians and the registration of nurses have indicated that statutory control in each of the forty-eight states would in the end be less effective than a central voluntary registration system."

There is also a possible danger of which the practicing clinical pathologist is apprehensive in the event a law of this kind is enacted, namely, a danger of permitting licensed laboratory technicians to feel capable of engaging in the practice of clinical pathology by operating or "taking charge" of a clinical laboratory without the supervision of a licensed physician.

There are a few among the laboratory workers in Minnesota, some well meaning, who apparently believe that their economic independence and well-being rests largely upon recognition by the state through compulsory licensing. By their desire to attain this goal they are apparently willing to sacrifice their professional standards. This is clearly evidenced by their readiness to join hands with the national group whose membership is composed of non-registered technicians including the so-called "graduates" of unapproved schools and others ineligible to register. This group, incidentally, is intimately identified with the American Medical Technologists, an organization composed of non-registered laboratory technicians recently formed by a male technician who conceived the idea of issuing certificates of registration to those who join it by paying a fee of \$5.00, which entitles the holders to identify themselves as medical technologists and suffix the letters M. T. to their names, making it impossible to differentiate them from the bona fide Registered Medical Technologists, certified by the American Society of Clinical Pathologists, the intent clearly being to confuse the minds of the medical public and embarrass the legitimate work of the Registry, the official agency of the organized clinical pathologists. (See Editorial Comment, *Jour. Am. Med. Assn.*, 114:1269, March 30, 1940.)

These facts are briefly outlined at this time so that physicians of Minnesota may be correctly informed of the movement, now being agitated by a certain group of laboratory technicians toward legislative enactment of a law governing the status of laboratory workers which the American Society of Clinical Pathologists as well as the American Medical Association considers ill-advised and unnecessary in view of the effective work which the Registry of Medical Technol-

ogists is carrying on for the maintenance of scientific and ethical standards of qualified medical technologists.

WILLKIE AGAINST SOCIALIZED MEDICINE

THE *Rocky Mountain Medical Journal* for September, 1940, printed the following letter, addressed to Dr. T. Leon Howard, Denver, Colorado, under date of August 7, 1940:

"My Dear Doctor:

You have asked my views on socialized medicine. I am against it. You can quote me any place on this.

Cordially yours,

WENDELL L. WILLKIE

Concise and to the point. He is opposed to socialized medicine. His reply contains no "ifs,"

If elected there will be no more interdepartmental committees appointed by the president and composed of socialistically minded government employees who formulate, with only contempt for the opinion of the medical profession, bills for Wagner to submit to Congress. If elected, no more of Thurman Arnold and his suit of the medical profession for its alleged constraint of trade.

What a relief this would be.

C. B. D.

SUGGESTED POLICIES AND PHYSICIANS' RECOMMENDATIONS FOR PUBLIC HEALTH NURSING SERVICES

(Revised 1940)

EDITOR'S NOTE: The above regulations have been revised by the Public Health Nursing Committee of the Minnesota State Medical Association and have been approved by the Council of the State Medical Association and the State Board of Health. They are published here in full to serve as a guide for counties that may have occasion to employ health nurses.

General Policies

It is highly important that public health nursing practices be consistent with the medical consensus of the community, and for this reason it is suggested that each county medical society approve certain policies involving nursing procedures and instructions for the guidance of public health nursing.

1. Any agency employing public health nurses should have its program approved by the physicians in the community.

2. The nurse shall emphasize the importance of medical care but shall not recommend *the selection of any individual physician*. She shall not give nursing care after the first visit except under the direction of a licensed physician. Records of nursing care shall be kept on file by the nurse. In special cases of economic need the nurse shall use the facilities provided by public and private agencies in coöperation with the family physician.

3. *The nurse does not diagnose nor prescribe treatment*. It is her function to follow the instructions of a physician. Public health nurses working under the direction of local physicians may be allowed to give and read various diagnostic tests, provided approval has been given by the physicians in the community.

4. The nurse shall make a written report to the physician or agency whose patient she has contacted. Such report may be given to the patient to take to the physician, or may be delivered directly to the physician. Carbon copies should be kept on file—a standard blank form is suggested in the Nurses' Manual, supplied by the Minnesota Department of Health.

5. The establishment of clinics or other health activities which involve medical service shall be undertaken only upon the approval of the county or district medical society.

6. Every public health nurse shall understand and support the state health laws and regulations and shall keep in direct contact with the local and state health departments.

7. Every nurse engaged in public health nursing should be approved by the Committee on Certification, for which provision has been made in the Minnesota State Health Laws and Regulations, Section 5353-4, PP. 26.

8. The work of every nursing service shall be carefully and consistently recorded. The nurse shall in addition to such reports as may be requested by the local agency make written reports through the board employing her to the state and local boards of health in such form and at such times as shall be prescribed by the State Board of Health.

9. It is suggested that all public health nurses at the time of employment, and periodically as requested by the employing agency or the State Board of Health, present a satisfactory personal health record that includes recent smallpox vaccination, evidence of immunity to diphtheria, and freedom from active tuberculosis as determined by tuberculin tests and/or x-ray and other procedures as indicated.

Physicians' Recommendations

The following recommendations are submitted to physicians for their approval, to be used as a guide to the nurse in her administration of nursing care, treatment and medication in those emergencies where no physician is in attendance, when orders have not been left by the attending physicians, or when the nurse has been unable to reach the physician for orders. In cases which will probably not require the services of a physi-

cian, the first aid treatment administered by the nurse should comply with that accepted as standard procedure by the American Red Cross.

Such recommendations should cover the general educational content of the nurse's teaching, as well as the procedures which she may perform. Physician's standing orders to nurses are concerned with:

- (1) Teaching content of health education in the home and school as regards the health and environmental sanitation of the family.
- (2) Nursing care of sick persons under or pending medical direction.
- (3) The health of school children through the nurses' part in the school health program.

Emergencies and Accidents.—Only first aid should be given. In the event of a severe accident, immediate medical care should be secured by calling the nearest physician or hospital, if it is impossible to locate the family physician of the injured person. If the patient is a minor, communicate with parent or guardian immediately.

All nurses are expected to be familiar with the standard technique adopted by the American Red Cross for the first aid treatment of accidents or injuries, and in caring for such conditions before the arrival of the physician she will limit herself to these accepted procedures.

Communicable Disease Control.—If communicable disease is suspected the nurse should explain to the family the elementary principles of isolation, concurrent and terminal disinfection, and such other measures which will aid in preventing the spread of the disease in question. (See "Home Isolation Procedures" Manual for Public Health Nurses.)

If the patient is attending a school, the school officials should be notified in writing in order that those who have had contact with him may be properly observed and the health officers of the sanitary districts in which the school is located and in which the child resides should be notified of the occurrence of suspected communicable disease as provided by Regulation 318 of the Minnesota State Health Laws and Regulations.

In the presence of suspected communicable disease the nurse is expected to make the patient as comfortable as possible, isolated from all other persons. Any of the following symptoms shall be considered sufficient reason for such isolation:

Fever 100° or more
Sore throat
Coryza
Vomiting
Rash
Inflamed eyelids
Running ears
Skin lesions, suggesting scabies or impetigo
Pediculosis

In aiding physicians in the control of preventable diseases public health nurses are expected to cooperate with the local health officer and to follow the Regulations of the State Board of Health as outlined in Chapter 6 of the Minnesota State Health Laws and

Regulations as issued by the Minnesota State Board of Health, 1938.

Immunizations.—The nurse should teach families that smallpox vaccination and diphtheria immunization should be done as early as possible, preferably before the end of the first year.

The administration of vaccines and other biologic products for the prevention of certain communicable diseases is the responsibility of the physician. Group immunization programs should be conducted under the auspices of a local medical society who may secure available biologics from the Minnesota Department of Health. The nurse's contribution to such programs involves preliminary education of the community, making the necessary arrangements for carrying through the programs, assisting the physicians when the immunizations are being performed, summarizing reports, and keeping local records of immunizations given.

Syphilis and Gonorrhea.—"Reg. 2512. All persons infected with a venereal disease shall continue under treatment or proper observation until no longer able to transmit the infection. In the case of gonorrhea this shall be until all clinical and microscopic evidence is negative.

"In the case of syphilis this shall be until all clinical and laboratory evidence is negative and sufficient treatment to reasonably insure a cure has been taken."

As problems in relation to syphilis and gonorrhea are encountered or brought to the attention of public health nurses, all available information regarding these problems should be referred to the Division of Preventable Diseases, Minnesota Department of Health, for consultation and advice regarding future responsibility of the nurse. Where cases are known to be under medical care, problems relating to them should first be discussed with the attending physician.

Any follow-up work done by public health nurses on cases brought to their attention should be reported to the Division of Preventable Diseases on a special form (L.N.G.) supplied for that purpose.

Public health nurses should always bear in mind that information relating to venereal disease should be kept confidential. See Regulation 2510, P. 63, Minnesota State Health Laws and Regulations.

Tuberculosis.—Infectious and potentially infectious cases (active or with tubercle bacilli in sputum) should be isolated preferably at a sanatorium following the diagnosis and recommendation of the attending physician or health officer. Such cases while awaiting admission to the sanatorium should be completely isolated at home. (See communicable disease isolation procedure in Public Health Nursing Manual supplied by the Minnesota Department of Health.) Special attention should be given to adequate terminal disinfection after patient has left the household. Hospitalization may also be advised for other forms of tuberculosis.

Medical examinations, including tuberculin tests and x-ray films, if necessary, should be urged for all other

members of the family and other close contacts.

Maternity and Child Health.—The public health nurse's work with mothers and infants should constitute an important part of the program. Group classwork offers a convenient medium for reaching large numbers of mothers and creating a general understanding of good habits of maternal, infant and child care. The nurse should discriminately distribute educational literature available from the Division of Child Hygiene, Minnesota Department of Health, and stimulate effective use through explanation and demonstration of the information. The public health nurse will find it desirable to secure standing orders from individual physicians for treatments and nursing procedures to be carried out for their patients.

In working with *expectant mothers* the aim should be to bring the patient under early and continuous medical care, to teach the elements of prenatal hygiene, and to carry out nursing care or treatments ordered by her physician. The nurse should help the mother plan for delivery and reception of the new baby. These preparations, and particularly the making of sterile supplies, are important when home delivery is planned.

For *obstetrical patients* nursing care may be given to mother and newborn infant. Every nurse should be concerned with the prophylactic protection of the infant's eyes and the registration of birth as required by state law. In the event of postpartum hemorrhage send for the physician at once, massage uterus against secum, elevate the foot of the bed, and keep patient quiet and warm.

Nursing care, such as bed bath and perineal cleansing, may be given to *postpartum patients*, as well as any treatment ordered by the physician. The nurse should emphasize the value of rest during the involution period and other aspects of hygiene, the value of the postpartum medical checkup, and teach the value of breast feeding.

Infants and preschool children should be visited to give instruction on diet, general hygiene, and immunizations. For the *premature* infant being cared for in the home, the field nurse can be of considerable assistance in making arrangements for maintaining the body temperature, feeding, isolation of the infant, and the giving of nursing care. The birth of a premature infant may create an emergency and obviously the best results will be obtained where the nurse is prepared and coöperating with the physician under a definitely prearranged program.

School Health.—Public health nurses in school health work are under the immediate direction of the school administration. It is recommended that a school health council be appointed with medical and dental representation to help guide the policies of the service, especially as they apply to medical and dental relationships. School nurses coöperate with physicians and dentists to improve the health of school children by means of

health education directed toward children and their parents and by consultation with parents on problems of child health and environmental sanitation.

The school nurse aids in controlling the spread of communicable disease by helping teachers recognize suspicious symptoms in children and recommending immediate separation from other children and exclusion from school until proper authorities have readmitted them.

"Reg. 318. All . . . pupils shall be reported to the school physician for medical examination unless in the opinion of the head of the school the pupil's condition requires that he or she be sent home immediately or as soon as a safe and proper conveyance can be found.

"In such cases the pupil shall be sent home and the health officer of the sanitary district concerned shall be notified immediately by the head of the school.

"In the districts where there is but one teacher for a school and in schools where there is no school physician or in the absence of the regular school physician it shall be the duty of the teacher or head of the school to exclude from school all pupils, who, in his opinion or that of the school nurse" appear to be ill or show signs of a communicable disease "and to report same to the board of health of the sanitary district in which the school is located and to the board of health of the sanitary district in which the pupil lives. The teacher shall continue to exclude such pupils until a properly signed certificate is presented from the health officer in each case.

"(Note.—A school nurse may perform the duties outlined, under the supervision of the health officer when there is no school physician.)"

GOVERNMENT TO NEED TEMPORARY AND PART-TIME CIVILIAN MEDICAL OFFICERS

The expansion of the Army creates a need for about 600 civilian medical officers in various grades for temporary and part-time service. The duties of full-time officers will be to act as doctors of medicine in active practice in hospitals, in dispensaries, and in the field. The duty of part-time officers will be to report for sick call at a fixed hour each day and to be subject to emergency call at all times.

The Civil Service Commission in making this announcement calls particular attention to the fact that part-time officers will be able to continue their regular practice. In order that this may be done, appointments to the part-time positions will be made of medical officers in the vicinity of the place of duty.

Information concerning these positions may be obtained from the Secretary of the Board of U. S. Civil Service Examiners at any first- or second-class post office, or from the United States Civil Service Commission, Washington, D. C. Physicians are urged to apply at once. This work is of the greatest importance to the success of the National Defense program.

MEDICAL ECONOMICS

Edited by the Committee on Medical Economics
of the

Minnesota State Medical Association

W. F. Braasch, M.D., Chairman

THE COUNCIL MEETS

Doctor and Defense

Medical problems of national defense chiefly occupied the Council at their fall meeting held Sunday, September 22, at the St. Paul Hotel.

Are a sufficient number of physicians available to take care of military needs and also to serve the civilian population?

What will be done with culls who are eliminated by the draft boards for physical defects?

What is to be done if blood tests for venereal disease and treatment of enrollees showing positive Wassermanns are required?

Will physicians be compensated for their work as draft board examiners?

What can the medical profession do to oppose demands for state medicine that will inevitably be made on a basis of total defense for the nation?

Answers Sought

Answers to these and many other questions are being sought by officials in charge of medical participation in national preparedness. In the nature of things they cannot all be answered now; but the following pertinent information was presented to the Council by Dr. A. J. Chesley, Secretary of the State Board of Health and Dr. H. S. Diehl, Dean of Medical Sciences at the University of Minnesota, both of whom have just returned from military conferences:

Must Give Preference

Dr. Chesley: The time factor in our preparedness is crucial. We are late, as always, and we can only hope that an act of God will save us this time as it did before. The problem that faces us today is the most important that ever faced the United States and the

medical profession and we must give preference to military preparedness before everything else in our program.

"Serious Situation"

"The majority of our trained personnel in the State Board of Health are in the Reserve or National Guard. We face a serious situation within the Department and outside the Department in all the health and sanitary departments in the state since, not only training but familiarity with local sanitary problems are essential to the smooth running of our services. The possibility of depleted personnel for these services must be faced.

"If all of the medical service suggested in some quarters for draftees is given, furthermore, it will require more physicians than there are in the United States to deliver it. For instance, if blood tests for venereal disease should be required as suggested for each man, the need for laboratory service and for competent medical service to interpret findings and undertake treatment would be immense.

Is Test Essential

"We will do what is required of us in Minnesota if we can; but it is a question if the venereal disease problem needs to be tackled on this scale. In the Army games and maneuvers in Wisconsin, for instance, it was discovered that venereal disease among the guard regiments encamped was about one-hundredth of what it is in the regular army.

"Is it essential, on that basis, that every man drafted be tested for venereal disease? And if he is, how is treatment to be given to those found infected? What is to be done about those who are found unfit, for other reasons, for service? Some solution to that problem will be demanded and the medical profession must be ready for it or—possibly—see

state medicine moving in unchallenged behind the draft."

Student Service

Dr. Diehl: As you know, all student service has been deferred for a year. First year internes will not be called and the probability is that all medical students will be allowed to complete their medical training or that student army training corps will be established at the schools.

8,000 Needed

"It is estimated that about 8,000 doctors will be needed out of the Reserve immediately this next year. About 11,000 are available in the National Guard and in the Reserve, and no more enlistments are accepted now in either, though negotiations are underway to reopen enlistment to medical men in the Guard.

"Those who are drafted and who are not in either the Reserve or the Guard will enter the service as regular enlisted men but will undoubtedly be transferred into the Medical Corps as soon as possible.

"No Compensation for Examiners"

"This is undoubtedly a long-time preparedness program and the probability is that essential teaching members of medical school staffs will not be assigned to military duty.

"It was assumed at the start that pay for medical examiners would follow the regulations of 1917. According to present plans, however, there will be no compensation for these examiners though discussions on this matter have not yet been concluded and the decision may not yet be final."

It was suggested that information brought to the Council by Dr. Chesley and Dr. Diehl, particularly problems which may involve government medical services to rejected enrollees, be submitted to the Committee on Medical Economics for study and discussion.

PREPAREDNESS CONFERENCE

A conference of great importance to national medical defense was held last week in the Headquarters Building of the American Medical Association in Chicago. Taking part in this Conference were Chairmen of the State Committees on Medical Preparedness, members of the National Committee on Medical Preparedness, rep-

resentatives of the Army and Navy and the United States Public Health Service, members of the Board of Trustees and officers of the American Medical Association.

One could not avoid being impressed with the enthusiasm and unselfish spirit of intelligent cooperation manifested by all of those assembled. The progress in medical preparedness made by the united efforts of the profession under the guidance of the American Medical Association, in cooperation with the Federal Bureaus, was most reassuring and should answer those who are skeptical regarding a democratic form of government. If all other activities were developing as rapidly as that of medical preparedness, national defense would be much farther advanced.

Main Objective

The officers of the American Medical Association are at present making the matter of medical preparedness their main objective. It is a prodigious task to assemble data concerning more than 160,000 physicians in the United States and to make such data available for practical purposes. Already more than 100,000 information cards have been turned in by physicians and it is the hope of the Bureau that the return will be 100 per cent. In order to carry on this great task the Bureau of Medical Economics, under the capable leadership of Dr. Leland, has greatly augmented its staff and is devoting its entire time to this purpose. Other problems affecting medical economics will, for the present, have to await the completion of this most important task.

Pamphlet Will Be Prepared

As previously announced, preparations are being made by Dr. Fishbein to publish a pamphlet, beginning the first of the year, which will be devoted to news and developments affecting military medicine. This will make available the rapid transmission and co-ordination of recent developments in all fields of medicine.

Efforts Hampered

Many officers of the American Medical Association find themselves in a rather anomalous situation in that in spite of their unselfish and able coöperation in defense of their country, they soon will be hailed into court in Washington, D. C. to defend themselves against the charge of conspiring to violate the federal laws of trade. It will be necessary for many of the officials of the A.M.A. to move to Washington and establish temporary headquarters there for an

indefinite period of time, since they will be held liable to summons any time after October 21. This will naturally hamper their efforts to carry on in the interest of medical preparedness.

way to more extensive federal methods of examination and therapy.

W. F. B.

Medical Committee Appointed

It is of interest that the national coöperating Committee on Medical Defense has finally been appointed by President Roosevelt. This includes the Surgeon Generals of the Army, Navy and United States Public Health Services, Dr. Weed, representing the Council on Medical Research, and Dr. Irvin Abell, representing the A.M.A. as Chairman. Apparently considerable controversy arose in inner governmental circles as to the advisability of appointing Dr. Abell; but the matter was finally decided in his favor. He holds the unique position of being Chairman of the Committee on Medical Preparedness which was appointed by the House of Delegates of the A.M.A., Chairman of the Board of Regents of the American College of Surgeons, and, as Past President, is a direct representative of the American Medical Association. American medicine is indeed fortunate to have a representative so able, not alone in his profession but in an executive capacity and as a diplomat, to represent its cause. He enjoys the confidence not only of his colleagues, but of the officers of the various federal health activities and other governmental leaders. Needless to say, his efforts will be ably aided by the officers of the A.M.A.

Test Proposed

One of the most interesting contributions to the program was included in the discussion by Surgeon General Parran of the United States Public Health Service. He proposes to have serologic test for syphilis included in the medical examination of every recruit. The suggestion would seem to offer a wonderful opportunity to determine the incidence of syphilis, to give it adequate treatment, and to go a long way towards its eradication. Whether or not, it is feasible and whether it will interfere with induction of the troops into service remains to be seen.

One thought occurs to those of us who are interested in maintaining the present form of the practice of medicine, and that is whether such examinations which are not strictly necessary, and which are made without charge by governmental agencies, will act as an example and open the

MINUTES OF THE CONFERENCE

The meeting of the State Chairmen of the Committee on Medical Preparedness of the American Medical Association held at the A.M.A. Headquarters in Chicago on Friday, September 20, 1940, was called to order by Dr. Paullin, Secretary of the Committee on Medical Preparedness. The roll call revealed that most of the states were represented by their chairmen of the Committee on Medical Preparedness.

Col. Charles B. Spruit from the Surgeon General's office of the War Department spoke of the selective draft program, explaining the various set-ups from the local board and its personnel to and including the Induction Board of the Army. He discussed the various classifications of selectees. In the course of the discussion he stated that the local medical examiner could not examine relatives; that the local board would be privileged to call in a physician in an advisory capacity. It was felt that the civilian physician who is in the second or third class would be the logical one to call for such duties. The status of the examining physician will be that of a government official without pay. The local examining physician cannot be a member of the armed force of the nation. The government has ruled that only practitioners of medicine can conduct examinations.

Medical Society to Indorse

A question arose as to the priority of reserve officers who would not be available for one reason or another, due to local circumstances and who would be placed on a priority list. When such men are called an endorsement will be made by the local medical society to the surgeon of the corps area from which the call came. He will in turn transmit this to the Surgeon General's office through military channels, and the Surgeon General will make the final decision. (In other words, if a reserve officer has assumed some obligation and is unable to get away at the time, the county society can state the reason to the surgeon of the corps area so that the applicant may be put on the low priority list.)

Internes in hospitals will not be called until

one year of service has been completed. They will also be placed, therefore, on a low priority list. Resident physicians, on the other hand, who are in their last few months of service, will be in the high priority list, subject to call. Students entering medical schools will not be drafted for at least one year. Registration of all students in the College of Science, Literature and the Arts will be necessary, but deferment will be made until July 1, 1941. Cadets of the Senior R.O.T.C. of the Army and Navy are exempt from registration.

No Group Deferments

There will be no exemption of any groups or agencies and deferment will not be made on any group basis. The merits of each individual case will be decided upon by the local board.

In case of a public health officer in a community being called, the State Board of Health will be consulted and will give its endorsement relative to the induction of such an official in a local community.

The Advisory Board is composed of specialists who will act in such capacity when called upon by the local examining board's physician.

Appeals

The Appeal Board, one for every 600,000 population, will review such matters as come before it in regard to individuals who do not wish to be inducted. Their decision will be final.

It was suggested that patriotic bodies, such as the American Legion, should use their influence to encourage selectees in registering.

Psychiatric Problems

The importance of neuropsychiatry was touched upon. Dr. Parran stated that 2.2 per cent of those inducted into service in the last war had evidence of neuropsychiatric lesions and that 2.2 per cent of every 400,000 men enlisted would eventually be government charges. It has been calculated that each individual costs the government \$30,000. In other words, in an army of 1,200,000 men the cost would be \$657,000,000.

Recruits to Be Radiographed

Col. Love of the Surgeon General's office stated that there would be approximately 15,000 men in the medical reserves, of whom 8,000 would be required by July 1, 1941. He also stated that x-ray examination of the chest would

be made in the case of all recruits before they are finally inducted and again at the time of discharge from federal service. These films are usually the 5 x 7 size, but Capt. Sutton stated that the Navy would use the 35 mm. film.

Navy Needs

Capt. Sutton, representing the Surgeon General of the Navy, stated that the Navy was having no difficulty in procuring the number of enlisted personnel up to the present time; that eventually 500,000 enlistments would be required for the naval services and that these would be trained in eight or ten training stations in the United States. There are 1,100 vacancies in the naval reserve and 208 vacancies in the medical corps of the Navy. The Bureau prefers the commissioning of recent graduates.

First Induction

The first induction will be that of 375,000 registrants. There will be 143,000 registration precincts in the United States. There will be 3,717 registration precincts in the State. There will be 412 in Hennepin County, 250 in Ramsey County, 242 in St. Louis County, and the remainder will be distributed throughout the state. There will be approximately 140 draft boards in the state. There will be 6,500 draft boards in the United States. Practically 16,500,000 men between the ages of 21 and 35 years will be examined. Out of every 100 men 63.7 per cent will be accepted.

The report of September 18 relative to the response of physicians to the questionnaire on Medical Preparedness reveals that the Seventh Corps Area, which includes Minnesota, has had the largest number of returns. On that date Minnesota had a return of 81.4 per cent.

F. L. SMITH

ATTACK BY AIR

With the shrewdness and determination worthy of a better cause, the Department of the Interior is now making use of the defense emergency to reform medical services to the civilian population.

Radio is the medium and the program which carried one telling blast was part of a series entitled, "This, Our America." It was called "Health and Education" and it was carried over the Blue Network August 21, 1940.

To begin with it is interesting to note that the government gives education in America a rating of 100 per cent both as to aims and accomplishment.

Inadequate Service Charged

Medical aims and accomplishments rate, by contrast, a small amount of perfunctory and grudging praise and a large amount of blame for inadequacy of services to one-third of the population with annual incomes under \$750.00, to mothers, to cancer sufferers, to workers in industry. By inference, indeed, medicine is accused of over-charging and of poor service generally to low income patients.

These programs are prepared and staged with all the latest radio tricks. Music and alternative narrators are used in the "Health and Education" broadcast, with a character named "Joe Average Guy" to ask questions and four victims to tell their distressful tales of neglect.

It is hard to see how any average layman who heard it could fail to be convinced of a terrible lack of medical and hospital services in this country. Most would hear between cues an equally terrible indictment of the medical profession for inertia and inability to handle its own problems—if nothing worse.

School System Praised

Many valid and even formidable criticisms of our educational system are heard within and without the ranks of educators these days but the Department of the Interior emphatically finds no fault or deficiency with the school system of the United States as a factor in our national defense.

Somewhat similar though less objectionable programs are also being offered to radio stations currently by the United States Public Health Service. One of these, recently submitted for study to the Committee on Radio, was a plea for earlier diagnosis of cancer and, incidentally, for more facilities where expert treatment might be available at little or no cost to patients. The Committee has not approved this program.

If War Fever Grows

The danger in all this is clear. Where the Wagner bill was halted in committee on its merits, a new health bill embodying actual state medicine as a defense measure will not be argued upon its merits at all, but upon its fancied con-

tribution to the total preparation for war. When and if war fever grows in the United States it may quickly become an act of treason to argue against any ill-conceived and unwanted measure for civil reform, if only it can be proposed in the name of national defense.

PROFESSION MUST ACT

Complete medical care for workers, particularly those engaged in defense industries, should be an integral part of the program of the National Defense Advisory Commission according to the Bureau of Co-operative Medicine, Dr. Kingsley Roberts of New York, medical adviser.

A statement to the Commission is printed in full in a recent bulletin from the Bureau in which attention is called to accumulated evidence gathered during the last ten years to prove that "we cannot rely upon present methods for the purchase and distribution of medical care."

"Industrial medical services to care for occupational injuries and illness are too limited to meet the need for increased efficiency," says this statement. "A proper program can admit of no less than complete medical care."

"With such a program there is reason to believe that absenteeism due to illness might be substantially reduced. A reduction of one quarter would have the direct effect of adding to our resources of skilled labor about six men for each thousand employed, or a saving of about 1,700 work days per year for each 1,000 men. The indirect effect of improved health upon productive capability is incalculable.

"As both labor and industry have a stake in the health of the worker, the role of the government should be to facilitate the initiation of organized medical services for these groups."

Danger Acute

Obviously from the above, there is a job to be done by organized medicine. Private advocates of compulsory sickness insurance, no less than government agencies, are losing no time in tying increased government medical services to defense measures. The danger to American medicine is acute. Physicians who see the danger will have to act as a body, definitely and promptly, not only in Washington but at the polls in November.

"ESSENTIAL INSURANCE"

(Monthly Editorial Prepared by the Medical Advisory Committee)

The carrying of liability insurance by drivers of automobiles is just as necessary the first hour of driving a new car as it is after years of use of the same car, the possibility of accident being just as great at one time as another.

Likewise, the possibility of a suit being brought against the beginner in the practice of medicine is just as likely, because of alleged malpractice, the first day of practice as it may be at any time during his professional career.

Most of the companies writing liability insurance in Minnesota have as one of their prime requisites that a purchaser of a policy be a member of his county and state society in good standing. This is rightly so but tends to work a hardship on the beginner in practice who may wish to buy a policy.

Your Medical Advisory Committee believes that to avoid this injustice a more liberal interpretation might be advanced by the companies under the following requirements:

1. That the applicant be licensed to practice in the state of Minnesota with the title of Medical Doctor.

2. That he make arrangements (the rental of an office, purchase of furniture, etc.) to become a settled practitioner in the community he proposes to practice in.

3. That he do nothing in the way of advertising to promote his acceptance in the community.

4. That investigation show him to be a man of high moral character, who from an ethical standpoint would become a valuable member of his medical society.

5. That after investigation, the president and the secretary of the County Medical Society must be willing to recommend him.

6. That he show his intention of becoming a member of organized medicine by filling out a tentative application for the county society at the time that the insurance company writes his policy, it being understood that the rules and regulations as to time of admittance into the county society are governed by the by-laws of that society and the approval of the board of censors.

7. That it be understood by him and the insurance company that if he is not elected to membership in the county society, the insurance policy which is issued to him becomes null and void and the unearned premium will be returned to him.

It might be well for the secretaries and members of component county societies to invite at once new men in their communities to medical meetings. This will promote future membership and give the newcomer in the community a feeling of the fellowship so necessary in these troubled times.

B. J. B.

MINNESOTA STATE BOARD OF MEDICAL EXAMINERS

Saint Paul, Minnesota

J. F. Du Bois, M.D., Secretary

Fake Doctor Pleads Guilty to Petit Larceny in St. Paul

Re. State of Minnesota vs. Edward Alvin Johnson, also known as Edward Alvin Yonnson.

On September 5, 1940, "Dr." Edward Alvin Johnson, twenty-eight years of age, who gave his home address as Inglewood, California, entered a plea of guilty in Municipal Court of Saint Paul, to a complaint charging him with the crime of petit larceny. The charge was based on the theft by Johnson of a physician's stethoscope from a Saint Paul Hospital on August 23, 1940.

Johnson was arrested at 1469 Lafond St. by members of the Saint Paul Police Department, on August 29, 1940, following their investigation into the theft of the stethoscope. Judge Robert V. Rensch sentenced Johnson to sixty days in the Saint Paul Workhouse and suspended the sentence upon Johnson's statement that he desired to return to his home in California where he stated that his mother and wife resided.

Johnson stated that he left Los Angeles for Saint Paul on August 5, 1940. Upon his arrival in Saint Paul he posed as a physician and visited at four Saint Paul hospitals, where he claims he viewed two surgical operations and one birth delivery. Johnson also admitted that he had represented himself as a doctor in Los Angeles. At the time of Johnson's arrest members of the Saint Paul Police Department found a prescription book in his room and a number of surgical instruments and various medicinal preparations. Johnson was arrested before he had an opportunity to examine, or treat, any patients, consequently he was charged with petit larceny rather than with practicing medicine illegally. The only excuse offered by Johnson for his fraudulent representations was that he enlisted in the army in 1934, and was assigned to the medical corps as a hospital orderly. He claims to

have studied pre-medical subjects at Golden Gate Junior College, San Francisco, California. He told the Saint Paul Police Department that he was married on July 28, 1940, to a former Wavonia, Minnesota, girl who graduated as a nurse from one of the Saint Paul hospitals.

Johnson was interviewed by a reporter for a Saint Paul newspaper and told a rather elaborate story of having spent three years in Alaska with the United States Public Health Service. He claimed to hold memberships in numerous scientific organizations and that he received his medical degree at Berkeley, California. It subsequently developed that the entire story was false.

The Minnesota State Board of Medical Examiners wishes to caution the medical profession, and the hospitals as well, about the responsibility that attaches when an unlicensed person is permitted in an operating room or in a delivery room. Without the consent of the patient such an act is an illegal invasion of the privacy of the patient and can result in a serious lawsuit. It is a simple matter to make inquiry with respect to an individual's status from the standpoint of medical licensure. Satisfactory proof of a licensure should be required in every instance when a stranger represents himself as a physician. The Minnesota State Board of Medical Examiners is only too glad to co-operate with every physician and every hospital in the State of Minnesota in making impossible any such situation as occurred in this case.

Quack Doctor Fined \$1,000.00 at Rochester, Minnesota

Re. State of Minnesota vs. William F. Awe. William F. Awe, fifty-three years of age, who gave Denver, Colorado, as his home address, and who stated that he was one-fourth Cherokee Indian, was sentenced

on September 21, 1940 by the Honorable Vernon Gates, Judge of the District Court at Rochester, Minnesota, to pay a fine of \$1,000.00 for practicing healing without a basic science certificate. Judge Gates ordered that Awe be confined in the Olm-

sted County Jail until such time as the fine is paid, not exceeding six months.

Awe was arrested on September 14, 1940, by Detective George Rohde of the Rochester Police Department, and E. L. Antletz, Agent of the Minnesota Bureau of Criminal Apprehension, following the discovery that Awe was treating an eight months old Chester, Iowa, baby for eczema for which Awe was to be paid \$40.00. The method of treatment consisted of bathing the baby in mineral water and also giving some of the mineral water internally. The Minnesota State Board of Medical Examiners was immediately notified and on September 17, 1940 Mr. Brist filed a complaint against Awe in behalf of the Medical Board, following which Awe was arraigned in the Municipal Court at Rochester, Minnesota, before Judge Burt W. Eaton. Awe waived a preliminary hearing and was held to the District Court with bail being fixed at \$1,000.00.

At the time of his arrest, Awe was accompanied by a twenty-four-year old Burlington, Colorado, girl who stated that she was acting as his secretary. The investigation disclosed that Awe obtained the mineral water, also some so-called mineral earth, at South Bend, Texas. Awe represented the mineral water and mineral earth as being a cure for blindness, cancer, eczema, rheumatism, kidney trouble and many other

ailments. Awe sold the mineral water at \$15.00 per gallon and the mineral earth at \$1.00 for a four-ounce jar. The mineral water cost Awe 35 cents a gallon, and he obtained the mineral earth at no expense to him. Awe admitted that he had been arrested four times previously, once in South Chicago, Illinois, twice in Milwaukee, Wisconsin, and once at Anoka, Minnesota, the last three arrests being for bootlegging. Awe admitted that he had no training in medicine, pharmacy, or any other form of healing. Awe's only explanation to the Court for attempting such illegal practices was his need of money. After denouncing the defendant in no uncertain terms, Judge Gates imposed the maximum fine permitted under the law. Awe was unable to pay the fine and was taken to the County Jail to serve his sentence.

The Minnesota State Board of Medical Examiners wishes to acknowledge the prompt and efficient work done in this case by Chief Harry N. Tompkins of the Rochester Police Department, Detective George Rohde of the same Department, and E. L. Antletz, Agent of the Minnesota Bureau of Criminal Apprehension. The Minnesota State Board of Medical Examiners also wishes to acknowledge the co-operation of Mr. Thomas J. Scanlon, County Attorney of Olmsted County.

Steele County Jury Acquits Woman of Massage Charge

Re State of Minnesota v. Harriet Hershberger.

On September 13, 1940 a jury in the district court of Steele county brought in a verdict of not guilty in the case in which Mrs. Harriet Hershberger was charged with practicing massage without a license. The state introduced evidence to show that the defendant was giving massage treatments in her home at 422 E. Vine Street, Owatonna, and that she was paid \$1.25 per treatment. Mrs. Hershberger admitted that she was not licensed but claimed that she was just giving olive oil baths and divine healing. She also claimed to be a practical nurse. Notwithstanding the fact that none of the claims advanced by the defendant constitute a defense under the healing laws of Minnesota the jury found her not guilty.

The case was well tried for the state by Mr. Axel Anderson, county attorney of Steele county. The State Board of Medical Examiners requests that any evidence indicating that Mrs. Hershberger is continuing in her practices, be promptly called to their attention.

COUNTER PRESCRIBING A FEDERAL OFFENCE

It is worth every doctor's time to study thoroughly the provisions of the new Federal Drug and Food Act. The act is now in effect and places significant restrictions on the dispensing of drugs, particularly by the pharmaceutical profession. Drugs like the barbiturates and sulfanilamide are specifically restricted in their sale, and providing the druggist obeys the law, counter prescribing of such dangerous medicaments is definitely hampered.

Not only the druggist, but the doctor who dispenses these drugs from his office is affected by the regulation. Physicians who dispense drugs must go to the trouble of marking the complete name, dose, and other pertinent information on the package before giving it to the patient. Whether this portion of the law will be rigidly enforced must be proven by time, but it is well to note it is now a Federal Act that compels one to do so, and can be enforced.

Gone are the days when samples may be dispensed with careless abandon.

Bulletin Oklahoma County Medical Association.—

OF GENERAL INTEREST

Dr. and Mrs. Ralph V. Ellis of Saint Paul vacationed for three weeks in Mexico in August. They visited in New Orleans on their return.

* * *

Dr. Henry Michelson of Minneapolis, who received minor injuries in an automobile accident, August 11, is now fully recovered and has returned to his practice.

* * *

Dr. Lawrence M. Larson of Minneapolis has been appointed medical examiner for the administrator of civil aeronautics of the Minneapolis district.

* * *

Dr. Robert E. Mattison has opened offices at 1951 Medical Arts Building, Minneapolis. His practice will be limited to obstetrics and gynecology.

* * *

Dr. George A. Pollock, who has been at the Mayo Clinic at Rochester, has returned to his home in Great Britain. His address is Peel Hospital, Clovensfords, Selkirkshire, Scotland.

* * *

Dr. Richard M. Hewitt of Rochester was in Washington, D. C., August 26, to attend the meeting of the Committee on Information of the Division of Medical Sciences of the National Research Council.

* * *

Dr. Northrop Beach, who recently completed an internship at Johns Hopkins Hospital in Baltimore, became associated with the University of Minnesota Hospitals as a medical fellow in pediatrics, September 1.

* * *

Dr. Charlotte M. Gast of Memphis, Tennessee, has been appointed assistant professor and assistant director of the course in medical technology at the University of Minnesota.

* * *

Dr. Edwin S. Fetcher, formerly of the University of Chicago, and Dr. Robert B. Dean of the University of Rochester, have been appointed instructors in the department of physiology, University of Minnesota Medical School.

* * *

Dr. Karl H. Pfuetze, who has been on the medical staff at the Nopeming sanatorium at Nopeming for the past three years, has accepted a position as physician on the staff of the Mineral Springs Sanatorium at Cannon Falls.

* * *

Dr. J. Willard Hanson, who has been a medical fellow in pediatrics in the University of Minnesota Hospitals, has accepted a position in the Health Service of the University of Kansas in Lawrence, Kansas. The appointment was effective September 1.

* * *

Dr. H. S. Diehl was in Washington D. C. about the middle of September to confer with Dr. Thomas Parran, Surgeon-General of the United States Public Health Service on health phases of the preparedness program.

Dr. Walter G. L. Tanglin of Mahomen, Minnesota, has taken over the practice of Dr. Philip C. Noble in Polson, Montana. Dr. Noble, a graduate of Rush Medical College, has become a volunteer fellow in the University of Minnesota Hospitals, Minneapolis.

* * *

The marriage of Dr. Rodney F. Sturley and Miss Jane Read of White Bear took place August 20. They are making their home in Minneapolis, where Dr. Sturley is a fellow in obstetrics and gynecology in the University of Minnesota Hospitals.

* * *

A fine new hospital to serve the people of northern Minnesota was opened recently at Roseau. Known as the Budd Hospital, it is under the supervision of Mrs. Marie Budd, who for years has maintained a hospital there.

* * *

Dr. C. O. Estrem of Fergus Falls recently suffered an attack of coronary thrombosis and has been a patient at St. Luke's Hospital in that city. He is convalescing very satisfactorily and expects to be able to resume his practice in a few weeks.

* * *

Dr. L. Gordon Samuelson, who has been practicing in Mankato, left early in September for Carlisle, Pa., where he took a five-weeks' training course before reporting for duty in the medical detachment at March Field, California.

* * *

Dr. Allen G. Johnson of Brainerd has taken over the offices and practice of Dr. N. J. Kulzer in Hastings. A graduate of the University of Minnesota Medical School, he completed his internship at St. Mary's hospital in Duluth in 1938. Prior to locating in Hastings, he practised in Duluth.

* * *

Minnesota physicians who took part in the program of the nineteenth annual American Congress of Physical Therapy in Cleveland, September 2-8, included: Drs. E. V. Allen, Earl C. Elkins, Roger L. Kennedy, Philip S. Hench, Frank H. Krusen and Edward F. Rosenberg, all of Rochester.

* * *

Dr. L. B. Wilson of Rochester, director emeritus of the Mayo Foundation, was principal speaker at the dedication of the beautiful new Museum of Natural History on the University of Minnesota campus, September 28. The dedicatory ceremonies took place at an open house in the evening. Other speakers included President Guy Stanton Ford, and James Ford Bell, principal donor of the museum. Completion of the Museum of Natural History is a dream come true for Dr. Thomas S. Roberts, director. A one-time practicing physician, Dr. Roberts has devoted many years in developing the museum.

OF GENERAL INTEREST

Dr. L. L. Kallestad has located in Hutchinson, opening an office in the Ritter Building. Dr. Kallestad, who was graduated from the University of Minnesota Medical School in 1938, interned at the Minneapolis General Hospital. During the past summer, he took care of the practice of Dr. Arthur Thompson at Cokato.

* * *

Dr. P. M. Mattill, assistant medical director of Glen Lake sanatorium, was chairman of arrangements for the eleventh annual homecoming for former patients of the sanatorium, September 14. The 300 visitors, all of whom have left the institution as cured, ranged in age from young folk to grandparents. The program included greetings by Dr. E. S. Mariette, superintendent.

* * *

Colonel Kent Nelson, M.C., U.S.A., who before his retirement last spring was Seventh Corps Area Surgeon with headquarters at Omaha, has been recalled to service at his own request and has been placed in charge of the Medical ROTC unit at the University of Minnesota. Colonel Nelson was graduated from the University of Minnesota Medical School in 1900.

* * *

Drs. J. A. Myers and Alex Blumstein of Minneapolis are scheduled to speak at meetings of the Minneapolis Nurses' Association, it is announced with the release of the organization's 1940-41 year book. Dr. Myer will give an illustrative lecture on "A South American Trip in the Air," November 13. Dr. Blumstein will speak March 12.

* * *

A proposal for the establishment of a \$250,000 fund to be collected through public subscription throughout the world for a memorial to the late Drs. William J. and Charles H. Mayo is being considered by the Mayo Memorial Commission, composed of seventeen representative citizens of Minnesota. State Senator William B. Richardson of Rochester is chairman of the commission, being appointed by Governor Harold E. Stassen.

* * *

Dr. Daniel F. McCann of Bemidji announces his association with Dr. T. P. Groschupf in the practice of medicine and surgery, effective October 1. Drs. Groschupf and McCann have their offices in the Barker building where Dr. Groschupf was located for a number of years in practice with the late Dr. E. H. Marcum. Dr. McCann has withdrawn from the firm of Drs. Johnson and McCann.

* * *

The Albert Lea Medical and Surgical Center is the name of a newly formed clinic in Albert Lea, of which Drs. W. L. Palmer, C. F. Palmer, D. L. Donovan, L. C. Barr and H. B. Neel are members. The clinic is located in the Hyde Building on East William Street.

With the exception of Dr. Neel all have been practicing in Albert Lea prior to the formation of the clinic. Dr. Neel recently completed a fellowship in the Mayo Foundation where he was a Fellow in Surgery.

* * *

Dr. John Mendenhall Snyder of Rochester, a fellow in surgery in the Mayo Foundation, accepted an invitation

of the trustees and General Alumni Society of the University of Pennsylvania to represent his alumni class at special convocations during the university's bicentennial celebration week. Dr. Snyder attended the School of Medicine at Pennsylvania, and is a member of the Class of 1934. As an alumni representative, he led his class in an alumni parade which was part of the program.

* * *

Renewed interest in the Minnesota Medical Foundation is reported by Dr. Erling S. Platou, president. The Foundation is sponsored by the Alumni Association of the University of Minnesota Medical School.

Already \$25,000 has been subscribed to the foundation for the benefit of needy superior medical students, and for aiding in worthwhile research projects for alumni.

* * *

Taking part in the dedication of a new 25-bed hospital in Warroad, recently, were Dr. A. F. Branton of Willmar, secretary, and Ray Amberg of Minneapolis, president of the Minnesota Hospital Association. This modern concrete hospital was built by WPA at a total cost of \$84,820, of which \$25,551 was contributed by the Village of Warroad and \$5,000 by the State of Minnesota through its Legislative Emergency Committee.

* * *

Dr. Charles F. Code, a former fellow in the Mayo Foundation, has been named a member of the staff of the Mayo Foundation and Clinic at the Institute of Experimental Medicine. Dr. Code was assistant professor of Physiology at the University of Minnesota Medical School from 1938-1940. During his fellowship in the Mayo Foundation, he studied in London as a Bayliss-Starling scholar. While there, he was lecturer in physiology in the University College.

* * *

In Ogden, Utah, the latter part of August to address a meeting of the Utah State Medical Association were Drs. J. T. Priestley and W. C. MacCarty of Rochester. Dr. Priestley presented two papers entitled "The conservative surgical treatment of stag-horn renal calculi" and "Carcinoma of the bladder with particular reference to total cystectomy." Dr. MacCarty spoke on "Is pernicious anemia a sign or a disease?" and "Classification of goiter."

* * *

"Common Communicable Diseases" is the Health Subject of the month. Special emphasis is being placed on scarlet fever, whooping cough and measles. Physicians may secure the monthly health packets from the Minnesota State Medical Association which distributes the bulletins as part of its Co-ordinated Medical and Public Health Education Program. The medical broadcasts by Dr. W. A. O'Brien tie in with the program.

* * *

"The Periodic Health Examination of the School Child" and "Tools of Health Education" are the subjects selected for the 1940-41 Continuation Study on Public Health Nursing. Centers for the three meet-

ings to be held in November, December and January are: Duluth, Virginia, Bemidji, Crookston, St. Cloud, Mankato, Rochester and Minneapolis, it is announced by Olivia T. Peterson, R.N., director of the Minnesota Department of Health, Division of Public Health Nursing.

* * *

Speakers at the thirty-fifth annual convention of the Minnesota Nurses' Association in Saint Paul, October 16, 17 and 18, will include Dr. Ralph W. Warnock of Saint Paul, whose topic will be "Heart Disease," and Dr. Herman E. Hilleboe of Saint Paul, medical coordinator for the Department of Social Security, Division of Social Welfare. The latter will discuss "The Proposed Public Health Program for the Prevention of Heart Disease Among Children."

Affiliated groups meeting with this association are the Minnesota League of Nursing Education and the Minnesota Organization for Public Health Nursing.

* * *

Dr. Peter D. Ward, superintendent of the Charles T. Miller hospital in Saint Paul, was reelected to the board of trustees of the American Hospital Association at its forty-second annual convention in Boston.

At the convention Dr. Ward presented a paper on "The Interdependence of Hospitals and Hospital Service Plans."

Dr. William A. O'Brien of Minneapolis gave the banquet address at the convention, September 19.

As part of the convention activities, the Minnesota Hospital Association sponsored a Minnesota Breakfast at the Statler Hotel, September 17, with President Ray Amberg of Minneapolis presiding.

* * *

Dr. E. S. Platou of Minneapolis was reelected president of the Minnesota State Board of Health at a meeting, August 29, and Dr. T. B. Magath of Rochester was elected vice president succeeding T. G. Bell of Duluth, who retired from the board.

Leo Thompson of Little Falls has been appointed to the board to succeed Mr. Bell, and Dr. F. W. Behmler of Morris has been named to succeed Dr. E. T. Fitzgerald, also of Morris.

Other board members are Ruth Boynton, M.D., Minneapolis; Prof. F. E. Bass, C. E., Minneapolis; A. G. Schulze, M.D., Saint Paul; A. C. Kean, D.D.S., Grand Rapids; and Prof. Gustav Bachman, Pharm. D., Minneapolis.

Dr. A. J. Chesley of Saint Paul was re-appointed by the board as secretary and executive officer.

* * *

Several Minnesota men will participate in the program of the American Academy of Ophthalmology and Otolaryngology when it meets in Cleveland, October 6 to 10, inclusive.

Drs. A. D. Prangen and Gordon B. New of Rochester will present papers at afternoon sessions. Dr. Prangen will also lead a discussion, as will Dr. Anderson C. Hilding of Duluth.

Among those scheduled to give instruction courses at the morning sessions are Drs. Frank E. Burch and

Hendrie Walter Grant of Saint Paul; Drs. Lawrence Randall Boies, Horace Newhart, and Walter E. Camp of Minneapolis; Drs. New, Henry P. Wagener, and Henry L. Williams of Rochester; and Dr. Hilding of Duluth.

Dr. Erling W. Hansen of Minneapolis is secretary of public relations for the academy, and Dr. William L. Benedict of Rochester is secretary for the Section of Ophthalmology.

Dr. Benedict will present a paper at the Pan-American Congress of Ophthalmology being sponsored by the Academy at the conclusion of its session. At this Congress, October 11 and 12, papers will be presented in the English, Spanish and Portuguese languages, with translations.

* * *

Seventy-three medical and administrative executives will make up the United States General Hospital unit, No. 26, which is being organized at the University of Minnesota under the direction of Dr. Harold Diehl, dean of medical sciences.

Plans for the organization of the unit were outlined by Dr. Diehl, who recently returned from Washington, D. C., where he conferred with officials about the formation of the wartime hospital unit.

The 73 medical and administrative executives will be taken from the faculty, the part-time faculty and the fellows doing postgraduate medical work at the university. Implemented with nurses, technicians and orderlies, such a staff could care for 1,000 wounded. Its rôle would be treatment well back of the lines of soldiers whose cases are too severe for care at front line first-aid stations.

In the unit will be specialists in communicable diseases, psychiatry, tuberculosis, heart diseases, skin disorders, metabolism, allergies, plastic, urologic and other types of surgery and a host of others including x-ray.

In addition to the physicians and the administrative staff, the hospital unit will consist of 120 nurses, 64 technical sergeants, 17 corporals, 140 first-class privates, and 279 privates.

Joining the hospital unit is solely on a volunteer basis at the university, yet not a single member of the staff has failed to forward his application. Not all are being accepted, however, because some are considered more valuable in their teaching capacities, and others are in categories already filled. The medical members join the unit by signing up with the army reserve corps. They will not be called into service, however, unless actual war breaks out. The nurses will be received through the Red Cross and military helpers will be assigned by the war department.

* * *

Among the seventy members of the University of Minnesota faculty promoted to a higher rank than they held last year, were thirty-two members of the Medical School staff. Of these, thirteen are from the Mayo Foundation staff.

Promoted from associate professor to full professorship were: Dr. Halvor O. Halvorson, bacteriology; Dr. Raymond N. Bieter, pharmacology; Dr. William A.

O'Brien, preventive medicine and public health, and director of Postgraduate Medical Education; Dr. Cecil J. Watson, professor of medicine, and director of the Division of Internal Medicine; Dr. William T. Peyton, professor of surgery and director of the Division of Neurosurgery; Dr. George O. Burr, professor of botany and of physiology and also director of the Division of Physiological Chemistry.

Raised to the rank of associate professor from assistant professor or other rank were: Dr. Starke R. Hathaway, clinical psychologist and associate professor of nervous and mental diseases; Dr. James B. Carey, clinical associate professor of medicine; Dr. Arthur C. Kerkhof, clinical associate professor of medicine; Dr. Wallace D. Armstrong, associate professor of physiology, and director of biological research in dentistry. Also Drs. Della G. Drips, Howard K. Gray, Samuel F. Haines, Howard R. Hartman, Howard L. Mason, Charles W. Mayo, Harry L. Smith and Marschelle H. Power (experimental biochemistry), all of the Mayo Foundation.

Promoted to assistant professor: Drs. Phillip Hallock, Charles J. Hutchinson, Horatio B. Sweetser, clinical assistant professors of medicine; Drs. Claude J. Ehrenberg and Everett C. Hartley, clinical assistant professors of obstetrics and gynecology; Dr. Herman E. Hilleboe, clinical assistant professor of preventive medicine and public health; Dr. L. Earle Arnow, assistant professor of physiology; Dr. Miland E. Knapp, radiology and physical therapy; Dr. Donald W. Cowan, Students Health Service. Also Drs. Byron E. Hall, H. Corwin Hinshaw, Charles H. Slocumb, Edward B. Tuohy and Marvin M. D. Williams of the Mayo Foundation.

* * *

OPENINGS IN THE NAVY

The Medical Corps of the Navy is being increased in strength proportionate with the expanding Navy and the Marine Corps. Examinations for appointments as commissioned officers in the Medical Department of the Navy will be held January 6 to 9, 1941.

Appointments are being made in the Medical Corps, United States Naval Reserve, of male citizens of the United States, graduates of class "A" medical schools, who are under 50 years of age and who meet the physical and professional requirements.

The examination to be held in January will be for appointment as Assistant Surgeon, in the Medical Corps of the Regular Navy, effective approximately two months from date of examination, and for Acting Assistant Surgeon (Intern), effective July 1, 1941. Requests for authorization to appear for these examinations should be submitted to the Bureau of Medicine & Surgery, Navy Department, Washington, D. C., in sufficient time to permit the authorization to reach the applicant prior to December 30, 1940.

Applicants for appointments as Assistant Surgeon must be citizens of the United States between the ages of 21 and 31, graduates of Class "A" medical schools and have completed one year of intern training in a

hospital accredited for intern training by the Council on Medical Education and Hospitals of the American Medical Association.

Applicants for appointment as Acting Assistant Surgeon (Intern) are not required to submit evidence of previous intern training, and are appointed for a period of eighteen months, during which time they serve as interns in the larger naval hospitals which are approved for intern training. After completion of one year of service Acting Assistant Surgeons are eligible for examination for appointment as Assistant Surgeons. Acting Assistant Surgeons and Assistant Surgeons receive the pay and allowances of a Lieutenant (junior grade).

The Medical Corps of the Navy is being increased in strength proportionate with the expanding Navy and the U. S. Marine Corps. Service for medical officers is active professionally and attractive in the shore duty, sea, and foreign shore station assignments. In the normal rotation of assignments every practicable consideration is given the officer's preference for the type of duty he desires. The Naval Medical School at the Naval Medical Center, Washington, D. C., offers a course of post-graduate instruction and instruction in those branches of medicine which apply particularly to the Naval Service. Under normal conditions newly appointed medical officers are assigned to this course upon entry into the service or during their first few years of naval service.

Naval medical officers are encouraged to develop a specialty after they have completed their first cruise at sea. Shortly before completion of his sea duty, the Navy doctor may request special training in the Medical Department specialty in which he is interested. Such requests are acted upon by a special board in the Bureau of Medicine and Surgery and, if approved, the Navy doctor is sent to a hospital for training and experience in that specialty for one year. Upon completion of this training, he is assigned to post-graduate instruction at one of the many medical centers in the United States for a period up to one year after which, in so far as is practicable, he is retained in that type of duty.

The service affords excellent opportunities for professional advancement. Medical officers receive the same pay and allowances as other officers of the Navy in corresponding ranks and the equivalent amount of service.

A circular of information for applicants for appointment as medical officers of the Navy, containing full information regarding physical requirements, professional examinations, rates of pay, and promotion and retirement data may be obtained by addressing the Bureau of Medicine and Surgery, Navy Department, Washington, D. C.

Applicants for appointment in the Medical Corps of the United States Naval Reserve should be addressed to the Commandant of the Ninth Naval District, Great Lakes, Illinois, who will upon request furnish complete information regarding vacancies in ranks, etc., of officers of the Medical Corps, United States Naval Reserve in the district.

In Memoriam

William Hugh Carroll

Dr. Walter H. Carroll, senior resident physician at Glen Lake Sanatorium, died August 7, 1940, at Eitel Hospital, Minneapolis. Dr. Carroll was thirty-one years old and had been ill seven weeks.

He was born at Gilbert, Minnesota, March 3, 1909, and moved with his parents to Hibbing in 1913. Here he graduated from high school in 1927 and Junior College in 1929. He received his medical degree from the University of Minnesota Medical School in 1932. In 1933 he finished a year's internship at the University Hospital and finished a six months' fellowship in surgery at the same hospital in 1934. After filling a locum tenens for three months at Aitkin he went to Glen Lake Sanatorium in October, 1934, and was senior resident physician at this institution at the time of his death.

On July 2, 1938, Dr. Carroll married Fern Carlson, a social service worker at Glen Lake Sanatorium, but formerly of Saint Paul. She and an infant daughter, born October 19, 1939, survive him. He is also survived by his father and mother, Mr. and Mrs. Edward G. Carroll of Hibbing; a brother, John E. Carroll of Chicago, and two sisters, Katherine of Minneapolis and Margaret of Hibbing.

Joseph Michael Hilger

Dr. Joseph M. Hilger, for thirty-six years a practitioner at Iona, Minnesota, died suddenly at his home on September 5, 1940.

Dr. Hilger was born in Mazeppa, Minnesota, December 29, 1879. He received his early education at the Mazeppa public schools and received his medical degree at the University of Illinois in Chicago in 1903. He was licensed in Minnesota in 1904 and began practice that year in Iona.

Dr. Hilger married Rosella Haumasser June 30, 1908, at Fulda. Nine children have blessed this union, four sons and four daughters surviving.

Dr. Hilger was a member of the Catholic Order of Foresters and the Knights of Columbus.

Dr. Hilger began his career before modern automobile transportation became what it is, when a physician was forced to rely upon the horse and buggy. He will be sadly missed by the families he has helped and counseled during his thirty-six years of practice.

Alvah H. Jensen

Dr. Alvah H. Jensen of Hutchinson, Minnesota, died suddenly of a heart attack on July 8, 1940, at the age of forty-four.

Dr. Jensen was born February 13, 1896, in Wisconsin. He moved with his parents to Minden, Nebraska, where he attended high school. After a year of medicine at the University of Nebraska, he continued his medical education at the University of Minnesota. In

April, 1918, he enlisted in the Navy and made several trips across the Atlantic during the war. After the war he completed his medical education at the University of Minnesota and served his internship at Bethesda Hospital, Saint Paul, and in the Shriners' Hospital. He practiced in Saint Paul a year before going to Hutchinson in August, 1926.

Dr. Jensen was a member of the McLeod County Medical Society, the Minnesota State and American Medical Associations.

Louis Watson Satterlee

Dr. Louis W. Satterlee, for over thirty years health officer of Alexandria, passed away at his home August 30, 1940, at the age of eighty-five.

Dr. Satterlee was born at Nunda, New York, April 21, 1856. In 1868 he moved with his parents to Etna, Pennsylvania. Later he attended Western University at Pittsburgh. From 1876 to 1878 he taught rural schools in Alleghany County, and the next twelve years were spent in Bradford, Sawyer City, West Hickory and Grand Valley, Pennsylvania.

On April 9, 1884, Dr. Satterlee married Mary Adella Prosser. Two children, Cleora Lois (Mrs. Harry J. Havens) now of Miltona, and Levi Herbert Satterlee, now of Sunland, California, survive.

Dr. Satterlee moved to Chicago in 1891 and studied medicine at the Hahneman Medical School there. After graduation in 189, he located in Murdock, Minnesota. Here his wife died in 1899.

In 1902 Dr. Satterlee moved to Clearwater, Minnesota, and September 12, 1903, he married Josephine Boutwell. Two children, Dorothy and Kenneth were born of this union.

In 1905 Dr. Satterlee moved to Alexandria, and with the exception of a few years spent at Pequot, Parkers Prairie and Villard, Alexandria has since been his home. He was a member of the Congregational Church and of the Modern Woodmen.

REPORTS and ANNOUNCEMENTS

MINNEAPOLIS CLINICAL CLUB

The program for the October tenth meeting of the Minneapolis Clinical Club in the Medical Arts Building follows:

"Kodachrome Photography in Dermatology"—Dr. Carl W. Laymon
"Factitious Proctitis Caused by Irradiation" and "Value of Macroscopic and Microscopic Examination of Excised Rectal and Anal Tissue"—Dr. Harry W. Christianson.
"Gastroenterostomy" (a motion picture)—Dr. James M. Hayes.

Dr. Lawrence R. Boies is president of the club, and Dr. Ernest R. Anderson, secretary.

MINNEAPOLIS SURGICAL SOCIETY

The Minneapolis Surgical Society will have Dr. Alton Ochsner of New Orleans as its guest speaker at its meeting Thursday, November 7. The topic of Dr. Ochsner's address has not yet been announced.

MINNESOTA PATHOLOGICAL SOCIETY

The Minnesota Pathological Society will hold its first meeting of the 1940-41 season at 8 p. m. October 15 in the amphitheater of the Institute of Anatomy at the University of Minnesota. The speaker will be Dr. Wesley W. Spink, whose topic is "Pathogenesis and Treatment of Staphylococcal Infections." There will be a discussion by Dr. E. T. Bell.

OLMSTED-HOUSTON-FILLMORE-DODGE COUNTY MEDICAL SOCIETY

Fourteen new members were added to the Olmsted-Houston-Fillmore-Dodge County Medical Society at a meeting in Rochester, September 4.

Accepted were Drs. R. Beck, John S. Drapiewski, Eldon W. Erickson, William J. Ferguson, Harry Penn Harper, Charles S. Joss, Wallace W. Lindall, Arthur J. Movius Jr., Harold A. Smedal, Charles S. Stroebel Jr., Ray D. Williams, Clyde O. Wood, William Walter Wood and Russell Grant.

SOUTHERN MINNESOTA MEDICAL ASSOCIATION

Officers of the Southern Minnesota Medical Association elected at the association's meeting in Red Wing, September 23 are: Dr. Walter Henry Valentine of Tracy, president; Dr. A. E. Benjamin of Minneapolis, first vice president; Dr. Edward H. Juers of Red Wing, second vice president. Dr. N. W. Barker of Rochester was re-elected secretary-treasurer.

Dr. James Morrow of Austin is the retiring president.

UNIVERSITY OF MINNESOTA MEDICAL SCHOOL ALUMNI

A program of scientific papers and clinics has been arranged for the annual homecoming and meeting of

the Alumni Association of the University of Minnesota Medical School, October 25, the day preceding the University Homecoming football game.

The morning session will be followed by a short business session, and a complimentary luncheon at noon at the University of Minnesota Hospitals. Dr. Harold Benjamin, association president, will preside at the annual meeting.

The program of scientific papers and clinics will continue through the afternoon. It is also planned to arrange tours of the Medical Science building and the University of Minnesota Hospitals for visiting alumni.

The Class of 1920 will be honored guests at this homecoming.

WABASHA COUNTY MEDICAL SOCIETY

The Wabasha County Medical Society will hold its seventy-second annual meeting at Plainview, Thursday, October 10, 1940.

The program will include a business session at 4 p. m., a dinner at 6:30 p. m., and a scientific session immediately following the dinner. Entertaining physicians are Dr. E. W. Ellis of Elgin, president of the society; Dr. D. G. Mahle of Plainview, vice president; and Dr. R. A. Glabe of Plainview. Entertainment for the ladies will be provided under the auspices of the Women's Auxiliary.

Dr. W. F. Wilson of Lake City is secretary of the society.

The program for the scientific session follows:

President's Address:

1. "Duties of Physicians in Relation to Medical Preparedness."
2. "Report of a Case of Ruptured Gastric Ulcer in a Diabetic Patient."—Dr. E. W. Ellis, Elgin.

"Review of Our Present Knowledge Concerning Acute Poliomyelitis."—Dr. F. M. Feldman, Rochester, District Director, Minnesota Department of Health.

"Report on Appendectomies."—Dr. C. G. Ochsner, Wabasha.
"Physical Therapy in General Practice."—Dr. M. E. Knapp, Minneapolis.

MAYO FOUNDATION ALUMNI

The twenty-second annual meeting of the Alumni Association of the Mayo Foundation for Medical Education and Research will be held in Rochester, October 23, 24 and 25.

There will be scientific programs in the mornings and afternoons.

A special program has been planned for the evening of October 23, with talks by Dr. Donald C. Balfour, director of the Mayo Foundation; Dr. Theodore C. Blegen, dean of the Graduate School at the University of Minnesota; Dr. Louis B. Wilson, emeritus director of the Mayo Foundation; Dr. Guy Stanton Ford, president of the University of Minnesota; and Dr. George E. Vincent, president of the University of Minnesota

Secretary, HARVEY NELSON, M.D.

Symposium on Fractures and Other Trauma

INJURIES TO THE SHOULDER JOINT

GEORGE D. EITEL, M.D.
Minneapolis

In reviewing injuries of this most movable joint, we are faced with many conditions which should be discussed but can only be mentioned because of the brief time allotted.

Contusions and sprains of the shoulder are common and my only purpose in mentioning them is because of the possible injury and rupture of the supraspinatus tendon and the injury to the long head of the biceps muscles. Diagnosis is sometimes difficult and may be overlooked. I also wish to mention very disabling sequelae following contusions, such as subdeltoid bursitis, and also arthritis and peri arthritis which may result from long continued immobilization and low grade infection. The treatment should consist of physiotherapy and more recently x-ray therapy has given excellent results.

Fractures of the clavicle are also common and treatment is directed toward obtaining extension on this long bone by various types of methods, all of which obtain the same result, which is usually one of union with some over-riding. Open operation is seldom necessary.

Fractures of the scapula are rare due to the firm attachment of muscles. A fracture through the blade seldom gives displacement. Fractures of the neck of the scapula or the lower edge of the glenoid require traction on the upper extremity in abduction or preferably in hypertension and abduction so that the capsular attachments will elevate the fragment. It must be held in this position for four to six weeks, depending on the amount of callus formation.

Injury to the brachial plexus of nerves must be kept in mind; this may be of varying degrees from a mild paresthesia to a complete paralysis. Treatment is directed toward relaxing tension on the plexus by placing the arm in abduction. Late pressure may develop from callus resulting from healing of severe fractures of the clavicle and removal of the callus from the inferior surface of the clavicle is sometimes necessary.

Dislocation of the clavicle both at the manubrial and acromial end occurs. Many times the patient says he has a bone sticking up on his shoulder which shows while he stands and the weight of his upper extremities makes the deformity apparent; but on lying down the end of the clavicle stays in place. Hence, x-rays should be taken with traction on the arm so that the acromioclavicular separation is demonstrable.

Dislocation of the head of the humerus is also a

common injury. One should be certain that there is not an accompanying fracture of the upper end of the humerus before reduction is attempted. For this, x-ray pictures are essential. If a fracture is also present, a different method of replacing the dislocation is used. The general rule is that the closer the fracture is to the dislocated head, the more difficult it is to replace the dislocation, and the lower down the fracture is, the easier to reduce the dislocation. This is due to the attachment of muscles on the proximal fragment. All dislocations should be reduced before the fracture is treated.

Fractures of the upper end of the humerus have been divided into fractures of the anatomical neck and of the surgical neck. However, we rarely see, or perhaps have never seen, a true anatomical neck fracture. Kocher, in 1896, classified them as follows: (1) supra-tubercular; (2) per-tubercular; and (3) infratubercular and he was experimentally on cadavers unable to produce a fracture of the anatomical neck in an adult. This classification, I think, is still the best and should be used more often.

Fractures involving the upper end of the humerus have caused all of us many difficulties: (1) in the reduction of the fractures; (2) in the maintenance of reduction by either an aeroplane splint, which has been in vogue for about twenty-five years, or by a massive plaster cast, or by fixed bed traction; and (3) in the long and many times permanent disability due to inability to abduct normally. The patient has likewise suffered from the cumbersome apparatus worn. We all have seen fractures in fairly good position with the upper extremity in the *adducted* position but when the conventional aeroplane splint was applied, the distal fragment was displaced into the axilla.

Drs. Howard and Eloesser of Stanford University, San Francisco, Cal., published a paper on this subject in 1934 in the *Journal of Bone and Joint Surgery*, and I would like to review briefly their most interesting work. All seventy-nine cases of fractures of the upper end of the humerus which they report were treated by the following method with excellent results and with a much reduced disability.

Briefly, their reduction is obtained by traction with the arm in the adducted position by virtue of the long head of the biceps bridging the fragments, and the remaining untorn periosteum. These structures hold the fragments in position. In three of their cases the long head of the biceps muscle was severed so the position could not be maintained, and open operation was done.

The dressing is as simple as the method of reduction. A small pad is placed in the axilla and along the

arm. The forearm is held flexed by a sling, while the arm is loosely bound to the body; the elbow is left free to allow the weight of the arm to act as a traction force.

The success of restoration of function rests on intelligent use of exercise. Gentle massage may be used from the beginning by removing the body bandage. A small range of passive motion may be used in the first week, carefully controlled by the surgeon himself. At the end of the second week active motion is instituted. The bandages are removed; the patient stands with the sound arm resting on a chair or desk and, bending forward, allows the injured arm to hang unsupported. The arm may be safely swung forward and backward and in small circles. The range of motion is increased so that by the end of the third week from seventy-five to ninety degrees of abduction are possible by tilting the trunk in this stooping-standing position. Such ranges of motion may be undertaken early, since at no time do the muscles bear the full weight of the limb as in the upright position. At the end of the fourth week more strenuous active motion, to the point of pain, is advised, and in eight weeks' time the patient has a painless, movable, and useful shoulder, with almost normal range of motion that increases as the arm is used in the daily tasks of the individual.

PERIPHERAL NERVE SURGERY

GEORGE R. DUNN, M.D.
Minneapolis

Peripheral nerve injuries of clinical importance occur quite commonly. Recognition of a nerve lesion prior to any operative or manipulative procedure in an acute surgical case is highly important. It is quite possible in a very short time to determine whether or not there is any nerve injury of magnitude. In making these quick, rough tests, it is not necessary to carefully test out the entire motor and sensory distribution. For example, the ulnar nerve usually supplies sensation to half the ring finger, the small finger and the corresponding portion of the hand on the palmar and dorsal surfaces; consequently, in testing for gross sensory loss in the ulnar nerve one can quickly test any loss of sensation on the small finger.

In the upper extremity we may consider rough tests for four important nerves:

Musculospiral. A gross lesion of this nerve produces a wrist drop, and impaired sensation over the dorsum of the thumb.

2. Median nerve. Injury to this nerve produces a loss of feeling on the palmar surface of the index and middle fingers and a corresponding area over the palm of the hand.

3. Ulnar nerve lesions produce a loss of sensation on the small finger and a corresponding area on the palm of the dorsum of the hand.

The circumflex nerve which winds about the neck of the humerus is frequently injured in shoulder joint dislocations and injury to this nerve produces a paralysis of the deltoid muscle and an impairment in sensation over the deltoid area.

In the lower extremity the nerves most frequently injured are:

1. The external popliteal branch of the sciatic which can readily be tested by checking the sensation on the dorsum of the foot and the power to dorsiflex the foot.

2. The tibial nerve, less frequently injured, can be checked by determining any gross loss of sensation on the plantar surface of the foot and the ability to plantar flex the foot.

3. Sciatic nerve injury produces signs referable to the external popliteal nerve, the tibial nerve or a combination of both.

4. Femoral nerve injuries cause a loss of power of the quadriceps muscle and a loss of sensation over the overlying skin area.

These nerves may be injured: (1) by trauma (without severance), (2) by compression in scar or callus; (3) by complete or partial division due to penetrating or incised wounds.

A nerve merely traumatized usually recovers in four to eight weeks with rest and proper splinting. The splint should be applied in such a manner as to relax the muscles which the nerve supplies to prevent overstretching of these muscles during the temporary cessation of the function of the nerve. The musculospiral nerve may be so affected. In this instance the hand, wrist and fingers should be supported by a cock-up splint in a position of dorsiflexion.

All these nerves described are mixed motor and sensory nerves and when one encounters a motor loss without any sensory loss one should bear in mind the possibility of poliomyelitis.

The physiological continuity of a nerve is occasionally, although rarely, interrupted by scar tissue formation or callus formation pressing on the nerve. Simple liberation of the nerve from the scar or callus (neurolysis) by an operative procedure and proper protection of the nerve by muscle or fat to prevent recurrence of the pressure usually give a satisfactory result.

Puncture, incised, or lacerated wounds may result in a partial or complete severance of the nerve. When the nerve is partially severed and the condition is not recognized at the time of the injury, a scar usually forms in the nerve preventing the establishment of physiological continuity. Whether or not a condition of this sort requires later operative procedure depends on the magnitude of the injury, the amount of pain, and the loss of function it causes. If the scar is small and discrete (Fig. 1, upper diagram), it is sometimes possible to resect the scar and suture without damage to the remainder of the nerve. By this method one can be fairly certain of not increasing the magnitude of the nerve injury irrespective of the result obtained in the partial nerve suture.

When the scar is diffuse and involves the entire nerve to a certain extent (Fig. 1, lower diagram), a complete division of the nerve may be necessary to remove the scar. Whether or not this is advisable will depend entirely on the extent of the nerve lesion. Nerve regeneration is never complete after resection and end-to-end suture. The question will naturally arise, in any incomplete nerve lesion of this sort, whether the

end-result after resection of a diffuse scar and suture of the nerve will improve the function of the nerve. Resection should not be advised unless improvement is fairly certain.

Causalgia is a painful condition which occurs in a variety of incomplete nerve lesions but on occasions

mattress suture of fine silk or catgut is placed to approximate the nerve sheath. Care should be taken in placing this first suture not to rotate either end of the nerve out of its natural position as each nerve has its own architecture. After placing the first suture, the devitalized portion of the nerve can be entirely cut

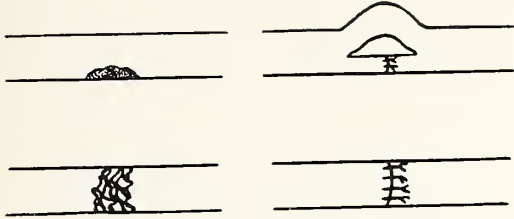

Fig. 1. Partial and complete resection of nerve for intrinsic scar (diagrammatic).

arises from intrinsic or extrinsic scars affecting the nerve. Pressure from extrinsic or intrinsic scars may give rise to considerable pain, circulatory and trophic disturbances. If the scar is extrinsic, neurolysis is the procedure of choice. If the scar is intrinsic, partial or complete resection of the scar may be indicated depending on the severity of the lesion. X-ray therapy in either case may be of some value. We have observed definite improvement following x-ray therapy in painful extrinsic and intrinsic scars affecting digital nerves which are difficult to treat surgically (intrinsic scars) due to the small size of the nerve.

Occasionally one encounters a scar confined to the nerve sheath, or nearly so, producing constriction of the nerve. Resection of the scar in the sheath in some of these cases gives excellent results.

Endeavoring to dissect out small groups of nerve fibers from an intrinsic scar may be possible in rare instances where the scarring is comparatively slight, not dense and confined to a limited area. Care and judgment must, however, be exercised in a procedure of this sort to avoid any extensive dissection of the nerve which will interfere with a later procedure.

After completing any surgical procedure on a nerve where formation of scar or adhesions may tend to invalidate the result, it is well to protect the nerve with fat or paratenon.

In cases where there has been a complete severance of the nerve from any cause, early diagnosis and primary end-to-end suture are indicated. The wound should be thoroughly cleansed, a careful debridement done and the nerve carefully sutured. The rough, uneven ends of the nerve should be carefully cross sectioned with a sharp knife until the normal fibers are visible.

At this stage of the procedure the nerve can be handled by placing clamps or forceps on the obviously devitalized portion of the nerve which is to be trimmed away and not cutting entirely through the nerve until after the first suture has been placed. After obtaining, by partial cross-section, visibly good nerve fibers on both the proximal and distal ends, a fine interrupted or

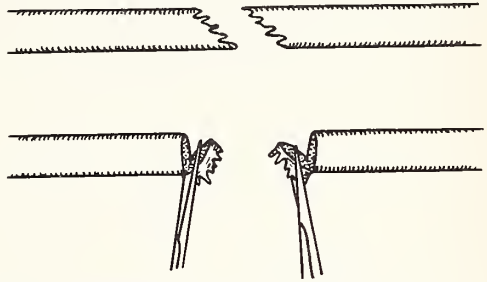

Fig. 2. Resection of lacerated nerve ends preliminary to primary suture (diagrammatic).

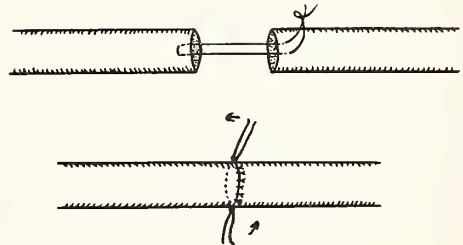

Fig. 3. Nerve suture half completed. By rotating the nerve by means of long sutures, the unsutured side of the nerve can be exposed and sutured (diagrammatic).

away and the second suture placed in the nerve sheath just opposite to the first suture. These two sutures can be left long. We thus have a suture at 12:00 o'clock and 6:00 o'clock, figuratively speaking. Using these sutures as retractors, the remainder of the sutures can be placed on one surface and, one of the original long sutures being passed beneath the nerve and the nerve rotated to present the opposite side, the remainder of the sutures are placed. This reduces to a minimum the handling of the nerve sheath by forceps. No sutures should be placed except in the nerve sheath. Close approximation of the nerve sheath throughout should be obtained.

Primary nerve suture permits approximation with minimal tension of the nerve, reduces the healing time, minimizes the degenerative process which occurs in the distal portion of the nerve, minimizes the muscular atrophy which follows a nerve lesion, prevents retraction of the nerve, and eliminates neuroma formation. If, through any complication, regeneration fails to occur after primary suture, the close approximation of the nerve ends simplifies secondary suture.

Secondary nerve suture is frequently done a considerable length of time after the original injury. Considerable separation of the nerve ends is frequently found. A neuroma will almost invariably be found on

the proximal segment of the nerve. Considerable atrophy of the distal segment of the nerve will have occurred and, consequently, the diameter of the proximal segment is considerably greater than the diameter of the distal segment.

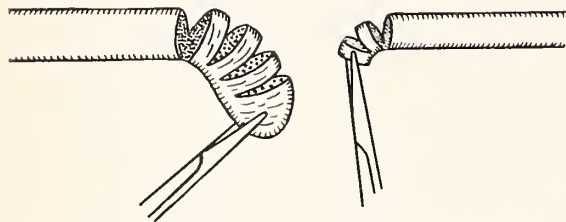

Fig. 4. Repeated cross-section of neuroma and scar, exposing good fibers for secondary suture (diagrammatic).

These conditions all interfere to a certain extent with nerve suture. Both the proximal neuroma and the scarred distal portion of the nerve must be repeatedly cross-sectioned until good fibers are visible in both segments. Due to the fact that the nerve fibers in the distal segment have undergone considerable degeneration, these fibers do not stand out as clearly on cross section as the fibers in the proximal segment and one must use considerable care in cross-sectioning the distal segment to remove all scar tissue and yet not sacrifice an unnecessary portion of the distal segment of the nerve. When good fibers have been exposed in both segments, the secondary suture is executed in the same manner as described for primary suture. Much larger portions of the nerve must, however, be sacrificed in secondary suture.

There may be a considerable gap between the nerve ends. This may be overcome by one or a combination of the following methods: (1) stretching the nerve; (2) flexion or extension of certain joints which tend to allow approximation of the severed ends; (3) transplantation of the nerve (for example, transplanting the ulnar nerve from its normal bed to a position anterior to the condyle of the humerus and flexing the elbow); (4) use of a nerve graft in the presence of a great gap.

All four methods lessen the chances of a fairly complete recovery compared with primary suture. Prompt recognition of a nerve lesion and primary suture is, therefore, highly important.

A nerve graft may be the only solution for an otherwise irreparable defect.

The type of graft diagrammed in Figure 5A may be used when a graft of proper diameter is available. For example, resection of an entire segment of the sciatic nerve in the thigh may be necessary because of a tumor. The external portion of the sciatic nerve (external popliteal group of fibers) may then be used as a graft to establish the continuity of the internal group (tibial fibers). In the event that sufficient regeneration takes place in the internal group of nerve fibers to supply some function to the plantar flexor muscles of the foot a drop-foot apparatus may be worn to com-

pensate for the paralysis of the muscles supplied by the external popliteal branch of the nerve, and the patient may be able to make some use of the leg.

In other instances two or more strands of a smaller nerve (Fig. 5B) may be used as a graft to bridge a

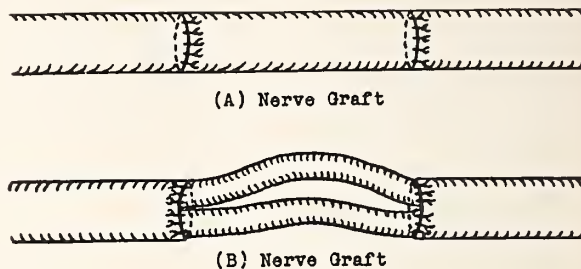

Fig. 5. Two types of nerve graft.

defect in a larger, more important nerve. The internal cutaneous nerve in the arm may be used in this manner to restore the continuity of the ulnar, median or musculospiral nerve.

Nerve fibers grow slowly and if a nerve graft 5 or 6 centimeters in length is used it will require a considerable period of time for the fibers to reach the distal line of suture. The possibility of scar tissue sealing off the second line of suture must be remembered and the advisability of resecting this area and resuturing at the proper time should be considered. I have only seen one fairly successful nerve graft.*

In doing either a primary or secondary nerve suture, one must be rather careful in the identification of structures for suture of a nerve to a tendon has occurred. This error is most commonly made in suturing the proximal end of a severed median nerve to the distal end of the palmaris longus or one of the other flexor tendons of the wrist or hand. The proximal end of a severed tendon retracts more markedly than the proximal end of the severed nerve so it frequently happens that the nerve will be first located in the wound. The nerve presents a greyish color, has a definite sheath, and a typical appearance on cross section as compared with the white, shiny appearance of a tendon. Rather firm traction on the distal end of the median nerve may produce slight flexion of the thumb, index and middle finger but this action is not easily confused with the definite response one obtains from traction applied to the distal end of a tendon.

Postoperative proper splinting to prevent joint movement throwing undue strain on the line of suture is important. Baking and massage and electrical stimulation tend to minimize muscular atrophy during the process of nerve regeneration. Care, however, must be exercised in instituting physiotherapy to avoid throwing undue strain on the line of nerve suture too early.

Of the commonly injured nerves, the musculospiral and the external popliteal frequently give the most satisfactory results. These nerves are both largely motor in function, have comparatively small numbers of

*Examined at 2nd Northern General Hospital, Leeds, England, in 1917.

sensory fibers and control coarse movements, the dorsi-flexion of the hand and foot respectively.

End-results of nerve suture vary between no return of function and approximately an 80% return of function. Generally speaking, the best results follow primary suture although very good results may be obtained by secondary suture performed at a considerable interval of time after the injury. The complete failures are usually due to separation of the suture line following suture under too great tension or improper immobilization of adjacent joints, thus allowing tension to be placed on the suture line.*

TREATMENT OF TRIMALLEOLAR FRACTURES OF THE ANKLE

M. C. NELSON, M.D.
Minneapolis

Because this paper has been accepted for publication in *Surgery, Gynecology and Obstetrics* and will appear in this periodical in an early issue, it is possible to give only a brief summary of the paper as presented before this Society. The presentation was prefaced with a few remarks of a historical nature, and then the results of the treatment of 359 ankle fractures treated at the Minneapolis General Hospital in a five-year period ending July 1, 1939, were summarized. From a detailed study of these fractures, several conclusions were drawn and these illustrated by lantern slides of drawings and x-rays.

Briefly, the conclusions are: A "classical" trimalleolar fracture, that is, one in which the posterior tibial fragment involves one-third or more of the distal tibial articular surface, is the most difficult of all ankle fractures to treat, and probably also the most poorly treated. Open reduction and internal fixation is practically always necessary. A "minimal" trimalleolar fracture, that is, one in which the posterior tibial fragment involves less than one-third of the distal tibial articular surface is a common ankle fracture and can be reduced by manipulation, and the reduction maintained by a plaster cast. Considerable offset of the posterior fragment does not preclude a good result.

INJURIES OF THE POSTERIOR URETHRA

T. H. SWEETSER, M.D.
Minneapolis

The subject assigned to me covers such a wide field that time forces me to limit my discussion to one type of injury. I wish to discuss the rupture of the posterior urethra where it passes from the prostate into the triangular ligament, since this is so often associated with fractures of the pelvis, and other serious injuries.

*For a summary of the bibliography on this subject up to January, 1930 (1958 references) see, "Peripheral Nerve Injuries" by Lewis J. Pollock, M.D., and Loyal Davis, M.D., published by Paul B. Hoeber, Incorporated, New York, in 1933.

That injury of the urethra is in itself a serious injury and demands prompt and accurate diagnosis and adequate treatment.

Occasionally the urethra in that location is partially severed and may be treated simply by drainage with an indwelling catheter. I can remember two patients whom I treated in that way with good results. One was an old man who was butted against a post by a bull, suffering fracture of the pelvis and partial severing of the urethra. The other suffered a similar injury when the wall of a trench fell in on him.

Occasionally there is simply the matter of proper diagnosis of some minor urethral lesion in the presence of a fracture of the pelvis or other severe injury. One patient recently had a severe head injury and a dislocation of the hip. He did not void and the house surgeon suspected rupture of the posterior urethra when he was unable to pass a catheter. He actually had a tight old stricture of the membranous urethra and was adequately relieved by passage of filiforms and followers.

The serious injury which I wish principally to call to your attention is a complete rupture of the urethra with a displacement of the prostate and bladder upward away from the triangular ligament and with collection of a hematoma in the intravaginal space. Fortunately the bladder is not usually ruptured and the patient has not voided any urine into the hematoma. He comes to the hospital usually in severe shock with a fracture of the pelvis and sometimes with a head injury or other associated trauma.

Drainage of the perivesical tissue is imperative and any attempt to put the patient in lithotomy position for perineal incision would risk further severe damage from the broken pelvic bones and would not adequately solve the problem of drainage and repair. A suprapubic cystotomy and evacuation of the perivesical hematoma is essential; the patient's condition may be so poor that no further initial treatment is justified. If anything further can be done without too much risk, the torn ends of the urethra should be brought together as well as possible.

My first attempt at accomplishing this last effect was in August, 1928, when I used a Pilcher Bag by the method which has since been described and illustrated by Ormond and Cothran in 1934.² In our case we exerted traction on the tube passing through the urethra by means of rubber bands running to the foot of the bed. Unfortunately a fistula was created at the penoscrotal junction by pressure of the tube, because of the fairly sharp curve at that point. The use of a wire basket to prevent this sharp curve would probably have prevented the formation of the fistula.

Another patient with a similar injury was treated by my associate, Dr. Polzak, by suprapubic cystotomy and insertion of a soft rubber catheter through the damaged urethra under suprapubic guidance without any attempt to bring the damaged segments together. This patient healed well but we have had considerable difficulty in treating the traumatic stricture and have had to remove one bladder calculus by cystotomy.

Still another child was treated by my associate, Dr.

Gingold, by suprapubic cystotomy. Because of the patient's extremely poor condition nothing more was done for twelve days, when bladder drainage was instituted through perineal urethrotomy; the suprapubic drainage tube was removed six days later and the perineal catheter sixteen days later still. Occasionally dilatation of the urethra was done for a time and the result was satisfactory.

It seems to me that one can depend on intra-abdominal pressure to push the bladder and prostate down into position without traction. When the patient's condition permits it, at the time of cystotomy, one need only place a catheter through the ruptured part of the urethra to guide proximal segments into close apposition with the distal segments. The method described by H. W. Martin in 1935¹ seems to me to best accomplish this mostly quickly and with less disturbance to the patient. A full curved sound is passed from the bladder through the prostatic and membranous urethra to the bulb where its end is pressed against the perineum. Without elevating the thighs the operator feels the end of the sound through the perineum and releases it through a small midline incision. A rubber tube is prepared with numerous holes on the side to insure drainage of the perivesical tissue, as well as the bladder. The end of this tube is placed on the end of the sound and guided from the perineum through the urethra into the bladder and is held in place by string fastened to the suprapubic wound.

The simplicity and effectiveness of this method can be appreciated by referring to the drawings which accompany the article by Ormond and Cothran and comparing the two methods.

EPIDEMIC ENCEPHALITIS. Third Report by the Matheson Commission, Willard C. Rappleye, M.D., Chairman, Columbia University Press, Morningside Heights, New York. Pages XI-493. Price \$3.00.

The Matheson Commission was established through the generosity of Dr. William J. Matheson in the spring of 1927. Its first two years of work consisted largely of collecting the published data on the epidemiology, etiology and treatment of epidemic encephalitis. The first report was published in 1929, the second in 1932. Laboratory research was begun by the group in 1929 under the direction of Dr. Frederick P. Gay and has been specially concerned with herpes-like viruses.

The section on etiology summarizes the work done throughout the world from 1930 to 1938 in regard to the etiology of epidemic encephalitis; St. Louis type encephalitis; Japanese B type encephalitis; human encephalitis caused by the viruses of Eastern and Western equine encephalomyelitis; post-vaccinal encephalitis; post-infectious encephalitis; Australian x-disease and

hemorrhagic encephalitis. The greatest emphasis, of course, has been placed upon the first three mentioned. Two extremely important discoveries have been made: namely, the isolation of distinctly individual viruses causing St. Louis type encephalitis and Japanese B type encephalitis.

An exhaustive study of the treatment of epidemic encephalitis is given with attention called to the fact that it is difficult to evaluate treatment in this disease because of the variability of symptoms in the acute, sub-acute and chronic stages.

Of the various medications and procedures used in acute epidemic encephalitis, few are viewed favorably.

In 1933 the first summer epidemic of encephalitis to appear in the Western Hemisphere was reported from St. Louis, Missouri. A small outbreak had been noted in Paris, Illinois, in 1932. Another epidemic appeared in St. Louis in 1937. Clinically and epidemiologically, the illness closely resembles Japanese B type encephalitis but the two are differentiated immunologically. The epidemics have been preceded by a period of great heat and drought. Increase of incidence with increasing age is striking. Females and males were affected in the same ratio that they occurred in the general population. The mortality rate was about 20% as contrasted with 45-50% for epidemic encephalitis during epidemic periods, and 60-75% in epidemics of Japanese B type encephalitis. As noted above, a distinct virus has been isolated and its specificity demonstrated. Transmission

by non-human agents, including insect vectors, was excluded early. Direct contagion is infrequently recorded. Here again transmission is most likely through unrecognized carriers.

The Matheson Commission has published a carefully compiled survey of the work done all over the world in regard to the etiology, treatment, and epidemiology of encephalitis. Its claims for the laboratory and clinical research of its staff are very modest. More than 3,500 references are listed in the bibliography. The material is clearly and interestingly presented. This report forms a very useful reference book for laboratory workers and clinicians working on this exceedingly interesting, important but complicated disease.

WALTER P. GARDNER, M.D.

INTRODUCTION TO MEDICINE. Don C. Sutton, M.D., Associate Professor of Medicine, Northwestern University School of Medicine. With introduction by Ada Belle McCleery, R.N., Superintendent, Evanston Hospital, Evanston, Illinois. With 144 Text Illustrations and 14 Color Plates. St. Louis: The C. V. Mosby Company, 1940.

The appearance of a new medical textbook is no novelty. Unfortunately too many books appear that could well have remained unpublished since they add nothing new in material advance in the science or in the method of presentation by which the subject matter is presented more concisely, more interestingly or more

SILVER PICRATE

BOOK REVIEWS

easily comprehended. Sutton's Introduction to Medicine is a very welcome addition to medical literature. It is a book delightful to read and is authoritative in context. The subject matter is well systematized and the discussion of each topic is clear and concise. The introductory paragraphs to the discussion of the various diseases give clear definitions and descriptions of the disease. The presentation of symptoms and treatment under the various diseases, though brief, is comprehensive and thorough. The main physical findings are well incorporated in the discussions.

This book gives a very satisfactory bird's-eye view of the whole field of internal medicine. There are brief chapters on Bacteriology, Parasitology, Pathology, Laboratory Procedures, Dietetics and other fields of interest to the nursing profession in addition to the main subject matter which deals with all the different types of diseases and their treatment. This book can be recommended unreservedly to all training schools, nurses in training and graduate nurses as well as all those interested in a brief but comprehensive view of the field of medicine.

MOSES BARRON, M.D.

DERMATOLOGIC THERAPY IN GENERAL PRACTICE. Marion B. Sulzberger, M.D., and Jack Wolf, M.D. \$4.50. 680 pages. Illus. Chicago: Year Book Publishers, 1940.

Most textbooks on dermatology follow a uniform style—that is, the texts are classified in sections and each entity is taken up in definite order, namely, etiology, pathology, symptomatology and treatment. In this book under review, the conditions are entirely different. The chief concern of the authors here is treatment, whereas in most books treatment occupies a very minor part of the chapter. The average general practitioner is looking for just such a treatise as this. It is not to be denied that symptoms are important as well as diagnoses. Nevertheless, the doctor who gets a dermatological case is concerned mainly with the cure of it, probably more than with recognition.

The book covers most of the skin entities which one encounters, and the conditions selected for discussion have been carefully and wisely chosen. We find, for instance, an excellent chapter on the eczemas and the allergies and these are most painstakingly considered, having in view the latest investigations on these subjects. A very good chapter also covers the acnes, emphasizing the importance of radiation treatment. In following the instructions laid down here, the average practitioner could readily treat all acne cases which come to his office. Similarly, psoriasis and the fungi are

mentioned, and particularly the skin tumors, such as basal and squamous cell carcinomas which are handled most painstakingly and accurately as to their treatment.

Throughout the book there is a list of the therapeutic agents which are useful in treating the various skin conditions, for instance, lotions, baths, powders, combinations which make up salves and a concise description of roentgen and radium therapy. The specialist will find in this book a concise condensation of everything used in everyday practice. The general practitioner will welcome this book because it is mostly therapy and therapy is what he wants.

E. Z. SHAPIRO, M.D.

NEWER NUTRITION IN PEDIATRIC PRACTICE. I. Newton Kugelmass, M.D. \$10.00. 1,155 pp. 183 illus. Philadelphia: Lippincott Co., 1940.

This is an overwhelming book. Its scope is tremendous; every possible relation of nutrition to the growth, development and disease of children is discussed at length.

The book is divided into three main units:

1. *Nutritional Physiology* discusses the maintenance and metabolism of the child's body both as regards organic and inorganic nutrients, for as stated, "an intimate appreciation of body mechanisms displaces empirical, traditional methods by scientific procedures.

2. *Nutrition in Health* takes us from the newborn, with the usual complete discussion of formulas for every need, through the childhood period and ends with an excellent discussion of the psychology of the poor eater.

3. *Nutrition in Disease* calls the roll of all disease; nutritional, deficiency, metabolic, allergic, infectious and regional. However, the author does not adhere strictly to his text, as witness the section on infectious disease, wherein many conditions are discussed which have little relation to nutrition.

It is disappointing that there is no separation of statement between material or opinions which are the writer's own and those of others, for although a bibliography is given at the end of each chapter, no direct credit is given in the text for material drawn from individual investigators. Many procedures are included as good practice, i.e., intraperitoneal fluid and sinus transfusion, which are no longer countenanced by many pediatricians. Also, one hesitates to recommend this book for general reading, since many statements are made which would indicate a final decision had been reached on problems that are still subject to some controversy.

CLINICAL AND SURGICAL ASPECTS OF SPREADING PERITONITIS COMPLICATING ACUTE PERFORATIVE APPENDICITIS*

JOHN O. BOWER, M.D.

Director of Research of The Foundation for Clinical and Surgical Research
Philadelphia, Pennsylvania

IN Philadelphia in 1922 a preliminary investigation revealed that the mortality of acute appendicitis was very high.†

A survey of 1,002 clinical records of patients operated upon for acute appendicitis in two of the largest hospitals disclosed the fact that the causes for the high mortality, delay in hospitalization and the administration of laxatives, are controllable. Through the efforts of Andrew A. Cairns, M.D., then Director of the Department of Public Health of Philadelphia, a city-wide survey of the clinical records of acute appendicitis cases in twenty-eight hospitals was made in 1930. The results obtained confirmed the findings of the initial survey and supplied statistics and facts with which a prophylactic campaign was inaugurated. The results of this continued education of the public show a consistent reduction of the mortality as shown by five subsequent surveys.

During the ten years the prophylactic campaign has been in progress surgical research on spreading peritonitis, the cause of over 92 per cent of the deaths, has been conducted.

In 1933 the Medical Society of the State of Pennsylvania appointed a Commission for the reduction of the mortality of acute appendicitis and a prophylactic campaign has been since conducted throughout the state by its members, one from each of the twelve Councilor Districts with

*Presented before the annual meeting of the Minnesota State Medical Association, Rochester, Minnesota, April 24, 1940.

†Dr. Hoffman of the Prudential Life Insurance Company had published a national statistical study which showed that the mortality of acute appendicitis in the United States was (1) 30 per cent higher than Scotland, (2) 51 per cent higher than Germany, (3) 73 per cent higher than England and Wales, (4) 76 per cent higher than New Zealand, (5) 83 per cent higher than Italy, and (6) 115 per cent higher than Irish Free State.

TABLE I. MORTALITY OF ACUTE APPENDICITIS IN
PHILADELPHIA

Six Surveys

Year	No. of Cases	No. of Deaths	Mortality Per Cent
1928-29	5,121	306	5.97
1930	3,095	149	4.01
1931	3,142	138	4.39
1932	3,546	122	3.44
1933	3,783	134	3.54
1937	4,186	102	2.44

their District and County committees, numbering over 300 physicians and surgeons.

The first Pennsylvania state-wide survey was completed April 1, 1940.

The results of the Philadelphia prophylactic campaign, surgical research, and now the results of the Pennsylvania campaign, indicate that:

1. Patients do not die from acute appendicitis; they die from spreading peritonitis.
2. Patients with appendicitis-peritonitis should be managed by surgeons who have some knowledge of the immunologic aspect of the problem.
3. The prophylactic campaign is the surest method of reducing the mortality.
4. In considering a plan for prevention of deaths from appendicitis-peritonitis the prophylactic removal of the appendix in the very young must not be overlooked, as there is no mortality other than the unavoidable catastrophe that can be attributed to the operation *per se*, approximately one in 1,000.

In Table II are listed the nine principal causes of death in the United States, with the number that die annually from each, and the age group in which most deaths occur.

ACUTE PERFORATIVE APPENDICITIS—BOWER

TABLE II. PRINCIPAL CAUSES OF DEATH IN UNITED STATES

Disease	Number of Deaths Annually	Group in Which Most Deaths Occur
Heart	371,675	70 - 80
Cancer	149,126	60 - 70
Nephritis	126,879	70 - 80
Pneumonia—		
Lobar	67,778	50 - 60
Bronchial	51,600	75 - 85
Accidents	110,249	20 - 30
Apoplexy	103,560	70 - 80
Tuberculosis	71,527	20 - 30
Diabetes	30,406	65 - 75
Appendicitis	20,000	10 - 20

Acute appendicitis is a disease of youth. The average age is twenty-three years; death occurs at the average age of thirty-four. It is estimated that over 18,000 die each year in the United States, 3,240 before the age of twenty.

Deaths from appendicitis-peritonitis can be eradicated by definite instruction in the schools. As shown by the following table, over 40 per cent of cases occur between the ages of ten and twenty and over 53 per cent between one and twenty.

In Philadelphia the high school students have been instructed for ten years, in Pennsylvania for only five. Notice the difference in the mortality (Table IV).

High school students are warned about the dangers of delay in hospitalization and the administration of laxatives. In all, 110,000 high school students in Philadelphia, and 630,293 in Pennsylvania were told that the mortality of appendicitis-peritonitis increases with each twenty-four hours.

We warned them about laxatives—when they develop acute abdominal pain Nature stops the movements of the intestines so that the inflammation will remain localized. If they take laxatives the intestines are thrown into activity which may result in rupture and appendicitis-peritonitis.

APPENDICITIS WARNING

For pain in your stomach—

Don't take a laxative or physic.

Don't take anything by mouth.

See your doctor immediately.

If he says it's appendicitis and advises operation—

Don't delay going to the hospital.

Laxatives and delay frequently cause spreading peritonitis and death.

This warning is published by The Medical Society of the State of Pennsylvania.

Each high school student should be given a warning sticker with the request that he take it home and affix it to the family medicine cabinet where it can be read by the other members of the family. They should be told that when anyone develops abdominal pain some organ inside the abdomen is not functioning properly. Pain is a warning. The first symptom of acute appendicitis is general abdominal pain which later centers in the lower right side, the region of the appendix.

High school students are being taught to recognize acute appendicitis. Does this plan pay in dividends of lives saved?

An attack may not be accompanied by nausea

or vomiting. There may not even be a rise in temperature. The most important thing to have done is a blood count. When the appendix becomes inflamed, tenderness develops and Nature stops movements of the intestine because of the urgency of keeping the infection confined to the appendix.

In the proposed plan to educate the high school student to recognize acute appendicitis, where does the family physician fit into the set-up? He has four vital functions: (1) he must establish or disprove his patient's "homemade diagnosis;" (2) if he concurs in the diagnosis he must see to it that his patient is placed in the hands of a surgeon—not an operator; (3) if he does not agree with the "homemade diagnosis" he must determine definitely what is wrong with his patient; and (4) he should participate in the prophylactic campaign.

Even when a youngster is intelligent enough to describe the character of the initial abdominal pain and can demonstrate with a finger the maximum point of tenderness, and even though in 90 per cent of instances he tells the physician what is wrong with him—a complete examination, which includes a rectal examination, should be made. Catastrophes have occurred because physicians have not examined patients' abdomens, and catastrophes have been prevented by youngsters refusing to take laxatives ordered by family physicians. The family physician must consider himself a consultant if fewer mistakes in diagnosis are to be made.

The selection of a surgeon by the family physician is important. It must be remembered and reiterated that an appendectomy may be the simplest or the most difficult of operations. I have mentioned that the family physician should consult a surgeon and not an operator. The difference is this: the operator operates; the surgeon manages. The operator can and does successfully remove intact appendices but he treats the perforated and the non-perforative appendices alike. The perforated appendix requires management. It requires the best the hospital affords. Why? Because over 92 per cent of the mortality is in this group. One of every four patients admitted to hospitals with perforated appendices dies.

When patients die following operation, the operator thinks they die of *what they had when he operated upon them*, and not *what he did at*

operation. The operator uses one kind of incision, one kind of anesthetic, and one kind of operation. He prides himself on how fast he can remove an appendix. He reports his successes in the form of appendiceal mortality, covering up the true mortality of spreading peritonitis by a camouflage of non-ruptured appendices, which have no mortality.

The family physician is the logical person to tell the public—which begins with his patients—about the prophylactic campaign to prevent death from appendicitis-peritonitis. He should use the warning stickers and he should be willing to speak before high school assemblies and lay organizations.

Finally, the family physician and surgeon should attempt to convince their State Health authorities that appendicitis-peritonitis is a public health problem; that it is as much an immunologic problem as the seven most frequent communicable diseases, and that the same amount of money should be spent in a publicity campaign as is spent in immunizing children against measles, diphtheria, typhoid, et cetera.

TABLE IX. PUBLIC HEALTH ASPECT OF APPENDICITIS-PERITONITIS

	Minnesota	Pennsylvania
Population—1937	2,652,000	10,158,000
No. High School Students, Junior and Senior	175,007	631,293
Deaths from Seven Most Frequent Communicable Diseases	223	945
Deaths from Appendicitis-Peritonitis	307	1,085

There is no mortality from acute appendicitis. Spreading peritonitis causes 92.4 per cent of the so-called appendicitis deaths. Patients do not die of acute appendicitis; they die of spreading peritonitis.

The facts in Table X were obtained from the abstracts of 38,085 clinical records.

Pennsylvania 1937	19,398	658	3.39	2,342	608	25.95

That patients die from spreading peritonitis, not appendicitis, is further corroborated by the fact that 22,000 clinical records previously abstracted in six Philadelphia surveys show the same results within a fraction of a per cent.

Patients admitted to hospitals with a diagnosis of acute appendicitis with an intact appendix do not die from this disease, statements on their clinical records to the contrary. These patients die a catastrophic death. Of the 658 deaths, 118 were catastrophes — twenty-nine unavoidable, eighty-nine avoidable.

The twenty-nine unavoidable catastrophes represent the hazards coincident to any group of comparable size. Surgeons accept them as inevitable. The majority occurred in the later decades of life. Only seventeen of the twenty-nine were unruptured. This number (17) represents the total mortality of the 16,046; only one in 944 died.

In the avoidable group, a total of eighty-nine deaths, errors in surgical management were responsible for seventy-one, errors in diagnosis for eighteen. Patients' relatives, as well as the sur-

geon, know when a death following operation is unavoidable. Explanations are unnecessary. Catastrophic deaths in the avoidable group, however, are difficult to explain, not only to the family, but to the family physician as well.

Errors in Diagnosis.—In this presentation it will be impossible to consider each of these in detail. Pneumonia, the most common error, occurs most frequently in the juvenile. A correct diagnosis can be made at times only by exhausting every possible means at our disposal; careful history, leukocyte count, x-ray, consultation.

Usually operation is decided upon because of rigidity. If rigidity is the deciding factor favoring operation then operation should be delayed, because an extensive rigidity is usually due to spreading peritonitis resulting from perforation. Delay for deliberation or deliberate delay until a definite diagnosis can be established is justifiable. The importance of the rectal examination should be remembered. It is far more important in a suspected acute surgical abdomen in children than a simple abdominal examination. Immediate operation in the presence of spreading peritonitis has a mortality rate of 27 per cent. The death rate of patients operated upon for suspected acute appendicitis, but who actually have pneumonia, approximates 75 per cent.

Intestinal obstruction is unusual but it occurs about once in 500 cases; an appendiceal abscess, partially blocking coils of intestine, is responsible. Deaths are due to spreading peritonitis, induced by the operator when he blindly inserts his hand into the peritoneal cavity and ruptures an abscess, in attempting to deliver the obstructed loop. It is better surgery to enlarge the incision.

Errors in Management. — Hemorrhage — a death has occurred from post-operative hemorrhage following removal of an acutely inflamed appendix in about 1 in 4,000 cases. This can be prevented by first ligating the stump and then inverting it with a very fine chromic catgut suture. If the suture is crossed at the mesenteric junction the purse string will compress a branch of the posterior ileocecal artery and the proximal branch of the appendicular artery, which are usually responsible for the bleeding.

Anesthetic Deaths.—Satisfactory notation regarding the anesthetics administered were obtained in only 14,894 of the 19,398 records abstracted. There were eight anesthetic deaths. The average age of those who died was forty; on admission to the hospital the average temperature was 99.4, pulse 105. Five of the eight had unruptured appendices; three had peritonitis. Six of the eight died on the operating table.

The results of this survey show that 3,640 patients were given ether without a death; 7,307 were given gas alone or in combination, with five deaths; 581 were given avertin alone or in combination, with one death.

A spinal anesthetic was given to 2,111 patients.

Two died. One was given spinocaine. The other anesthetic was not mentioned. Local anesthesia was used in only 114 instances. There were no deaths. Ether is still the safest anesthetic.

acute Perforative Group.”—This catastrophe occurred once in each 200 patients operated upon with intact appendices.

Two years ago a clinical pathological classification of Acute Appendicitis-Peritonitis was published, based on what is found by the surgeon at operation—not what he leaves in the peritoneal cavity after operation or what the pathologist finds at postmortem. The pathological process can be described as either an inflammatory mass or an inflammatory process.*

Let us consider first the localized mass. The mortality is 1 in 169. Of the 15,976 clean cases, 14,136 were not drained. There were no deaths. 1,840 were drained and 6 died.

These surgeons should question their surgical judgment in draining non-perforative cases when they study the results shown in the drainage table above. If a surgeon at operation finds a perforated appendix, if he is doubtful as to whether or not the serous coat is intact, or if hemorrhage cannot be controlled by ligature, the insertion of drains is justifiable. It is not only definitely unnecessary but undesirable to insert drains of any kind into the peritoneal cavity to remove serous, serosanguinous or purulent fluid if the serous coat of the appendix is intact, because this fluid has a definite protective value. It is one of the earliest manifestations of Nature's attempt to develop resistance to microörganismal invasion. Titration of this fluid against the toxin of the *Clostridium welchii* shows that it contains antitoxin in 33.33 per cent of cases. The antitoxic titre of this fluid is highest in patients suffering from a non-perforative recurrent attack, in which the serous coat of the appendix had ruptured in a previous attack, but was subsequently sealed.

The amount of antigen absorbed during the average attack of acute inflammation of the ap-

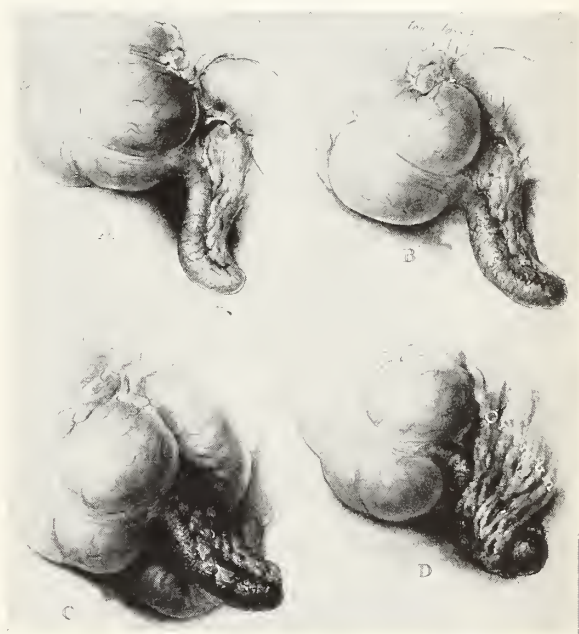

Fig. 1. Localized Mass. The inflammatory mass may be an acute catarrhal, ulcerative, suppurative, or gangrenous. The removal of any of these will result in cure. Because of catastrophic deaths the chances of dying are one in 169.

pendix is so small that antitoxin appears in the blood serum in only 22 per cent of instances; but following perforation, antigen in larger amounts is absorbed, and if the patient lives, antitoxin is found in the blood serum of over 70 per cent of instances. Another important reason for withholding drains in the non-perforative cases is that complications, such as peritoneal infections, resulting in fecal fistulas and intestinal obstruction occur more frequently and the morbidity and mortality are increased over the non-drained cases.

In seventy-one hospitals of the 181 surveyed, 118 operators did not drain the peritoneal cavity following removal of a perforated appendix in 126 patients and seventy-four, or 58.73 per cent, died.

Those who have not instituted drainage of the peritoneal cavity in the presence of a perforated

	118	126	74	58.73

appendix or following its removal have, undoubtedly, read or heard of some operator advocating this procedure. They justify themselves by reasoning that appendices rupture and abscesses develop which are absorbed. It is true that this is not uncommon, but such patients recover not so much because pus is absorbed, but because toxins are absorbed slowly. Nature accomplishes this by the formation of a pyogenic membrane within the wall of which microorganisms become attenuated. Monomicrobial infections of the peritoneum are the most virulent and do not tend to localize or form this protective membrane. Fortunately, in the majority of instances, more than one organism is responsible for the peritonitis secondary to acute perforative appendicitis. In over 90 per cent of instances, the infection is not only polymicrobial but both anaerobes and aerobes are present. It is possible that this is responsible for the low virulences of the microorganisms present in the appendiceal abscess, simple drainage of which rarely results in death.

Table XVII shows the number of patients and deaths with the percentage mortality of those operated upon for intact appendices which ruptured on removal but were not drained; patients operated upon for spreading peritonitis; the localizing process, and abscess.

There is no operation for lesions involving organs within the peritoneal cavity of man, in which streamlined-brain-management pays as high dividends in deaths as operation for the distended appendix which ruptures on removal where the operator closes the wound without drainage. The mortality is high because of the rapid absorption of virulent antigen.

The percentage mortality of each of the lesions in Table XVII diminishes with the development of local and general immunity.

Approximately 11 per cent of the 1,705 surgeons failed to place or failed to leave out drains in the peritoneal cavity when the diametrically

opposed procedure was indicated. This observation is in part responsible for the term "appendicitis-peritonitis." It is used to describe the peritonitis following rupture of the appendix and does not refer to the peritoneal reaction preceding perforation, which results in the extravasation of serous, mucoserous or serosanguinous fluids. The other reason for this term is that surgeons have camouflaged their spreading peritonitis mortality under the so-called acute appendicitis mortality. The mortality of the twelve councilor districts of Pennsylvania shows how this may occur.

The mortality of acute appendicitis and spreading peritonitis in Councilor District No. 1 is low. Councilor District No. 12 ranks second in appendiceal but eighth in spreading peritonitis mortality. Table XVIII is interesting in showing the results of the prophylactic campaign. The mortality is highest in those districts where the high schools have not received the educational talks.

The rupture of a membrane several microns in thickness is responsible for the high mortality. The percentage mortality depends upon when and how this membrane is ruptured.

The hyperacute perforative group shows what happens when perforations occur early and are accompanied by peritoneal trauma. Fifty-eight patients, average age 25, normal health, abdominal pain, death in 216 hours—tragedy condensed in 14 words. That twelve of the seventy operated upon lived, that 80 per cent of those that died received laxatives, that everyone did his utmost to save those that died must be remembered. But if surgeons responsible for these patients' lives are to profit, then we must not forget that while these patients had every reason to live—average age twenty-four, average temperature 100, average pulse 104—they were operated on forty-eight hours after onset of symptoms and every one of the seventy appendices ruptured on removal.

ACUTE PERFORATIVE APPENDICITIS—BOWER

TABLE XVIII. COMPARISON OF MORTALITY BY DISTRICTS

Councilor District	Population	Students	Appendicitis Mortality			Spreading Peritonitis Mortality		
			Cases	Deaths	Mortality %	Cases	Deaths	Mortality %
1	2,497,029	132,796	5,084	122	2.39	711	116	16.32
12	613,650	45,966	1,534	42	2.73	136	39	28.67
2	627,966	37,420	1,514	44	2.91	185	40	21.62
7	231,306	15,434	581	17	2.93	51	12	23.52
6	366,542	26,483	895	27	3.02	115	26	22.61
11	766,330	51,857	1,159	36	3.11	137	35	25.54
4	446,165	29,494	1,250	43	3.44	77	38	49.35
8	439,303	31,124	898	33	3.67	106	28	26.42
9	385,044	25,611	647	24	3.71	40	22	55.00
3	543,890	36,546	1,219	48	3.94	158	41	25.94
5	797,700	50,825	1,439	66	4.58	168	60	35.71
10	1,916,425	147,737	3,178	156	4.91	458	151	32.96
Totals	9,631,350	631,293	19,398	658	3.39*	2,342	608	25.96**

*3.39 is misleading because it includes the deaths due to peritonitis.

**25.96 is definite—it shows what has happened to 608 of the 2,342 patients who developed a spreading inflammatory process of the peritoneum.

TABLE XIX. HYPERACUTE PERFORATIONS—INDUCED SPREADING PERITONITIS

TOTAL			AVERAGE				
No. of Patients	Deaths	Mortality Per Cent	Age	On Admission		Onset Symptoms to Operation	Operation to Death
				Temp.	Pulse		
70	58	82.86	24	100	104	48 hrs.	168 hrs.

TABLE XX. THE SPREADING PROCESS

TOTAL			AVERAGE				
No. of Patients	Deaths	Mortality Per Cent	Age	On Admission		Onset Symptoms to Operation	Operation to Death
				Temp.	Pulse		
1,118	26	24.06	22	101.4	118	69 hrs.	144 hrs.

This group of patients is unique, not only because of the startling death rate, 82.86 per cent, but never before, to the writer's knowledge, has it been possible to analyze and report at one time so large a number of cases where the period of time between perforation and death has been accurately recorded. The abstracts tell exactly when, how, and why perforation occurred in these seventy cases. Rupture occurred on an average of forty-eight hours after onset of symptoms. Some of them ruptured as delivery was almost completed. Most of these patients recovered; only the peritoneum adjacent to the incision became infected. The majority, however, were ruptured in the peritoneal cavity in various locations. The appendix was frequently abnormally situated and difficult to locate because of poor visibility.

Without exception, the peritoneum was literally prepared for the rapid absorption of toxins. Every move of the surgeon's hand was attended by trauma or death of endothelial cells with consequent exposure of lymph and arterial capillaries.

The average time between perforation and death was 168 hours. Some patients died so quickly that their abdominal walls were rigid at death. Distention, the usual accompaniment of the spreading peritonitis deaths, did not have time to develop. Most of them developed hyperpyrexia almost immediately after operation, and an uncountable pulse within forty-eight hours. Many of them never regained consciousness after operation and died in a toxic delirium.

These patients were operated on twenty-nine hours earlier and died seventy-two hours sooner

ACUTE PERFORATIVE APPENDICITIS—BOWER

TABLE XXI. THE LOCALIZING PROCESS

TOTAL			AVERAGE				
No. of Patients	Deaths	Mortality Per Cent	Age	On Admission		Onset Symptoms to Operation	Operation to Death
				Temp.	Pulse		
1,154	281	24.35	30	99.7	100	98 hrs.	216 hrs.

The acute perforation which results in fulminating peritonitis within four to twelve hours after onset of symptoms is not common. The subacute perforation, however, occurs frequently. More than twenty-four hours usually elapse between onset of symptoms and perforation. During this time—the preperforative state—the cells in the tissues in proximity to the potential perforative site undergo changes which are protective. This is local tissue immunity.

In all, 1,118 patients, average age twenty-two, were operated upon sixty-nine hours after onset of symptoms with a temperature of 101.4, pulse 118, and 269, or 24.6 per cent, died on an average of 213 hours after onset of symptoms.

Of the 658 deaths, 621 were the result of spreading peritonitis. The records show that fifty-eight of these 621 were induced at operation—hyperacute group. What about the others? Let us consider the localizing process.

Of the 19,398 cases, 1,154 were admitted with subacute perforations — localizing processes. These 1,154 patients, average age of thirty, were operated on ninety-eight hours after onset of symptoms with an average temperature of 99.7 and a pulse of 100, and 281, or 24.35%, died 314 hours after onset of symptoms.

Why should the mortality of this process be as high as that of the spreading process? Because of time of operation and what the surgeon did at operation. Time as it relates to the out-

Fig. 2. *Localizing Process*. The localizing process, the spreading process, the localized mass are stages of a peri-appendiceal inflammatory process. All inflammatory processes of the peritoneum following rupture of an appendix are primarily spreading. As soon as the serous coat becomes devitalized permitting egress of microorganisms and their toxins, the contiguous peritoneum becomes involved. If the perforation is not large and laxatives have not been administered, the protective mechanism attempts to close the perforation by plastic exudate, omentum or intestine. This is the localizing process. When operated upon the localizing process is converted into a spreading process and one in four dies.

than those with the localizing process. Why? Because the vulcanizing plastic-lymph patch was blown off or the cemented intestine or omentum was detached by laxative induced peristalsis.

TABLE XXII. CLINICAL PATHOLOGY CLASSIFICATION—MORTALITY

Pathology at Operation	Number of Cases	Per Cent of Cases	Number of Deaths	Per Cent Mortality
Localized Mass	16,046	82.72	95	.06
Spreading Process	1,118	5.76	269	24.06
Localizing Process	1,154	5.95	281	24.35 ?
Localized Process	1,080	5.57	13	1.20
	19,398	100.00	658	3.39

ACUTE PERFORATIVE APPENDICITIS—BOWER

TABLE XXIII. THE LOCALIZED ABSCESS

TOTAL			AVERAGE				
No. of Patients	No. of Deaths	Mortality Per Cent	Age	On Admission		Onset Symptoms to Operation	Operation to Death
				Temp.	Pulse		
1,080	13	1.20	30	100.1	99	123 hrs.	235 hrs.

come of these patients will be considered under antigen—antitoxin and appendicitis. How, “what was done at operation” affects the mortality is shown in Table XXII. Has surgery failed in its purpose if individuals aged twenty-seven, with temperature of 100.2 and a pulse of 99, die after operation? Was something done which should not have been done at operation?

Does the explanation graphically shown in Table XXII seem reasonable?

The localizing process can develop into a spreading process or a localized abscess. A large percentage of localized abscesses were previously localizing processes. The mortality in the 1,080 with localized abscesses is 1.20 per cent, or one in eighty-three. *When appendices are removed in the presence of a localizing process the mortality is the same as the spreading process—one in four.*

How many of these 281 deaths were induced? The majority of these patients died with hyperpyrexia, tachycardia and distention, much the same as the hyperacute, except that delirium was less frequent and they lived forty-eight hours longer after operation.

Did time of operation and what was done at operation have anything to do with these patients' deaths? Is there any significance attached to the fact that both in the localizing and spreading group the mortality is one in four?

In the localized process group, 1,080 patients, average age thirty, were admitted to hospitals with an average temperature of 100.1 and pulse of 99, and thirteen, or 1.02 per cent, died. Those that died lived 235 hours (almost ten days) after operation.

From the standpoint of mortality this group approximates more closely than any other the acute intact group. There are comments and criticisms that can be made regarding the thirteen deaths, but we believe the surgeons who read this report will profit more by a comparative study of the results obtained in the management of 345

Fig. 3. Localized Process. The localized process—the appendiceal abscess—the end-result of the localizing or the spreading process; one in eighty-three die.

surgeons operating in Philadelphia, and 1,705 in Pennsylvania.

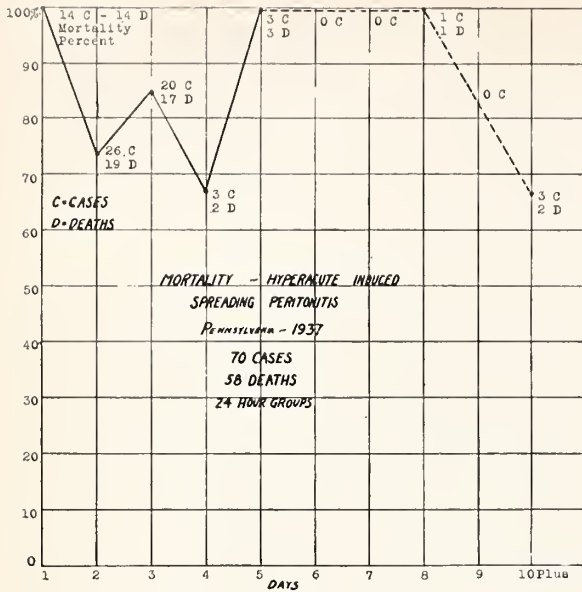

Table XXIV is shown to illustrate the improvement in management of this group of cases; the higher mortality in the State group is due in part to the greater number of catastrophes.

TABLE XXIV. APPENDICEAL ABSCESS

	Year	No. of Cases	No. of Deaths	Mortality Per Cent
Philadelphia	1928-29	1,502	57	3.79
	1930	625	11	1.76
	1931	618	10	1.62
	1932	572	5	.87
	1933	538	5	.93
	1937	458	3	.65
Pennsylvania	1937	1,080	13	1.20

Table XXV contains data which summarize the active and potential factors responsible for the appendicitis-peritonitis deaths.

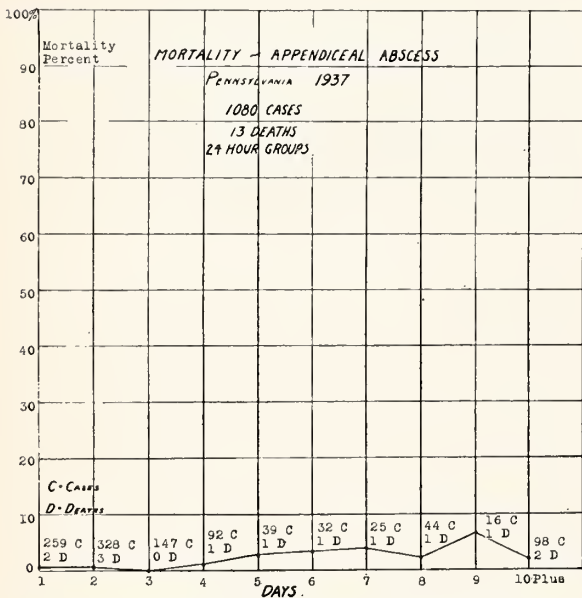

ACUTE PERFORATIVE APPENDICITIS—BOWER

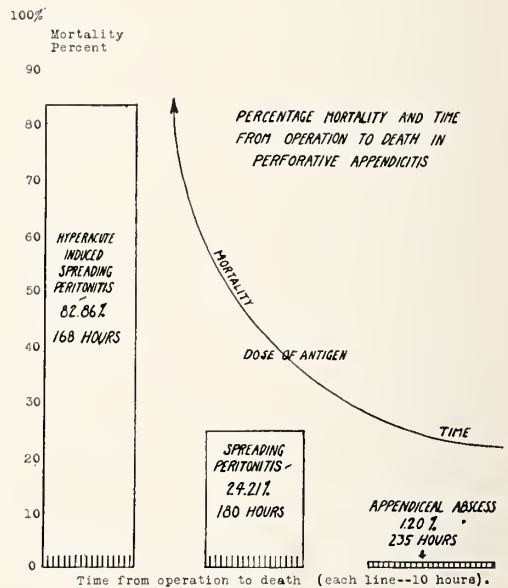

Graph 1.—Hyperacute Spreading Peritonitis. Before immunologic processes had developed, a large amount of antigen was projected into the peritoneal cavity—purulent distended appendices were ruptured at operation.

Graph 2.—Spreading Peritonitis. Immunologic processes are in the early stages of development—operative procedures 83.73 hours after admission.

Graph 3.—Appendiceal Abscess. Nature—patient's resistance—immunity is permitted to develop almost to its maximum—surgery is instituted after 123 hours.

Graph 4.

A summary of each of the four groups with comments has been presented. The problem at hand is the presentation of factors influencing the mortality which are common to all four groups. The writer is convinced that man is provided with but one system of defense against microorganismal invasion, that patients recover from spreading peritonitis following a perforated appendix in the same manner that they recover

from a pneumonia or a typhoid fever. This is the premise on which the following rests. This conclusion was arrived at before it was realized that the answer to the query, "why do some patients live, and others die, of spreading peritonitis?"—probably awaits those who are interested in the science of immunology.

It has been shown by animal experimentation by many investigators, and it is demonstrated

DISEASE OF THE CORONARY ARTERIES—WHITE

TABLE XXV. APPENDICITIS-PERITONITIS

	TOTAL			AVERAGE				
	No. of Cases	No. of Deaths	Mortality Per Cent	Age	On Admission		Onset Symptoms to Oper. Hours	Operation to Death Hours
					Temp.	Pulse		
Hyperacute Induced Spreading Peritonitis	70	58	82.86	24	100	104	48	168
Spreading Peritonitis	1,118	269	24.06	22	101.4	118	69	144
Localizing Induced Spreading Peritonitis	1,154	281	24.35	30	99.7	100	98	216
Appendiceal Abscess	1,080	13	1.20	30	100.1	99	123	235

here, that absorption is increased in acute inflammation of the peritoneum. As the process diminishes in severity, absorption is diminished. *Time is an important factor.*

Microorganisms and their toxins vary markedly in virulence, but attenuation does occur as emphasized in the following: the highest mortality occurred in the group admitted within 48 hours (Graph 1), the second highest in those admitted within 83.73 hours (Graph 2), and the lowest occurred in the group admitted in an average time of 123 hours (Graph 3). Again, *time is an important factor.*

Time is also important in "what the surgeon does at operation." Is it necessary for him to hurry? The average time that has elapsed before admission to the hospital in the appendicitis-peritonitis group is forty-eight hours. The patient is one of the best surgical risks. Is it not best to make haste slowly?

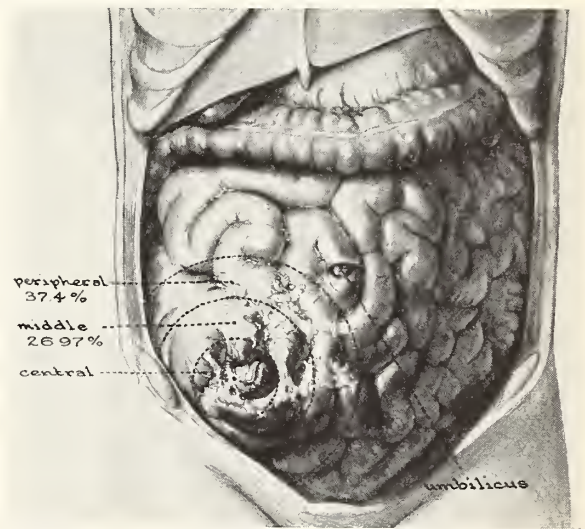

Fig. 4. *Spreading Process.* This is the spreading process. While the localizing process is regressing when operated upon, the spreading process is progressing. The mortality in this group is dependent upon the resistance of the patient, the time of operation, and what is done at operation.

DIAGNOSIS OF DISEASE OF THE CORONARY ARTERIES*

S. MARX WHITE, M.D., F.A.C.P.
Minneapolis, Minnesota

NO attempt is made here to consider systematically all the factors in determining whether or not the coronary arteries are diseased. While this is important, it is still more worth while to determine by examination the nature and circumstance of the disease condition as a whole, which is in truth the diagnosis.

Until or unless pathological changes in the coronary arteries cause impairment of the cir-

culatation in the myocardium, such pathologic changes are not recognizable during life. A single exception might be made in those rare cases where the fluoroscope or x-ray film have given evidence of calcification in the heart wall distinguishable from the calcification occurring in the aortic or mitral valve. Even this isolated type of demonstration is relatively insignificant because almost without exception when an atheromatous area is so far advanced as to give demonstrable areas of calcification, there is already impairment

*Read before the annual meeting of the Minnesota State Medical Association, Rochester, Minnesota, April 23, 1940.

of circulation in the myocardium beyond the point of calcification in the vessel wall.

For practical purposes then, it may be stated that the importance of coronary artery disease lies in its effect upon the myocardium and further that it is the effect upon the myocardium which we recognize, while the part played by the coronary arteries is largely a matter of inference. In other words, the true diagnosis from the clinical standpoint relates to the nature and circumstances of the disease condition in the heart muscle, and let us here include its conduction paths. We may infer the cause to lie in conditions in the blood vessels. Circumstantial evidence may make the inference valid.

It is necessary to consider, though with the utmost brevity, certain facts in the physiology and pathology of the coronary arteries, with particular attention to what is now known concerning the existence of anastomoses in these vessels and the possibilities in the development of collateral circulation.

The concept of Cohnheim, published in 1881, that the coronaries are end-arteries has been almost universally discarded. The work of Lewis Gross in 1921, of Spalteholz in 1924 and of Campbell in 1929 has been strikingly suggestive of the development of an increased anastomotic circulation with increasing age. Throughout all the discussions the suggestion of the importance of the Thebesian circulation has been heard, but it seems quite clear that this circulation is not of major importance, at least in the muscle areas which constitute the wall of the left ventricle and the interventricular septum.

It has been held for many years that the existence of anastomoses and the development of collateral circulation are the most important factors in the favorable response made by many individuals, even in the presence of more or less extensive, sometimes severe and acute, obstructions in the coronary arteries. It is probable that there is a wide difference in individuals in the extent of the anastomoses existing originally and in the capacity for the development of collateral circulation. The evidence of such suggested collateral circulation has not been readily secured. However, Blumgart, Schlesinger and Davis¹ have recently published the best planned study of collateral and anastomotic circulation in the heart to date. Their demonstration of extensive anastomoses in the heart with occlusions in coronary

vessels is complete. In their conclusions they state that anastomotic circulation develops when and where it is needed, and that the development of such anastomoses is not related to age, for they are not present even in the hearts of senile patients when little or no coronary arteriosclerosis is present.

That obstruction in a coronary artery can cause damage up to and including actual tissue death, i.e., infarction, in the myocardium has long been known. In such a case this means, of course, that any collateral circulation which might be present at the time of the occlusion is inadequate. On the other hand, extensive and often multiple obstruction may be found without gross evidences of infarction, and the puzzle has been in the past to determine what underlies these extraordinary differences noted. The work of Blumgart and his associates goes far towards clarifying our concepts in this field.

In the management of the disorders dependent on disturbances in the coronary circulation the clinician has long been impressed with the part which time plays in the progress of the patient in whom evidences of myocardial damage have developed. Under favorable conditions of rest and with time and more time and still more time, each observer has seen cases of angina pectoris improve to the point of disappearance for a time at least, of the syndrome; has seen cases of myocardial infarction surviving the acute phase, return to more or less, and at times surprising, capacity; has seen remarkable improvement in the congestive failure group, though here as a rule the results are not so striking; and lastly may see sometimes favorable progress in those cases in which the chief expression of myocardial damage is through changes in conduction and in rate and rhythm of the heart.

For the clinician several problems present themselves. Such problems are:

1. Under what circumstances may the most effective collateral circulation develop?
2. How long a time is required for the maximum development?
3. How can the presence of effective collateral circulation be surmised or proved?
4. What methods of therapy and management, if any, will aid in the development of the desired adjustments?

These questions are not posed in order to ef-

fect an answer. When they are set before one in the study of a case they provide a stimulus for a more effective and useful appraisal.

The factors most important in the development of collateral circulation in the heart wall are as yet not clearly evident. Two factors, however, play the largest part.

The first of these is the individual variation. There is no opportunity to study this clinically and we can only surmise that it plays a part in the survival of one individual while another with an apparently similar lesion may succumb. The second factor is the element of time. It is important for us to study this factor because in the past we have relied upon it not knowing exactly why. Unfortunately we cannot see the processes of development of collateral circulation during life in the heart wall and can only estimate their presence by indirect evidence. A somewhat analogous situation, however, can be studied visually during life when there is an obstruction in the external iliac or the femoral vein on one side. Careful observation of the entire venous circuit visible over the upper thigh and lower abdomen in such cases shows venous dilatation in the collateral area very early, but the establishment of the maximum dilatation of the collateral veins and relief of the circulatory embarrassment takes many months and in some instances is not complete until two or three, and occasionally even more, years have elapsed.

Whether the development of collateral channels in the coronary arteries is more rapid or less so than in the venous circulation cited, one does not know as yet. It would not be surprising if the thicker, more resistant walls of arteries took longer for the development of the effective dilatations and anastomoses.

Until a sufficient series of well studied autopsy specimens can be secured in cases with authenticated dating of occlusion, we must rely upon clinical impressions. My tentative conclusion, based on the study of favorable progress in many cases of coronary occlusion and of angina pectoris, is that the full development of collateral circulation in the coronary arteries takes many months, a year or two and sometimes more.

After a myocardial infarction is demonstrated, it is seldom that an informed physician today will require less than two months, and will demand often more, before any activities whatever are allowed. If then symptoms or signs of cir-

culatory embarrassment develop, it is usual that many more weeks and even months of relative quiet will be required.

Emphasis is placed upon the subject of the collateral circulation when considering diagnosis because it is the estimate of this collateral circulation and its effectiveness which plays a most important part in management. The diagnosis of the existence of circulatory inadequacy is not enough. An appraisal of the progress of compensation is essential. The realization is growing that this progress is in good part dependent upon compensatory collateral circulation.

There are four great groups of phenomena dependent on impairment of circulation in the myocardium and due to changes in the coronary arteries. These groups are: (1) The angina pectoris syndrome; (2) myocardial infarction; (3) myocardial damage with "congestive failure"; and (4) myocardial damage with changes in conduction and in rate and rhythm of the heart.

In many cases one or more groups of these phenomena are combined in the single individual. These combinations may be helpful in suggesting and in recognizing the vascular origin of the lesion. Time does not permit of a systematic study of the diagnostic features but a few remarks may be in order.

The angina pectoris syndrome when occurring without manifestations of any of the three other groups will at times present one of the most difficult diagnostic problems in medicine. This is particularly true when the economic problems of compensation and disability benefits are involved. The purely subjective character of the evidence in at least one-fourth of the cases will at times call for the greatest acumen and experience with even then the true answer not always immediately at hand. Some patients are unable to express themselves adequately and others may be so glib and well versed in a recital of typical symptoms as to arouse suspicion. Genuine differences of opinion between honest observers can thus develop. The credibility of a witness does not always impress itself alike upon all hearers. When to the subjective is added objective evidence, such as changes in heart size and in the electrocardiogram, the difficulties in diagnosis may disappear.

Although myocardial infarction has been receiving increasing attention since the publications

of J. B. Herrick beginning in 1912, it is still, I think, a condition which does not receive adequate attention by the majority of physicians. In my opinion the interests of the patient demand that whenever suggestive symptoms occur a careful continuing persistent study should be instituted promptly and this in satisfactory surroundings so that the question can be definitely answered: Is there in this case actual necrosis of tissue, i.e., definite myocardial infarction? To do that it is necessary to obtain evidence along all possible lines and to differentiate clearly from several conditions which may at times simulate it. It is not sufficient to acquire one or two lines of evidence but several must be studied, including a study for fever, leukocytosis, acceleration of sedimentation rate of red blood corpuscles, significant changes in blood pressure, signs of localized pericarditis or evidences of intraventricular or intra-auricular thrombosis, as shown at one time or another by embolism. Disturbances of rate and rhythm and the significant changes in the electrocardiogram are considered in another paper in this symposium. Later on in the case

studies for the development of mural aneurysm with or without calcification are in order.

The importance of all this study in suspected myocardial infarction lies in this: That if a true infarct has developed and the patient survives the immediate event, a long, painstaking and studiously supervised period of rehabilitation is in order. The aim during this period of rehabilitation is to guide the patient with the greatest efficiency so that the proper combination of rest and time may be given to induce the development of the most effective collateral circulation possible. If it has been possible to stimulate a more intensive study of the angina pectoris syndrome and of myocardial infarction, the purpose of this paper will have been accomplished. The congestive failure group will be presented elsewhere and the electrocardiographic studies are considered by another participant in this symposium.

CORONARY DISEASE—ITS TREATMENT*

F. J. HIRSCHBOECK, M.D.

Duluth, Minnesota

THE "treatment of coronary disease" to the medical mind suggests the treatment of angina pectoris and coronary occlusion. For the sake of brevity and to limit the discussion to this most frequent phase of coronary disease, I shall not discuss the therapy of the various effects of coronary sclerosis on the myocardium of a more chronic nature, with or without heart failure. Naturally, some of the measures used in the treatment of the various manifestations of coronary disease overlap, but I shall restrict myself to the consideration of the treatment of angina pectoris and coronary occlusion.

Coronary Disease with Angina Pectoris

Angina pectoris is a functional state, and may be due to several causes, among them relative conditions of myocardial anoxemia due to par-

oxysmal tachycardia, hyperthyroidism or anemia; and due, in coronary sclerosis, to a diminished, quantitative supply.

Once the symptoms of angina pectoris are noted, certain therapeutic measures must be immediately instituted. If the anginal symptoms are in relation to an anemia, treatment must be directed to its cause. Thyroidectomy will relieve patients who have anginal symptoms in association with hyperthyroidism. Paroxysmal tachycardia related to hyperthyroidism can also be relieved by surgery. If due to other causes, quinidine is usually helpful. Syphilitic lesions affecting the coronary ostia in such a way as to diminish the blood supply to the myocardium must be treated with anti-syphilitic measures, preferably a milder non-reactivating agent.

Certain general measures are advisable in the treatment of angina pectoris with coronary sclerosis. Of these measures rest is by all means the

*From the Duluth Clinic, Duluth, Minnesota. Read at the annual meeting of the Minnesota State Medical Association, Rochester, Minnesota, April 23, 1940.

most important; restricted to bed rest, if pain is provoked on the slightest exertion or allowed to an extent and degree consistent with the patient's limited tolerance to exercise. Coöperation with the patient in eliciting the degree of tolerance usually enables one to arrive at a safe procedure. Patients may note how long a distance they may walk on the level before pain is induced, and how soon the pain response is developed by climbing stairs or walking uphill. It is emphasized to the patient that he must learn to keep his activities below the threshold which causes pain, and if pain comes on with any activity he must immediately discontinue such corresponding effort until pain no longer is initiated. As the condition of the patient appears to improve the amount of exercise indulged in may be prolonged gradually, until a fair or adequate compensation is arrived at.

Excitement and worry act similarly in inciting attacks, by accelerating the heart action and augmenting its work. The patient must be cautioned to avoid, when possible, situations which tend to excite him too much—quarrels, sad situations, watching or listening to the recital of athletic contests over the radio, etc. Many patients fail to recognize the influence of intercourse in affecting angina or coronary occlusive symptoms. Relinquishing a job because of anginal symptoms is a subject, however, that must be thought over very carefully before decided upon, because of the many personal economic and social factors which interplay. If the patient is overweight, weight reduction is undertaken. Since the patient cannot reduce by increasing his exercise, dietary management is oftentimes our only recourse. Weight reduction should be accomplished gradually and consistently rather than to enforce too marked a nutritional deficiency with the hazards of an avitaminosis added.

The consensus seems to be that tobacco should be avoided, and its indictment seems to be founded on a clinical and experimental basis. Compromising with the patient to reduce the amount of smoking is usually ineffective, and complete abstention should be insisted upon. Alcohol in medicinal doses apparently is of benefit in promoting vasodilatation, but should be used in medicinal proportions and not in excessively stimulating amounts. Kerr has suggested the use of a belt for support of the abdomen, so as to facilitate diaphragmatic function and respiratory ef-

iciency. In a very limited experience its use has been satisfactory, and apparently pleasing to the patient.

Medicinal Treatment.—Whiskey has already been mentioned as of value. The nitrites have been found most useful in relieving attacks of angina pectoris, and according to several clinicians, have also been used to prevent attacks with evident success, administered just before effort. Nitroglycerine tablets dissolved under the tongue or crunched between the teeth, and thoroughly dissolved, in doses of 1/100 gr., seem to be the most effective method of use. Amyl nitrite is satisfactory, but less easy to handle, and because of its odor, conspicuous in its use. Recently, inhalers containing octyl nitrite have been advised as beneficial. The routine use of the nitrites is of doubtful value.

The xanthine derivatives have been widely used in routine practice, and good results reported in a large percentage of cases. There is, by no means, universal agreement among writers, however, as to the relative merits of this group or various members of the group, some preferring theobromine compounds, others theophylline preparations. These drugs may be used for a long period of time unattended by any ill effects. I believe there is a tendency to use xanthine derivatives in too small doses. Recently, Clerc and Sterne¹ drew attention to a group of substances influencing anginal crises, which unite the antifibrillatory properties of quinic substances, and the beneficial effect of theophylline on the coronaries. It is known as 1262-F, the diethylaminoethoxydiphenyl, and is administered by mouth, up to daily amounts of 0.15 to 0.2 gms.

Many patients with anginal symptoms are nervous and high-strung, and even in the more calm, mild sedatives are frequently advantageous. For the simple nervous situation, bromides or the barbiturates are sufficient. With more active pain, codeine may be used. In 1939, Master, Jaffe and Dack² made a study of sixteen drugs, including a placebo, namely, milk sugar, on angina pectoris, to note evidences of any specific effect on the anginal syndrome. They included several xanthine derivatives, alcohol, sedatives such as phenobarbital, chloral and bromide, the nitrites, tissue extracts, digitalis, and two narcotics, codeine and dilaudid. Some patients were helped by all the drugs; others by none. No

drug was consistently successful in a significant number of cases, and equally satisfactory results were obtained with the use of the placebo as with the supposedly more active drugs. The writers believe that much of the benefit is derived from psychologic factors and a reduction in the emotional status. Their observations do not apply, of course, to the acute attacks. Long clinical experience, I think, tends to support the view of these writers, at least, in part. The value of routine medication must not be over-estimated.

I believe there is little basis from the standpoint of clinical results as far as the use of tissue extracts is concerned. In certain instances the exhibition of sedatives, xanthine derivatives, nitrites or alcohol seems beneficial; in others not. The choice of the agent used and the duration of its administration must depend upon the personal desires and choice of the physician. Personally, I am inclined to the use of small doses of sedatives, with one of the xanthine derivatives, and frequently, alcohol in proper doses.

In the hands of a few, the surgical treatment of angina pectoris has been highly extolled. On experimental evidence, and occasionally in humans, good results are reported by such men as Beck, O'Shaughnessy, and others. The basis of the procedure is an effort to promote collateral circulation to the myocardium by the use of adjacent normal tissue, such as muscle or the omentum. Such procedures are not within the province of this discussion, and not recommended at this time for general practice. Thyroidectomy, as first advised by Levine, is apparently justifiably falling into disfavor. In some instances, where the patient's anginal symptoms are frequent and difficult to relieve, even with a most careful regimen, peravertebral alcohol injections may be used. They are not unattended with danger, and should be used only by the experienced, and with due caution. In ideal circumstances, the results are good, but it is to be borne in mind that though the pain discomfort may be diminished, the pathologic process, which is the basis of the disease, is not altered.

Treatment of Coronary Occlusion

The first consideration in the treatment of patients with coronary occlusion is the relief of pain and shock. The latter varies considerably in its degree, but one can never tell when the physiologic mechanism of the heart may be interrupt-

ed and death result, even in the absence of shock. Hence, rest (using the term in a broad sense) is an imperative therapeutic necessity. If the patient's condition is critical it may be injudicious to move him, unless the attack comes on in the street or in a shop. Oftentimes, it is best not to disturb him by undressing him except for his outer clothing. If the patient breathes more easily in the semi-upright position the body should be adequately supported by pillows. Effort should be made to keep the body warm. Occasionally in syncopal attacks the head may be kept flat. No one should be allowed in the room except the immediate attendants. The alarmed relatives should be in the background. These measures suffice for the immediate situation. Morphine is the best remedy for the relief of the excruciating, wearing-down pain. In vigorous persons $\frac{1}{2}$ gr. morphine sulfate by hypodermic, or $\frac{1}{4}$ gr. by the venous route is not excessive, even with due regard to certain unfavorable after-effects, as for example, vomiting and respiratory depression. Vomiting is so commonly associated with severe attacks that one is not justified in always blaming morphine for its occurrence. I see no great advantage in substitutes, such as dilaudid or pantopon. If the patient's resistance to pain seems to be good, or the attacks associated with less pain, smaller doses of morphine may be sufficient. It is my belief, however, that pain, combined with shock, is so distressing to the patient that its relief should be occasioned as rapidly as is consistent with safety. Atropine and/or papareline may be tried first or as accessories to morphine.

There is also evidence, as pointed out by Epfinger, that under the influence of morphine a smaller cardiac output is required, and the resultant diminution of work on the part of the heart may be of importance. Nitrites are of no value in acute coronary occlusion. Most physicians are inclined to give an initial dose in the hope that it may relieve what might be a simple anginal attack. An additional agent of undoubted benefit in the relief of the immediate attack when other measures fail, is the inhalation of oxygen in adequate percentage amounts. It is indicated in all cases where there is an increase in the pulse rate, respiratory rate, dyspnea, or cyanosis. Oxygen relieves all of these if the condition is not irreversible. It also tends to lessen pain, and is an adjuvant to the effect of morphine. Concentra-

tion should be at about 50 per cent, and because of the ease of its administration and the lack of physical annoyance, an oxygen tent is the better method, though the nasal catheter is of great benefit.

It is not necessary to give the patient any food for the first few hours after the attack, but fluids may be administered by mouth, preferably slowly, and with due regard to the likelihood of vomiting. Water (cold, if desired, or hot if the patient is in shock) in frequent small amounts is usually sufficient until the patient recovers from the initial shock. After this occurs it may be increased in amount to an optimal level, or even increased to 2 or 3 liters per day if the patient perspires excessively. If vomiting continues, physiological salt solution, with isotonic glucose, may be given subcutaneously slowly. This is much more satisfactory than the rectal drip, and less likely to be harmful at this stage than intravenous medication. The use of hypertonic glucose solution in one form or another (50 c.c. in 50 per cent solution, one to three times per day) is advised by some clinicians, on the basis of improving the myocardial nutrition. Theoretically, it might be considered of advantage, but I should consider an isotonic subcutaneous administration sufficient for the purpose if the patient is not able to take sugar by mouth, in the form of fruit juices, to which sugar may be added. In patients with pulmonary edema or passive congestion, I am inclined to its use in higher concentration. Because of the dehydrating effect of concentrated glucose solutions on the tissues, adequate water intake must be supplemented.

The function of the bowels may be maintained by giving an enema in from twenty-four to seventy-two hours, depending, on the one hand, upon the degree of shock, and on the other, the presence of abdominal distention, which may be relieved by such measures. Individual circumstances must help the clinician in making a decision, but insistence on having the bowels move once a day is, I believe, in most cases unnecessary. After the first few hours, food, in liquid form, may be administered, to be followed by semi-liquid preparations, such as cooked cereals, light puddings, pureed vegetables, soft eggs, et cetera, and later supplemented by articles of food which can be prepared by being well cooked and yet pleasing to the patient's palate. Just as it is important not to disturb the patient too much

physically by getting him on the bed pan frequently to permit of bowel function, it is equally important not to examine the patient too frequently by turning him over on his side or by raising him up in bed. There is no condition in which greater caution must be exercised in needlessly moving the patient about for the desire of a thorough examination of the lungs posteriorly, than in coronary occlusion.

After the treatment of the initial shock and the insistence upon absolute rest, the question of further safeguarding the patient's physical capacity and stamina must be considered. The question of bed rest requirements as far as duration of time is concerned is frequently brought up by the patient himself as he begins to improve. I do not believe that any patient should be allowed to get up in less than four weeks after a coronary occlusion, and oftentimes he must be kept in bed for a much longer period of time, depending upon various contingencies. A period of six weeks is the average. One is guided by certain clinical laboratory findings—the white blood count, differential blood count, and the sedimentation rate. The temperature curve and pulse rate and the character of the physical findings are also criteria for evaluation. No patient should be allowed to get up for one week after all evidences of activity, as manifested in one way or another, subside.

When the patient is allowed to get up it must be done in very gradual increments of time. It must be remembered that reclining in a chair is frequently no more burdensome than lying in bed, and probably less so. The hazard lies more particularly in the effort to transport him between the bed and the chair. From the time the patient takes his first step, the time and distance involved in exercise may gradually be increased, with small excursions about the room, to the bathroom (on the same floor), and as the patient improves, gradual descent and ascent of the stairs. In people of small stature and weight it frequently helps the morale considerably to carry the patient downstairs and up for a change of milieu. It is said that descending the stairs involves five times the physical exertion encountered in walking the same distance on the level, and ascending the stairs, fifteen times as much effort. This may be used as a rough criterion for an increase in effort. As soon as the patient is able to do so, short walks out of doors, or rid-

ing about in an automobile may be indulged in, future increases dependent upon the response to each added effort. It is needless to go into greater detail. The resumption of the patient's usual activities must also be gradual. When possible, a sojourn in warmer climes in the wintertime is of benefit, because of the lack of necessity of combating the severe element of climatic change. The patient should be safeguarded first in going outdoors in inclement weather, and the necessity for donning heavy clothing to combat the winter atmosphere should be avoided.

Medicinally, the patient may be given sedatives if his rest is disturbed, or if he is unduly apprehensive about his condition or his future. The barbiturates are effective, with no contraindication. Routine medication with the xanthine derivatives is a moot point, but is used by most clinicians for a few weeks to a few months, in the hope that it may increase the circulatory efficiency generally, as well as in the myocardium. Theophylline derivatives may be used in smaller doses, but as compared to the theobromine derivatives probably have no superiority, and may, in fact, be somewhat less efficient, when given by mouth. The use of quinidine as a preventive of ventricular fibrillation or other physiologic disasters may be helpful, but convincing evidence is lacking. If the patient presents premature ventricular contractions the indication is more definite. Three to 5 grains may be repeated three times a day.

The consensus is that digitalis should not be used except where indicated for reasons consistent with cardiotherapeutics in other conditions. If there is a fibrillation present and the rate increased, nothing is so effective and if the patient exhibits signs of stasis in the lungs or general circulatory insufficiency it may be used according to the same method as employed in heart disease due to other causes. When a threshold digitalization has been attained the dosage should be reduced to 1 or 1½ cat units per day.

Certain situations may arise as complications in coronary disease which demand other measures. In patients who are in shock and in whom the blood pressure is low, adrenalin may be of benefit. There may be some objection from the standpoint of physiologic experimentation, but clinically, in discussing the matter with other

cardiologists, they admit of certain clinical enthusiasm in regard to it. If the patient has pulmonary edema during or after the attack of occlusion, morphine is necessary; adrenalin may be used as well as aminophylline in 7½ gr. doses intravenously once or twice a day. Concentrated glucose preparations one to three times per day are indicated. Measures for the promotion of absolute rest must again be enjoined, in the event of such attacks occurring sometime after the actual occlusion.

In the patient with congestive heart failure digitalis is the sovereign remedy, combined with a reduction in the fluid intake, at the same time observing a record of the intake and output, and the use of diuretics. It is in these instances that the xanthine derivatives, given by mouth, are of benefit, and less disturbing to the digestive apparatus than corresponding large doses of the ammonium salts, etc. Mercupurin, salyrgan, esidrone, or any similar preparations, with or without theophylline, intravenously, two or three times a week, are of great benefit in relieving the patient, not only of the mechanical distress of the congestion, but also in yielding physiological relief. In patients who are in shock, the question of giving stimulants, such as coramine, caffeine, or strychnine, usually lies within the choice of the physician. Except as a gesture, I have relatively little faith in them.

I think there are a few points in the treatment of coronary occlusion that are needful of particular emphasis; namely, the insistence upon absolute physical and mental rest, and the sufficient administration of morphine and atropine and possibly oxygen in the early phases of the attacks; the need of keeping the patient quiet long enough so as to permit of anatomic restitution, at least in part, to the injured structure; and the avoidance of over-treatment of the patient by needless medical and nursing manipulation. Generally speaking, the patient, after the initial attack has been treated and overcome, should be permitted to coast along in his convalescence, until he is permitted to resume his activities gradually.

THE ELECTROCARDIOGRAM IN CORONARY DISEASE*

HARRY OERTING, M.D.

Saint Paul, Minnesota

IN considering the electrocardiogram in coronary disease, I will not present lantern slides of typical and atypical tracings, and I will not explain the technicalities of the electrocardiograph itself, but limit my discussion with you to what you can expect to learn from an electrocardiographic tracing and what the limitations of this procedure may be.

In discussing this subject it is necessary that we first state briefly the fundamental facts regarding the electrocardiograph. The electrocardiograph is an instrument primarily concerned with furnishing evidence of the anatomical state of the heart muscle and of the coronary arteries, and in no way does it aid one in determining the functional capacity of the heart or its ability to do work. In the very small proportion of cases of cardiac irregularity, that cannot be differentiated clinically, the electrocardiograph can clarify the exact nature of such an irregularity. The electrocardiograph has almost no value in diagnosing valvular lesions.

The typical case of coronary occlusion can be diagnosed from the clinical picture alone and the electrocardiogram is needed only to localize the site of the infarction. In the atypical or questionable cases an electrocardiogram will often definitely decide the matter immediately, although at times when the clinical history and findings are inconclusive, serial records may be necessary to rule out or establish the diagnosis. It is imperative always to bear in mind the fact that occasionally all records may be within normal limits and yet the patient dies of coronary occlusion. This is usually in rapidly fatal cases where cardiographic changes do not have time to manifest themselves. It is well to reemphasize that serial records are not only very important in the diagnosis of coronary occlusion, but they also give a graphic picture of the course of the disease and thus make the most efficient management possible.

In the arteriosclerotic age group, serial electrocardiograms give an important picture of the ageing process in the coronary blood vessels and

may indicate changes long before there is any clinical evidence. Therefore, in systemic diseases in which heart disease of an arteriosclerotic nature is common, it is prudent to make periodic electrocardiographic records. The electrocardiogram correctly correlated with the clinical history and physical findings, materially aids in judging the progress of coronary disease.

Substernal pain and distress is one of the most serious problems confronting the private practitioner and the entire mode of life, economic position and happiness of the patient and his family depends upon a correct diagnosis. As we all know, chest pain is not always due to coronary disease or coronary insufficiency, and the electrocardiogram will often assist us in arriving at a diagnosis. Unfortunately electrocardiographic records are not always diagnostic. We all know that one can have organic heart disease with the pain due to other causes and that chest pain of cardiac origin does occur in some cases even in the absence of electrocardiographic abnormalities. Successive changes in the serial electrocardiogram is the most important diagnostic aid of electrocardiography and often the electrocardiograph is able to eliminate the heart as the source of symptoms suggestive of myocardial disturbance.

The electrocardiograph is a most useful instrument but routine electrocardiograms in the absence of clinical findings of heart disease, certainly are of no value to the clinician in arriving at a judgment of the condition of the heart.

All electrocardiographic records must be correlated with the clinical history and physical findings and the electrocardiogram of and by itself is not able to make a diagnosis or a prognosis for you. Owning and using an electrocardiograph involves more than just making a record—a twelve-year-old can do that after fifteen minutes' instruction. You must be willing to undertake sufficient study to enable you to make an intelligent interpretation of the records you secure and properly correlate them with the clinical findings, or in lieu of this, your records must be interpreted by a qualified person and in order that this

*Read at the 87th annual meeting of the Minnesota State Medical Association, Rochester, Minnesota, April 23, 1940.

interpretation may be of the utmost value, the interpreter must have a summary of the clinical history and physical findings.

Summary

1. The electrocardiograph definitely aids in the diagnosis and management of coronary disease and serial electrocardiograms are invaluable.

2. The electrocardiograph is only informative on the anatomical condition of the heart and in no way aids one in determining the functional capacity of the heart or its ability to do work and

it is of almost no value in the diagnosis of valvular defects.

3. The electrocardiograph may eliminate the heart as a source of symptoms suggestive of myocardial disturbance.

4. The interpretation of the electrocardiogram must be made by a thoroughly trained individual and the findings must be correlated with the clinical history and physical findings.

5. The electrocardiograph, of and by itself, cannot make the diagnosis and prognosis for you.

PNEUMOCONIOSIS*

A. J. LANZA, M.D.

Assistant Medical Director
Metropolitan Life Insurance Company

New York, N. Y.

PNEUMOCONIOSIS is a generic term whose use at times has been attended with some confusion. It embraces the reactions of pulmonary tissue to industrial dusts, which in some instances present clear-cut diseased conditions; in others, conditions which are not entirely clear; and in still others, conditions which have little or no clinical significance. Much water has gone over the dam since attention was first called to the importance of dust exposure in industry as a cause of pulmonary disease. A little over thirty years ago, when the campaign against tuberculosis was well under way, the statisticians began to call attention to the fact that workmen in dusty trades had a consistently high death rate from tuberculosis. It was surmised that many kinds of dust, by virtue of their physical properties of hardness, sharpness, and insolubility, produced a mechanical injury of the lungs which paved the way for a tubercle infection. With respect to certain organic dusts which did not have physical properties calculated to injure the pulmonary tissue, it was felt that these probably acted as conveyors of the tubercle bacillus. This seemed a reasonable explanation for the excess mortality from tuberculosis observed among certain groups of textile workers, tobacco workers and leather workers.

Disability and a high mortality were so conspicuous in what was commonly termed the hard rock mining industry that it was but natural that

anti-tuberculosis workers should stimulate investigation of that type of underground work and the first clinical study of pulmonary dust disease was made about twenty-five years ago by the United States Public Health Service and the Bureau of Mines, to be quickly followed by others in various parts of the country. These early investigations were mostly confined to the mining industry, except for the studies made in the textile industry by a group of physicians in Philadelphia.

Investigations were made in industrial communities over long periods of time. This procedure offered the tremendous advantage of observation of industrial workers ranging from those new in the industry to those who had been employed for many years, and thus made possible a correlation between the symptoms they presented and the length of employment and the working conditions in various occupations in the same industry. There was gradually built up a comprehensive knowledge of the etiology of pulmonary dust disease which led to a clearer understanding and did away with many false preconceptions. The most conspicuous fact was that where workmen were exposed to dust containing free silica in large amounts, they contracted a definite and specific type of pulmonary fibrosis; that this fibrosis produced characteristic appearances on an x-ray film, and was accompanied by a consistent progressive clinical picture, in which dyspnea on exertion was the outstanding symptom.

It was learned in time that the symptoms pre-

*Address at the annual meeting of the Minnesota State Medical Association, Rochester, Minnesota, April 23, 1940.

sented by any group of workmen bore a definite relationship to the severity of such silica exposure. In other words, the symptoms and progress of the disease were directly proportionate to the amount of silica which invaded the pulmonary tissue. It was conspicuously apparent that in communities where men were exposed to a severe silica hazard, the incidence of and mortality from tuberculosis was extremely high, in some instances so high as to be hardly credible. This tuberculosis mortality, however, was in sharp contrast with that of surrounding communities and even with that of the workers' families.

There was built up a concept of an occupational disease resulting from the inhalation of free silica dust, manifested primarily as a fibrosis evenly distributed throughout both lungs, which, dependent upon the circumstances of exposure to silica dust, would progress with the gradual development of disability. Secondly, especially where the silica damage to the lungs was of a considerable extent, tuberculous infection was apt to appear. Infection with the tubercle bacillus was more than merely a terminal episode and these two conditions reacted upon each other, definitely increased disability, and frequently led to a fatal termination. When death occurred as a result of pulmonary involvement in the great majority of cases, infection with the tubercle bacillus was present.

There came to my attention within the past month the report of the Miners' Phthisis Prevention Committee of Johannesburg, South Africa, for the three-year period 1935-1938. The authors summed up the experience of thirty years' study of silicosis in the gold mining industry and it was interesting to note how largely the observations concerning the etiology and clinical course of silicosis made in the early studies in this country had stood the test of time. Laboratory researches which have been carried on in this and other countries have modified our earlier ideas as to the manner in which silica affects the lung and have greatly increased our knowledge of the pathology of dust disease. Modern roentgenology has made possible early and accurate diagnosis and also has enabled the physician to watch the progress of affected individuals.

I might state here that organic dust has not been shown to produce a reaction of the pulmonary tissue and the pronouncement of Landis some twenty years ago that organic dusts played

no part in causing pulmonary fibrosis has held good.

Attention was naturally directed to other industries which involved exposure to dust containing silica in many forms—that is to say, combined silica—as well as exposure to other types of non-siliceous inorganic dust. Here investigators found that the picture of disability and disease seen among those exposed to free silica was conspicuously absent. Various terms such as chalicosis and siderosis fell into the discard and other designations, such as potters' rot, grinders' rot, miners' phthisis, and miners' consumption were found to relate to identical conditions and were supplanted by the term silicosis.

Field studies of various industries went hand in hand with animal experimentation in which were employed dusts similar to those found in industry. Animals were exposed to the inhalation of these dusts in specially prepared dusting chambers and Gardner, at the Saranac Laboratory, was the first to demonstrate silicosis in experimental animals. The method of intraperitoneal injection, with the technique of Miller and Sayers, was also used. The underlying motive for all this was to determine which industrial dusts were harmful, that is, would cause a pneumoconiosis of such a type or degree as to produce disability.

Among the dusts investigated both in industry and in the experimental laboratory were limestone, calcium carbonate, gypsum, cement, feldspar, soapstone, talc, precipitator ash, artificial abrasives, sericite and others. None of these, whether they contained silica in combined form or no silica, produced disease in animals, nor was evidence of disease found among workmen exposed to these dusts except in those instances where free silica was also present.* That the failure to find evidence of pulmonary disease among workmen was not due merely to lack of a sufficiently severe exposure was indicated by the uniformly negative results in animals where the conditions of exposure were known and controlled and similar to those of silica exposures. X-ray films of individuals exposed for a number of years to these inorganic dusts, which contained no free silica, may show peribronchial thickening or accentuation of the bronchial tree. The same appearance can be found in individuals who have never been employed in dusty industries. Occa-

*Talc is one exception. See U.S.P.H.S. study 1935.

sionally x-ray films of some of these workers will show a diffused haziness or increased density that might be construed as due to the action of dust. However, these workmen are healthy and neither symptoms nor disability can be ascribed to this x-ray appearance. Hence, my opening comment that pneumoconiosis, as a generic term, has a limited importance from a clinical standpoint.

Two specific and distinct types of pneumoconiosis are important, namely silicosis and asbestosis. Asbestosis is the exception to the general rule in that it is a silicate, a form of combined and not free silica, which does produce a characteristic fibrous reaction in the pulmonary tissue and which may produce disability and death. In animal experimentation, intraperitoneal injection of asbestos dust produces an inert reaction—that is, there is no cellular proliferation as is observed with the various forms of silica. Inhalation experiments produce a pulmonary fibrosis similar to that in human beings, with the curious anomaly that fibrosis did not result when the finer dusts were used. This has led Gardner to believe that the action of asbestos in the lungs is probably mechanical and due to the peculiar shape of the asbestos spicule and the constant movement of the lungs. Further support is given to this theory in that, unlike silica, asbestos will not produce its characteristic reaction in animals in other than the pulmonary tissue.

Asbestosis first came into prominence in this country about 1930, since when a number of industrial studies have been made. The symptoms are largely similar to those of silicosis but the pathology and the appearance on an x-ray film are entirely different. The x-ray shows a diffuse haziness or ground glass appearance, especially in the lower half of the lungs; nodulation is absent, and the factor of infection appears to be much less important than in silicosis, at least that is our experience in this country. The total number of workmen exposed to asbestos dust inhalation is very much smaller than for silica and strenuous efforts have been made by asbestos plants to control their dust hazard. Asbestos fabrication is a factory industry, largely textile in character, and the control of dust is less difficult than the control of silica dust in mines and foundries. Consequently, there has not been and probably never will be, the opportunities for the clinical study of asbestosis such as have been

made possible by the wide variety and extent of silica occupations.

A small number of deaths from asbestosis have been reported and not all of these have been followed by postmortem. Mostly other organic disease was also found or diagnosed, which tends to confuse the rôle of asbestos in these cases, but in some cases death undoubtedly resulted from uncomplicated asbestosis.

There has not been sufficient opportunity in field surveys of asbestos plants to acquire enough information to correlate the production of asbestosis with varying degrees or intensities of dust exposure nor have the conditions of dustiness, as evidenced by particle counts, run as high as in the more severe types of silica dust exposure. We have had under observation for ten years a small group of workmen with asbestosis. Some of these have shown a progression on their x-ray films. They are still working and in seeming good health. However, in the meantime the plant has been cleaned up and the dust controlled so we do not know what would have been their history had they continued to work under the former, presumably hazardous conditions.

Our original concept of silicosis was based on studies of industries in which there was generally a more or less severe exposure to dust containing a high percentage of free silica. As industrial investigations came to include a wider variety of industries, our concept broadened and underwent some modifications. The data gained in industrial surveys, when correlated with laboratory findings, cleared up a number of apparently conflicting and puzzling observations. Not only did we learn that the incidence and progress of silicosis in any location depended upon the amount of silica dust in the air and the length of exposure, but it was demonstrated that in many instances other substances were present in the dust with the silica and that these substances modified the action of silica. Furthermore, it was shown that the action of silica was not due to its physical properties but to its chemical properties. Also, where certain substances had been accused of causing a pneumoconiosis, the offending agent was in fact the silica which was also present. Metallic dust, for instance, which in the early writings had been considered as more dangerous than silica, was found to be relatively harmless. There came a better understanding of what caused the variations in the clinical appearance

and course of silicosis as observed in different locations and in different industries. Men engaged in iron ore mining and in quarrying and cutting granite are exposed to dust containing silica and other substances as well, which tend to retard the action of silica upon the lung tissue. The pathologic process is altered and the appearance on the roentgenogram is altered sufficiently for the experienced physician to distinguish one type of exposure from another. With the mixed dusts, the progress of silicosis is usually slower and when infection occurs, it tends to be more chronic but the amount of tuberculosis found among granite workers and iron ore miners is nevertheless inordinately high. Cases have been reported of workmen exposed to dust containing silica and caustic alkalis which produced a rapidly developing and fatal type of silicosis with early infection.

On the other hand, certain industries have been studied in which the silica hazard was found to be of a degree which would not produce disabling silicosis within the average working lifetime. After forty or more years of such exposure, many workmen would show typical nodulation on the roentgenogram, but their symptoms were few or absent and they were still working every day, many of them being well over sixty years old. All of this emphasizes how necessary it is to study the etiological factors in order to arrive at a correct solution of the silicosis hazard in a given location or in a particular industry. It also explains the apparently conflicting conclusions that are sometimes drawn from isolated cases of silicosis when the work conditions, that is, the nature and type of exposure, have not been or cannot be determined.

The pneumoconiosis of coal miners illustrates very well the modifying action of one dust upon another. Miners' asthma had for years been recognized by physicians in the anthracite industry as a definite clinical entity. It was difficult to believe, however, that coal, an organic substance, could produce a disabling pneumoconiosis. The Public Health Service made a thorough study of the anthracite industry in 1933 and the results of this confirmed what many observers had suspected, namely, that disabling miners' asthma was, in fact, a silicosis; a form of silicosis modified by the combined action of silica and anthracite dust, and to which the term anthraco-silicosis might justly be applied. The incidence and prog-

ress of disability was, as in other silica dust hazards, proportionate to the extent of dust exposure. The silica was accounted for by the fact that the veins of coal lie between rock formations which frequently have a fairly high silica content, and, also, that there was some silica in direct association with the coal itself. Consequently, the workers had some silica exposure. Anthracite mine dust varied in its silica content from about 11 per cent for miners working directly in coal to about 60 per cent for men working in rock, with various types of exposures falling between these two extremes. Pulmonary tuberculosis was associated with anthraco-silicosis to a very considerable extent.

Below the age of thirty-five, hard coal miners showed an incidence of pulmonary tuberculosis slightly less than that found among male workers in general. In the age group of thirty-five to forty-four, the tuberculosis incidence was twice as great, and from forty-five to fifty-four, five times and above fifty-five about ten times the rate for all adult male workers. Or, to express it in another way, clinical pulmonary tuberculosis was found in 15 per cent of those with early anthraco-silicosis and in 43 per cent of those in the more advanced stages. The x-ray appearances, while similar to the silicosis of hard rock miners, can usually be differentiated from the latter.

With respect to bituminous coal mining, the silica factor is apparently less in extent or lacking entirely. A number of studies have been made by the Public Health Service but have not yet been published. Death certificates of soft coal miners were analyzed for a five-year period and showed no appreciable difference, with respect to deaths from tuberculosis, between the coal miners and the farmers living in the same counties.

Inhalation experiments with bituminous and anthracite coal (1.76 per cent SiO_2) have produced a very slight reaction and anthracite dust proved inert on intraperitoneal injection. We may conclude that in the absence of silica, coal will not produce a specific fibrosis associated with disability.

The relationship between pneumonia and silicosis is not entirely clear. The data obtained from various studies and from animal experimentation are not always consistent. The high incidence of pneumonia in some industries with a silica hazard can not be disassociated from ex-

posure to extremes of heat or cold or both. Coal miners have a high incidence of pneumonia and it is a common cause of death among the older men with anthraco-silicosis. My own impression is that individuals with any considerable amount of silicosis have a more unfavorable prognosis in pneumonia than would otherwise be expected but this experience is not very recent. It remains to be seen whether silicotics respond to specific serum treatment or chemotherapy as well as do those who do not have dust fibrosed lungs.

Summary

There is still much to learn about the action on the lungs of many kinds of dust. The effects of pure silica (SiO_2) have been demonstrated under many conditions in this and other countries with a high unanimity of agreement among investigators. Where the silica damage to the lungs is extensive, the incidence of tubercle infection is high. Where the silica exposure has been extreme, a tuberculous infection is almost inevitable, but every physician who has had wide experience with these cases has seen exceptions to this rule.

Today in American industry, severe exposures are uncommon. They occur mostly as isolated instances as when a sandblaster has been working with faulty protection. Tuberculo-silicosis may run a very chronic course, but if the silica damage is extensive, the progress may be fairly rapid, but many exceptions will be found to the general rule.

We are acquiring a constantly broadened knowledge of the action of mixed dusts, that is, dusts containing other substances along with the silica, but the more intense the silica exposure, the more these cases run true to type. Naturally the clinical picture of silicosis is changing as industrial dust control becomes more and more perfected so that we may expect to see more and

more of the type or degree of silicosis which is accompanied by little disability. I am convinced, however, that where the reaction has proceeded to cause nodulation, even though moderate in extent, a definite, increased susceptibility to tuberculosis takes place.

Finally, we must consider the criteria upon which the diagnosis of silicosis can be based. Undoubtedly, the early manifestation of silica dust reaction is peribronchial thickening with an increase of the hilum shadows, as seen in a roentgenogram. The same may be seen in workmen exposed to dusts other than silica and in individuals who have never had any sort of dust exposure. Consequently, those of us who got together several years ago under the leadership of Dr. Pancoast, felt that for practical purposes, a diagnosis of silicosis was not justified unless the specific reaction of nodulation, as found in experimental animals as well as in human subjects, was present.

In addition to a characteristic film, there must be a history of exposure to silica dust adequate to produce disease. Where an industrial investigation is being made, and the working conditions previously determined, it is usually not difficult to separate the silicotics from the non-silicotics and usually the presence of infection can be recognized or ruled out, careful consideration being given to the physical signs and the symptoms as well as the x-ray film. The isolated case that may turn up in hospital or clinic service may present considerable difficulty. Such patients are apt to be suffering from a combination of illnesses. They usually cannot give a sufficiently informative work history and even with a characteristic film, it may be difficult to say that a patient has silicosis (or even more difficult, asbestosis) and to what extent his pulmonary condition may be responsible for his symptoms or his disability.

INFECTED DERMOID CYST OF THE THORAX SIMULATING CHRONIC EMPYEMA*

HOWARD K. GRAY, M.D. and ROBERT WOODRUFF, M.D.

Rochester, Minnesota

AN INFECTED dermoid cyst of the thorax which simulates chronic empyema is interesting from two standpoints: first, because of the rarity of this manifestation of a dermoid cyst, and, second, because of the difficulty of diagnosis.

began in 1925 when he was four years old with an acute illness which was diagnosed pneumonia. After this postpneumonic empyema was thought to have developed on the right side and drainage of the right pleural cavity was instituted. Drainage gradually subsided and after a period of about two months the

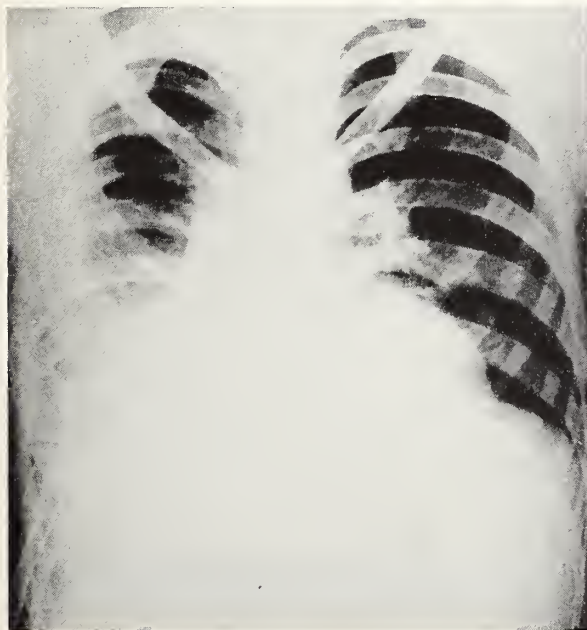

Fig. 1. The thorax prior to operation. The increased density in the lower lateral and posterior portions of the right side of the chest was interpreted as being due to markedly thickened pleura, probably associated with chronic empyema.

Fig. 2. Pedunculated growths removed at operation. The epithelial nature of the covering can be noted and a few fine hairs can be seen protruding from the tumors.

Dermoid cysts of the thorax arise practically without exception of the mediastinum, although they may arise within the lung. It is not rare for them to encroach on one or both pleural cavities but for a dermoid cyst to produce symptoms which seem to be in a pleural cavity without any obvious evidence of a mediastinal counterpart is rare. Harrington, in 1937, reported sixteen cases of mediastinal dermoid tumors from The Mayo Clinic. In none of these was the clinical course similar to that in the case which we are reporting.

The patient, a youth fifteen years of age, was first seen at The Mayo Clinic May 29, 1939. His trouble

wound was entirely healed and the patient seemingly was restored to normal health.

The patient was free of symptoms for nine years. Then after a period of anorexia, sweats, chills and fever, a diagnosis of chronic empyema of the right side was made elsewhere and right thoracotomy was performed for drainage. The patient's father said that at that time considerable yellow cheesy material drained from the wound. In the next five years four more operative procedures were performed to facilitate drainage.

General examination at the clinic revealed nothing abnormal other than the condition in the thorax and slight emaciation. Early clubbing of the nails was noted. There was a draining sinus on the right in the posterior lateral portion of the chest wall which contained a rubber tube. The patient was 64 inches (162.6 cm.) in height and weighed 95 pounds (43 kg.).

*From the Division of Surgery, The Mayo Clinic (Gray), and the Mayo Foundation (Woodruff), Rochester, Minnesota.

The value for hemoglobin was 11.4 gm. per 100 c.c. of blood. Erythrocytes numbered 3,850,000 and leukocytes 12,000 per cubic millimeter of blood. A roentgenogram of the thorax revealed the drainage tube in place and thickened pleura on the right (Fig. 1).

Fig. 3. Squamous epithelium and the skin appendages, hair follicle and sebaceous glands, which are diagnostic of a dermoid, are well shown ($\times 50$).

A diagnosis of chronic empyema of the right lung was made and on May 30, 1939, surgical intervention was instituted. The sinus was explored with a probe and was found to extend outward and upward for approximately 18 cm. Accordingly, a portion of rib immediately over this sinus was removed and the cavity unroofed. A large quantity of purulent material mixed with a caseous looking substance was scooped out. A cavity which measured about 10 cm. in diameter was revealed. Several peculiar looking rounded tumors, covered with skin and hair, were firmly attached to the inner and lower portions of the cavity (Fig. 2). Communicating with the main cavity in the mid-portion was a small cavity which probably represented an empyema pocket associated with the dermoid cyst.

As much of the contents as possible were removed from the cavity but it was impossible to remove all of the wall of the cyst. Consequently, the lining was destroyed with phenol and then the part treated was well cleansed with alcohol. The communication be-

tween the cyst proper and the empyema pocket was enlarged in order to establish free drainage. The whole cavity was packed lightly with plain gauze. The pathologist reported the tissue removed to be a dermoid cyst lined by squamous epithelium with hair follicles and sweat glands and containing sebaceous material. A section from one of the pedunculated growths demonstrated clearly the fact that this intra-thoracic lesion contained all of the elements of the skin (Fig. 3).

The patient's postoperative course was uneventful. A transfusion of 500 c.c. of citrated blood was administered on the second postoperative day as a supportive measure. The drainage gradually subsided and the cavity slowly began to fill in with healthy granulation tissue. The patient was dismissed from the clinic July 5, 1939, and at that time the cavity had filled in partially with clean granulation tissue and there was no sign of any remaining portion of dermoid tissue.

Since dismissal reports have been received from the patient and his attending physician. Convalescence was satisfactory and the boy rapidly gained weight and strength and soon was able to engage in all the activities of his associates. The cavity continued to fill in and when the last report was received in February, 1940, there was only slight drainage.

The ultimate prognosis in this case must be guarded because it is possible that a remnant of the cyst wall has escaped destruction by the phenol. However, the chronically infected cyst which was gradually undermining the patient's health has been eliminated and the immediate prognosis at least should be favorable.

Although an infected tumor simulating chronic empyema is undoubtedly rare, the possibility of such a syndrome should be considered in cases of a persistent draining from the thorax. Not infrequently chronic empyema may be allowed to persist indefinitely because adequate drainage of the empyema cavity has not been effected. The exact nature of the lesion in this instance was determined only after adequate drainage had been established.

OBSERVATIONS ON THE OCCURRENCE AND PREVENTION OF SUDDEN DEATH

JOSEPH F. BORG, M.D.

Saint Paul, Minnesota

THE frequency of unexpected sudden death calls attention to this condition as a problem to be studied from the aspects of occurrence, mechanism and prevention. It may occur in individuals apparently in good health or in patients whose conditions give no indication that such an outcome might occur. Since a structural defect is only exceptionally found to account for it, it has been logical to consider it as predominantly a cessation of cardiac function on a physiologic basis.

Under two known mechanisms, ventricular standstill and ventricular fibrillation, the heart may suddenly cease functioning. These may be transient but ventricular fibrillation is rarely so. Experimentally, Hering³ was unable to produce death by ventricular standstill. In patients with Stokes-Adams syndrome, the syncopal attacks are nearly always due to transient ventricular standstill, and it is probable that sudden death in these patients may be explained on that basis. This group accounts for a very small proportion of those dying suddenly.

Ventricular fibrillation, however, rarely reverts to an effective ventricular rhythm and it has therefore been considered by many to be the most likely cause of sudden death. Animal experiments and clinical observations in recent years have tended to verify this opinion and much has been done to explain the mechanism by which this accident occurs. Thus Hering³ claimed that ventricular fibrillation in animals was an irreversible process, with lethal outcome. It is well known that experimental ligation of a coronary artery will produce ventricular fibrillation. Furthermore, the occurrence of frequent ventricular premature contractions and ventricular tachycardia shortly before sudden death in coronary thrombosis suggests that the latter accident is due to ventricular fibrillation, especially since these irregularities have been described by Schwartz¹³ and his co-workers as prefibrillatory arrhythmias announcing the imminence of transient ventricular fibrillation in the cases they reported.

Of great importance have been the recent contributions which indicate that the intimate mechanism of sudden death is to be explained on the

basis of sympathetic nerve stimulation of a myocardium sensitized by some toxin or disease state. In view of the evidence that general sympathetic nerve stimulation acts through chemical mediation of an epinephrin-like substance produced at its site of action, it seems probable that the innervation of the myocardium acts likewise. This view is supported by a number of observations by various investigators. Thus, Rothberger and Winterberg¹² found that in dogs partially poisoned with barium chloride, sympathetic nerve stimulation or the use of epinephrin would produce ventricular fibrillation. Otto¹¹ showed that the ventricular fibrillation caused by coronary ligation in dogs was prevented by section of the sympathetic fibres. Hooker⁴ has reported experiments in dogs in which areas of fibrillating ventricular myocardium were cut away from the heart with a resulting cessation of the fibrillation, even a return to rhythmic contraction being recorded. While he did not attempt to draw the inference from these experiments, it seems likely that some substance was being elaborated by nerve action on the myocardium and resulted in ventricular fibrillation which stopped in a segment of the heart muscle when it was cut away from the whole. Whether this substance is identical to epinephrin or is an epinephrin-like substance (sympathomimetic amine) it is probable that it plays an important rôle in the production of ventricular fibrillation in human subjects.

This conception of the mechanism of ventricular fibrillation leads to the consideration that sudden death due to this cause might be preventable if it were possible to select those patients who after clinical study were considered liable to this condition and if some measure were available to counteract the action of epinephrin or reduce the irritability of the heart muscle. An attempt to throw some light on these two problems is made in the present study.

Concerning the first, a study was made of the records of all patients who, among the 22,490 admissions to Ancker Hospital during 1934-1935, died suddenly, unexpectedly and with no indicated or proved structural defect to account for

such outcome. (Autopsies were performed on 50 per cent of these patients). From this analysis certain facts emerged which indicate the type of patient in which this accident has a tendency to occur. These will be discussed.

Concerning the second, recognition was given the probable rôle of epinephrin or an epinephrin-like substance in the mechanism of ventricular fibrillation. Nathanson has shown that no satisfactory antagonist to epinephrin can be used clinically. However, it is possible to depress myocardial irritability, and in view of the effectiveness of quinidin in the treatment of auricular fibrillation, it has been used therapeutically and experimentally with apparent success in producing this effect in conditions of known myocardial irritability. It has been considered successful in preventing ventricular arrhythmias (Scott, Levine and Fulton).¹⁴ Cases have been reported (Dock,¹ Escamilla²) where quinidin seemed to prevent attacks of paroxysmal ventricular tachycardia. Levine⁶ and Jackson, Friedlander and Lawrence⁵ showed that quinidin inhibited experimental ventricular fibrillation in animals. Nathanson⁹ in experiments on human subjects, was able to inhibit by quinidin the onset of pre-fibrillatory rhythms which were produced by sympathomimetic amines. Morawitz and Hochrein⁸ used quinidin empirically with success in an attempt to prevent sudden death. These contributions indicate that quinidin modifies the action of the substance which presumably produces ventricular fibrillation, and provides a rational basis for the possibility of attempting to prevent such a development in individuals who may be considered liable to sudden death.

The present study is based on an analysis of the cases of sudden unexplained death in a large general hospital (Ancker Hospital, Saint Paul) over a three-year period, 1934-1935-1936, during the third year of which quinidin sulphate was administered to patients who seemed liable to sudden death as shown by the experience of the first two years. The series consists of fifty-one patients in whom death was unexpected at the time, sudden in its appearance, and unexplained on a basis of structural change. Omitted therefore were the sudden deaths due to rupture of the heart, ruptured aortic aneurysm, and other conditions where demonstrable cause for this type of death was present. Autopsy verification of the diagnosis was obtained in twenty-five of

TABLE I. UNEXPLAINED SUDDEN DEATHS—
ANCKER HOSPITAL

Diagnosis	1934	1935	1936
Coronary Sclerosis	8	3	0
Cor. Scler. + Hypertensive Heart Disease	3	6	3
Coronary Sclerosis + Aortic Stenosis	3	4	0
Coronary Thrombosis	5	4	1
Hypertensive Heart Disease	1	3	0
Aortic Stenosis	0	1	0
Syphilitic Aortitis	1	1	0
Miscellaneous Group	2	1	1
Total Admissions	11,036	11,454	10,753
Total Deaths	896	786	888
Sudden deaths	23	23	5
(Per Cent of Total)	(2.57%)	(2.93%)	(.56%)

the fifty-one cases. As shown in Table I, this material is derived from a total of 2,570 deaths occurring in a total of 33,243 admissions to Ancker Hospital, Saint Paul, during this period.

While the number of cases is not large, certain facts stand out in a study of the 1934 and 1935 sudden unexplained deaths (twenty-three such fatalities each year) which were helpful in indicating the patients most liable to such exitus.

Sex.—Divided according to sex, these cases show a great preponderance of males. In 1934, there were twenty males and three females, and in 1935, nineteen males and four females.

Age.—A marked tendency for these deaths to occur at advanced ages was demonstrated, 76.1 per cent occurring after the age of sixty, with the peak decade being that of the seventies.

Electrocardiography.—Electrocardiograms were recorded in twenty-one of the cases. All of these showed abnormal T waves and eight showed QRS abnormalities, notching, slurring and widening.

Congestive Failure.—As might be expected in a group of hospital patients congestive failure was not uncommon, although all cases in which this condition was the direct cause of death were eliminated. Twenty-nine were in congestive failure when sudden death occurred and seventeen patients were in a state of good compensation.

Arrhythmias.—Since it is known that arrhythmias, especially premature contractions, precede the onset of ventricular fibrillation, it is of interest to note that fourteen (30.4 per cent) of

the patients showed numerous ventricular premature contractions. Auricular fibrillation was present in seven (15.2 per cent) of the patients.

Diagnosis.—In all except two cases a definite diagnosis of heart disease was made (Table I). The exceptions might possibly have been included had autopsies been permitted. These were patients with involutional melancholia, aged fifty-seven, and convalescent hemiplegia, aged seventy-two. Degenerative heart disease is seen to be outstanding, coronary sclerosis alone or associated with hypertensive heart disease, coronary thrombosis, or aortic stenosis accounting for 78.3 per cent of the patients. This does not present the real incidence of coronary sclerosis since one patient in a miscellaneous group, an asthmatic, showed coronary disease at autopsy, and other deaths occurred at ages where such condition is common. Another observation of interest relates to the diagnosis of aortic stenosis. This was made in eight instances, in seven of which there was a complicating coronary sclerosis. All of the seven patients were between fifty-eight and eighty-eight years of age. Sudden death in uncomplicated hypertensive heart disease ranked relatively low in the group, only four cases being found. Syphilitic aortitis contributed two cases, and the miscellaneous group is composed of one case each of asthma, hemiplegia, and involutional melancholia.

In view of the foregoing experience of the years 1934 and 1935, with the coöperation of the various hospital services, it was decided to administer during 1936 quinidin sulphate three grains three times daily to all patients with degenerative heart disease, aortic stenosis or syphilitic aortitis upon admission to the hospital. The drug was given in addition to any other indicated therapy and stopped if not well tolerated.

The figures presented for this year show a marked decrease in sudden deaths although the general hospital mortality was higher than in the previous years. Only five deaths occurred, four in patients with coronary sclerosis complicated by hypertensive heart disease or coronary thrombosis with congestive heart failure, and one in a patient with advanced pulmonary tuberculosis on whom an autopsy was refused but no recognized cardiovascular disease had been found. Of the four cases with degenerative heart disease quinidin had not been given in three. A

brief review of these five histories is presented as follows:

Case 1.—A woman, aged sixty-five, was admitted with severe dyspnea, substernal pain, auricular fibrillation and shock. Onset had been sudden and diagnosis on a previous admission was hypertensive heart disease, electrocardiogram showing left axis deviation and inverted T waves in lead I. Admission diagnosis was coronary thrombosis. The patient died suddenly twelve hours after admission. Quinidin was not administered.

Case 2.—A man, aged seventy-two, was admitted complaining only of pain in the left foot. The diagnosis of coronary sclerosis and diabetes complicated by gangrene of the left foot was made. The electrocardiogram showed auricular fibrillation, QRS notching and T wave inversion. Compensation was good. The patient died suddenly in bed. Quinidin was not administered.

Case 3.—A woman, aged seventy-two, was admitted with edema, dyspnea, cyanosis and auricular fibrillation. A diagnosis of congestive heart failure on basis of hypertensive heart disease and coronary sclerosis was made. Quinidin was administered. Clinical course was not favorable, but the sudden termination was unexpected. Diagnosis was verified by autopsy.

Case 4.—A woman, aged forty-five, complained of nocturnal dyspnea and precordial pain on exertion. Clinical diagnosis was hypertensive heart disease with auricular fibrillation. No congestive heart failure was present. The electro-cardiogram showed QRS and T wave abnormalities. Quinidin was not administered. The autopsy showed cardiac hypertrophy, coronary sclerosis, myocardial fibrosis and cerebral malacia.

Case 5.—Male, aged fifty-four, was a patient on the tuberculosis pavilion with no significant complaints and heart disease was not suspected. Clinical diagnosis of advanced pulmonary tuberculosis was made. Autopsy was not performed.

From these results it is obvious that the desired administration of quinidin to all patients for whom it was intended was not entirely accomplished. While the total number of omissions was not determined there is reason to believe that it was small. It is of particular interest therefore to note that only one of the patients who died suddenly in 1936 had received the drug, and the question may be properly raised as to whether or not the rather advanced state of congestive heart failure here should not have contraindicated its use.

Discussion

Inasmuch as it is impossible to state what percentage of patients suffering from heart disease died directly from this cause it is therefore im-

possible to determine what proportion of these die suddenly. However, some idea of the importance of the subject can be obtained from the studies of Nathanson¹⁰ who found that 60 per cent of 113 patients dying of occlusive coronary disease died suddenly. These figures are high because they include deaths outside of the hospital, much more often sudden than in the hospitalized group in this class of patients. Nevertheless they emphasize the problem as more important than its casual consideration would suggest.

While it appears that the majority of the sudden deaths in the years surveyed were not associated with congestive heart failure, these figures may be misleading. The state of compensation described was that present at the time of death, while many of the compensated patients had been decompensated on admission to the hospital. The present study at least suggests that sudden death occurs more often in those without congestive failure.

The general hesitancy in the use of quinidin in congestive heart failure merits consideration as to whether its use was justified in such patients included in this study. Unless Case 3 could possibly be considered as a quinidin death, no patient who had received the drug in 1936 died suddenly or developed the arterial emboli so feared by some investigators.

The desirability of the use of quinidin in an attempt to prevent sudden death is open to discussion. Considerable difference of opinion exists as to the justification for the use of a drug continuously over a patient's lifetime when a certain clinical picture presents itself. Much can be said on both sides. As far as risk is concerned in the continued prophylactic use of quinidin no known well controlled studies point to danger, and the present study would not indicate such to exist. The psychologic effect on the patient of the use of a drug designed to prevent sudden death would be most unfortunate if the purpose were made known, although the matter of pro-

longed administration should not be a serious objection. On the other hand this study would suggest that such a prolonged regime of quinidin administration may in many instances extend a comfortable and useful existence for many patients with heart disease. Further studies should be made of this subject before any crystallization of opinion can take place.

Conclusions

Results obtained by the use of quinidine sulphate in the present study furnish clinical support to the belief that ventricular fibrillation is the usual cause of sudden death.

Observations are made which support the suggestion that quinidine sulphate may be effectively used in preventing sudden death in patients liable to it.

This study indicates that the patients in whom sudden death is most apt to occur are of advanced age, suffering from degenerative or syphilitic heart disease, showing abnormality of the electrocardiogram and frequently manifesting arrhythmias.

WHAT'S WRONG WITH THE PATIENT WHO IS ALWAYS TIRED?*

WALTER C. ALVAREZ, M.D.
Rochester, Minnesota

EVERY week I see a number of patients whose main complaint is that they are tired and exhausted. They have no "pep," and the least exertion makes them feel worn out. Many complain that they cannot do their work properly and they can't get much fun out of life. The stenographer or clerk can't go out with her beau in the evening and the wife can't go anywhere with her husband and enjoy it. The school teacher can barely get by until Friday, and with her it is always a race between a nervous breakdown and the end of school in December and May. We physicians are all seeing these persons, and we all wish often that we knew what is wrong with them.

From the letters from prominent physicians which many of these patients bring with them, I gather that the medical profession today is inclined to look on these complaints as due to some localized disease or focus of infection somewhere in the body. As a result the patients are put through one expensive and exhaustive laboratory and roentgenologic examination after another. All possible foci of infection are removed or treated, and occasionally in desperation a surgeon will explore the abdomen and remove the appendix.

When nothing is found, the patient moves on, and the next clinician promptly puts the patient through another complete examination. He and the patient both hope that some local disease will be found which was missed before. Unfortunately the pressure on the physician to find some local cause is so great that he is likely to grasp at whatever diagnostic straw is offered and to make all he can of one basal metabolic rate of —15, one blood pressure reading of 105 mm., one blood sugar determination of 85 mg. or a little spasticity of the colon.

All this does not mean that when a patient who has been strong and well begins to feel tired out a careful examination should not be made. It most certainly should be, and this is particularly true when the failure in strength and energy and the loss of a sense of well-being come to a man

or woman past middle age who has previously enjoyed good health. In such cases it usually means the coming of some serious disease, and the physician must hunt through the body for carcinoma or for signs of pernicious anemia, hypothyroidism, hypertension, diabetes, or a failing heart or kidney.

If the fatigue and loss of "pep" and interest in life come suddenly in a person past middle age, the cause is almost certainly a small stroke. Curiously, physicians rarely think of this possibility when the thrombosis does not happen to involve the centers for speech or for arm or leg. Commonly the episode is thought to be due to an "acute indigestion" because it is so often associated with dizziness and a storm running down the vagus nerves to produce vomiting and abdominal discomfort. Sometimes careful history taking will show that there were several of these small episodes. Often they come in the morning when the patient wakes. Especially after several of them there is likely to be some loss of memory, a loss of interest and zest in life, and perhaps an inability to work. Unfortunately, this sudden and marked change in the temperament of the patient is seldom mentioned when the victim and his family are in the physician's office. The story must be dug out. It is important that the physician recognize the true nature of these little upsets because then he will know that it is useless to try to help the patient or to cheer him up. His brain is injured and he cannot be helped.

In younger patients the physician will, of course, check the lungs carefully. Occasionally the main symptom of chronic appendicitis in a previously healthy college student will be a mental slowing up and a feeling of toxicity and loss of "pep." If the physician can then dig out a story of one or more attacks of cramping abdominal pain, appendectomy is indicated. Occasionally a tired youngster will be found to have hypertension or hyperthyroidism. Young women are often worn down by the recurrence of episodes of painful menstruation. They do not recover completely from one spell before they are into another. Other young women are anemic from repeated flooding. The blood must always

*From the Division of Medicine, The Mayo Clinic, Rochester, Minnesota. Read before the meeting of the Minnesota State Medical Association, Rochester, Minnesota, April 22 to 24, 1940.

be examined carefully to rule out a beginning leukemia. Especially if a little fever is noted on some days it will be wise to see if the patient's serum agglutinates *Brucella abortus* in high dilutions.

Often the story will be that the fatigue state followed an influenza, and then in rare cases the physician may think of the possibility that there was a mild encephalitis. More commonly, after a respiratory infection, there will be a mild generalized arthritis or fibrositis; the patient will ache all over, and with this there will be a feeling of fatigue and toxicity. Occasionally the story will be that the patient thought he was poisoned by tainted food, and after the diarrhea stopped he was left with an irritable, gassy bowel and a tendency to diarrhea. In these cases one will suspect that a small intestinal enteritis has not entirely cleared up.

In most cases in which the patient is young or middle-aged, none of these things are found, and then the question arises: Did the patient overwork badly or did he have enough strain, unhappiness, sorrow or insomnia to break down the nervous system of a normal person? One sees this type of breakdown often in the case of a woman who has had several children in rapid succession. Perhaps she has been without a maid, and perhaps a mother-in-law in the home has been adding to her strain. Perhaps she had an operation, an auto accident, a difficult labor, or a bad attack of influenza, and then tried to go back to work too soon. Or the patient may be a shop girl whose hours are too long, or she is a factory girl whose work is too heavy, or the victim may be a hard-driving business man or a too busy physician who has never had a vacation. In all these cases, instead of repeating the examinations indefinitely, it seems to me more logical to make the patient take a rest and then see if there are any symptoms left.

In another large group of cases one will find that the patient was frail and asthenic to begin with, and then had heavier burdens put on him or her than could be borne. In such cases it will be obvious why the patient got into trouble.

Finally, there is a large group of tired patients who, so far as one can find, have not been under any unusual strain. They seem to break down only because the tendency was lying latent in the nervous system, inherited from some ancestor. Often bad psychic habits bring on the crash.

Thus, I remember once asking a fine looking young woman with a lovely home and a nice husband why she was on the edge of a nervous breakdown. I wondered what was wearing her out. Her answer was, "I wear myself out." As I came to know her I found how true this was. She was the type of psychopathic person who can't make a decision even on minor matters, or if at last she makes one she can't stick to it. Her sister was insane, and her tendency to indecision was apparently her share of the family curse.

As I said, many of the persons in this group wear themselves out by using their brains unwisely, uneconomically, and to no useful purpose. In one hour of frantic worrying, or in one riot of emotion over some little happening, or in one "post mortem" over some unpleasant experience or ancient family row, a woman will use up more energy than a calm sensible person uses in a day. Some of these persons are so psychopathic, touchy, shy, diffident, or irritable that all the problems of working and living and adjusting to contact with their fellows are difficult and wearying. Others, and particularly women about the age of forty, are perfectionists: They want everything just so, and they wear themselves out trying to reform husband and to make the home spotlessly clean.

But every so often the physician will find a tired and depressed patient who apparently hasn't many bad mental habits, who hasn't had obvious strain, and who has had no grief or cause for worry. What then? Then if the physician will only take the trouble to get a good history, often from a relative, he is likely to find that one or more of the patient's close relations have suffered with melancholia or depressions of some kind. In many such cases there can be no question that the patient's real difficulty is a mild depression. It represents what he or she got out of the family grab-bag of inheritance. One can be even surer of this when one can get the patient to tell how between periods of depression he or she has been too energetic and talkative and ambitious. Such persons have a cyclic temperament with their ups too high and their downs too low. Fortunately, in most of these cases the defect that sent a mother or an aunt to the insane asylum was diluted by good genes from the other side of the family, and hence such depressions are compatible with the maintenance of a useful life.

It always saddens me to see these persons who have so definitely a psychiatric problem being put through all sorts of medical overhauls and being treated strenuously for amebiasis, low blood pressure, low blood sugar, or low blood calcium, or perhaps being operated on in the hope that some causative lesion will be found in the abdomen. It is unfortunate that we physicians at college had practically no training in psychiatry, and hence we are so unprepared to recognize the insanity of those many persons who remain quiet and well behaved. Worse yet, when consulted by these patients, clinicians will often ignore or ridicule the diagnosis of insanity after it has been made for them. I have seen them keep ignoring it until the patient finally gave up and took refuge in a sanatorium for "mental cases."

The point I would like to emphasize is that when a patient is depressed and apparently exhausted without obvious cause, when two or three overhauls have failed to reveal any organic disease, and when one or more near-relatives have suffered with melancholia, the physician should begin to suspect that the trouble is a mild depression.

Summary

Many patients complain primarily of fatigue and easy tiring. They get put through one thor-

ough examination after another with the hope that some local disease or focus of infection will be found. Usually this isn't found. Naturally one careful examination should be made, especially when ill health comes after middle age to a person who has been previously well. Then one may find serious disease such as cancer, anemia, hypertension, diabetes, hypothyroidism, or a failing heart. If in older persons depression, fatigue, loss of interests, change in personality, and an inability to work come suddenly, the cause is probably a slight stroke. In the case of college students, ill health with indigestion and feelings of fatigue may be due to subacute appendicitis.

In many cases nothing is found on thorough examination. Then the physician must be careful not to grasp at diagnostic straws. Then he must see if the patient has had enough strain, unhappiness, sorrow or insomnia to account for the situation. In many cases, with or without strain, a person with a psychopathic inheritance breaks down. In some cases the patient's fatigue and nervousness represent an equivalent of melancholia in a near relative. It is most unfortunate that mild melancholia is today rarely recognized by clinicians. The average physician today has little ability to recognize the patient with borderline insanity.

POLYNEURITIS WITH FACIAL DIPLEGIA (NEURONITIS) FOLLOWING SERUM SICKNESS IN AN ADULT

GORDON R. KAMMAN, M.D., F.A.C.P. and M. WEISBERG, M.D.

Saint Paul, Minnesota

DESCRPTIONS of the syndrome of polyneuritis with facial diplegia have appeared in medical literature under a variety of names. Different authors have referred to the disease as acute febrile polyneuritis, curable polyradiculoneuritis with albumino-cytologic dissociation, radiculoneuritis, meningoradiculoneuritis, myelodradiculitis, et cetera. Probably the first description of the disease in English was given in 1898 by Mills² who called it "neuronitis." Since then various authors have used this term but among neurologists controversy exists as to the proper name for the syndrome. We prefer the clinical designation of polyneuritis with facial diplegia for the reason that the pathological changes in

the central nervous system are variable, and any nosological designation embodying a description of these changes would not be sufficiently broad to include all cases.

In spite of the confusion in the literature over what this condition should be called, the clinical picture is a fairly constant one. The disease in the majority of cases is preceded by a mild transitory infection which may represent the stage of invasion of the causative agent. There then is a latent period of from one to fourteen days, followed by the appearance of signs of polyneuritis predominantly of the motor type. Some cases show mild sensory changes in the early stages, some have fibrillary twitchings, and in some there

is impairment of vesical or rectal function or both. The weakness and parasthesias usually begin in the lower extremities, involving the muscles of the trunk and upper extremities to a lesser degree in from one to four days. In about one-third of the cases facial paralysis of the nuclear type is present¹ and we have seen choked discs in a few cases.

The most constant feature of polyneuritis with facial diplegia is the albumino-cytologic dissociation in the cerebrospinal fluid. Although we have seen cases in which there were as many as 30 lymphocytes per cubic mm. of cerebrospinal fluid, the cell count in the great majority of cases is within normal limits. There *always* is an increase in the amount of spinal fluid protein. This increase might be slight, ranging around 50 mg. per 100 c.c., or it may be enormous reaching 1200-1500 mg. per 100 c.c. Without this albumino-cytologic dissociation one is not justified in making a diagnosis of polyneuritis with facial diplegia or of neuronitis.

The course of the disease is usually benign and recovery occurs in from six months to two years. Death may occur from respiratory paralysis, intervening sepsis, or general debilitation. In a series of thirty-five cases, Gilpin et al¹ encountered a mortality of 14 per cent. This is somewhat higher than our experience.

The number of pathological studies has been quite limited but Gilpin et al¹ found the pathological changes to be limited to the peripheral nerves and the dorsal root ganglia. The anterior horn cells as well as the rest of the spinal cord is not involved in the process which consists mainly of a patchy degeneration of the myelin with fragmentation of the axis cylinders of the peripheral nerves, without any evidence of inflammation.

The case we are reporting is unusual because the onset was not preceded by the usual type of infection, and the course of the entire illness was only a few weeks.

S. K., an unmarried male, thirty-two years of age, was a grocery clerk. His family history was irrelevant. He had acute rheumatic fever in 1913, a tonsillectomy in 1917, and influenza in 1919. No history of allergy in either the patient or his family could be elicited. Mr. K. was well until June 17, 1939, when at about 3 P. M. he stepped on a nail and sustained a puncture wound of the sole of the right foot. He applied tincture of iodine to the wound and continued to work. A few hours later, he began to have pain in the foot. Several hours later, one of us (M. W.) was consulted and

magnesium sulphate foot baths were prescribed. About thirty-six hours following injury, the patient received 1,500 units of tetanus antitoxin subcutaneously into the left upper arm. The foot improved and the patient returned to work on June 20th. He felt well the next day, June 21, but noticed a few hives over both upper extremities. That evening he had a chill and the next morning complained of aching in all his joints and he felt feverish. He went to work but about 4 P. M. had to stop because of general malaise. The temperature rose to 103 degrees. On June 23 the hives became more generalized and he stayed in bed. Two days later, June 25, he had diarrhea with vomiting, and temperature of 102.6. He remained in bed for four days and gradually improved. On June 29, his feet became numb and the next day both hands were numb but there was no muscular weakness. The numbness ascended to the wrists and knees and on July 1, fifteen days following injury, patient complained of backache. On the morning of July 4, he awoke with pain in back of neck, jaw and face. That afternoon he developed a paralysis of the left side of his face, and was admitted to Bethesda Hospital in Saint Paul.

Upon admission Mr. K. had a left facial paralysis of the peripheral type. The cranial nerves were otherwise normal. There was weakness of both grips and the supinator reflexes were absent. The muscles of the lower extremities showed a flaccid weakness of all groups. Deep reflexes were absent but no pathological reflexes were elicited. Touch, pain, passive motion and vibration sense were diminished in the hands and feet. The laboratory findings were as follows: Hemoglobin 78 per cent, red blood cells 4,070,000, white blood cells 8,400. Differential count normal. Urine normal. C.S.F. was under normal pressure, contained 155 mg. protein per 100 c.c., 7 lymphocytes per cubic mg. The Wassermann reaction was negative and the colloidal gold curve was flat. Temperature remained normal throughout patient's stay in the hospital.

During the first four days in the hospital Mr. K. became worse. The right side of his face became paralyzed and he had a complete facial diplegia. The right triceps jerk disappeared and the muscles around the shoulder girdles became weak. Pilocarpine sweats, potassium iodid by mouth, and daily subcutaneous injections of thiamin chloride were prescribed and in about three weeks definite improvement could be noticed. Sensation and muscle strength improved, the deep reflexes returned to normal and on August 9, 1939, the patient was released from the hospital with only a slight weakness of the left side of the face. On August 30, the examination was negative except for a slight weakness of the left side of the face and Mr. K. was permitted to return to full time work.

Comment

While the association between the serum sickness and the polyneuritis may be wholly fortuitous, it is not unreasonable to suppose that the serum sickness was the precipitating factor in

the disease. The possible rôle played by allergy in this condition has never been determined, but there are those who think that many of the more obscure types of involvement of nervous parenchyme are allergic in nature. In our case we were dealing with a perfectly healthy, robust, young adult male. He had not had a recent infection of any kind. Directly upon the subsidence of an attack of serum sickness which followed the prophylactic administration of tetanus antitoxin, he developed the early symptoms and, subsequently, all of the typical symptoms of polyneuritis with facial diplegia. The only way in which the course of the disease differed from the classical picture was that it was very much shorter.

This patient was injured during the course of his employment and the question of compensation was raised. Because of the close temporal relationship between the serum sickness and the involvement of the nervous system, and because of the absence of any other demonstrable etiological factor in the disease, compensation was

granted. One of our main purposes in reporting this case is to stimulate others to report cases of a similar nature should they occur.

Summary

1. Polyneuritis with facial diplegia (neuroitis) is a well established clinical entity, the etiology of which is obscure.

2. In the majority of cases the symptoms are preceded by a mild transitory infection.

3. A case is presented in which the symptoms appeared following an attack of serum sickness due to the prophylactic administration of tetanus antitoxin.

4. The patient was injured during the course of his employment and was granted workmen's compensation.

1044 Lowry Medical Arts Building.

PRIMARY ADENOCARCINOMA OF THE APPENDIX AND CARCINOID TUMORS

F. C. SCHULDT, M.D., F.A.C.S.
Saint Paul, Minnesota

R. S., aged sixty-four, was seen July 18, 1938, complaining of a sore spot on the right side of the abdomen just above the iliac crest. He had had pain of moderate severity for the preceding three days without nausea. For the last two days he had had no appetite. The pain in the abdomen was increased on deep breathing and coughing.

On May 15, 1937, I had seen him in the office when he consulted me concerning a pain in the right abdomen of two week's duration. At one time the pain was completely relieved after a laxative. On examination at this time there was no tenderness at all over the appendix area, but there was a tenderness above the right iliac crest. White blood cells were 11,000. Three days later the pain was gone and on examination there was no tenderness. I did not see the patient again for fourteen months. There had been no weight loss. No definite diagnosis was made at this time.

On July 18, 1938, his temperature was 99°; urine, normal; heart, normal. There was slight tenderness over McBurney's point and marked tenderness above the crest of the right ilium. White blood cells were 14,250.

A diagnosis of an acute retrocecal appendicitis was made.

On July 19, 1938, under special anesthesia, a right rectus incision was made. As soon as the abdomen was

opened free thin pus was found. The appendix was retrocecal. The head of the cecum and all of the intestines showed a general peritonitis. The appendix was removed in two pieces. The appendix lay wide open in its mid-portion and at this point the tissue of the appendix had a peculiar tumor-like appearance (Fig. 1). The appendix was gangrenous at its distal portion. The abdomen was drained.

Pathologic report: appendix was 10 cm. long; pus exudate in proximal portion. Near the mid-portion was a gelatinous tumor mass. Section showed a suppurative appendix and also an infiltrating epithelial tumor, portions of which had undergone gelatinous change with some differentiation into glandular elements (Fig. 2).

Diagnosis: 1. Adenocarcinoma with gelatinous degeneration. 2. Perforation with suppurative peritonitis.

Suction decompression was necessary, postoperatively. Convalescence was then normal and the patient was quite well.

On April 3, 1939, he complained of general pain in the abdomen after eating a heavy meal. He felt bloated but obtained relief after a satisfactory stool. A hard nodule was found at the upper end of the incision.

By May 8, 1939, he had lost some weight. The nodule in the fascia of the incision was larger and more tender. It was recognized as a possible metastasis and he was advised to have it removed.

At the time of operation the malignancy was recog-

nized while the appendix was *in situ* and the utmost care was used to prevent implantation. No forceps were used to clamp the appendix. But our exhibition consists of a ruptured appendix, a rupture due to a neoplasm. As the abdomen contained considerable free pus the possibilities of carcinoma cells being widespread had to be considered.

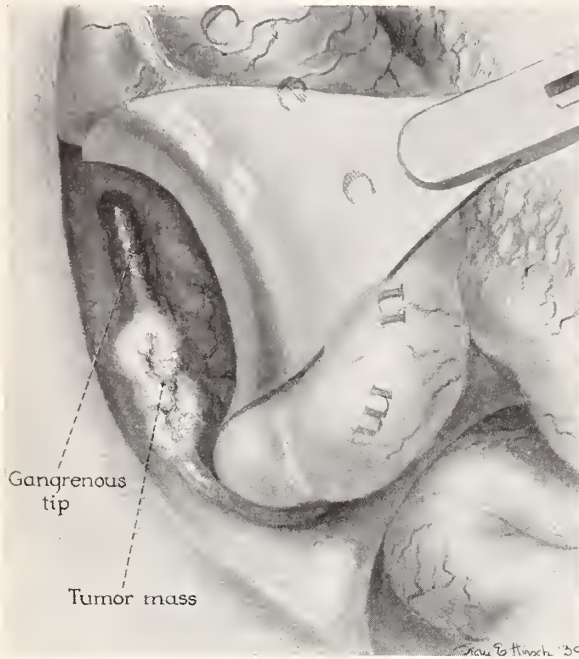

Fig. 1. Drawing showing appearance of appendix at operation.

On June 1, 1939, this nodule, which measured 3.5 cm. in diameter, was excised under local anesthesia. The nodule was not infiltrating and could be lifted while it was being removed from the rectus muscle. On gross section it appeared malignant and on microscopic section proved it to be a gelatinous adenocarcinoma.

Following this ascites required the tapping of three to four litres of a straw-colored fluid every ten to twenty days. The fluid became eventually definitely bloody. There was a steady loss of weight and constant pain throughout the abdomen. No masses could be felt after the fluid was removed, but another nodule formed in the incision.

Discussion

The pre-operative diagnosis in this case of carcinoma of the appendix was acute retrocecal appendicitis. All references in the literature stress the point that there has been no pre-operative diagnosis made of carcinoma of the appendix.³

In our case the carcinomatous involvement had caused a perforation and thereby an acute peritonitis. The malignancy was recognized before the appendix was removed from the abdomen. All of the small intestine and the cecum had a surface injection like that of an acute peritonitis. As the cecum was retracted medianwards the

appendix became visible with its proximal third injected, its middle third nodular and neoplastic and the terminal portion discolored and gangrenous.

Wagh and Findley¹¹ report a case of mucocele of the appendix which had degenerated into a carcinoma and then ruptured with a consequent generalized metastatic process of the whole pelvis. Our case is a parallel to this as here a carcinoma had been growing for some time until it ruptured through the malignant area without producing the classical picture of a ruptured appendix.

In the classification of the neoplastic processes occurring in the appendix the following four forms are to be recognized:

1. Appendicitis fibroplastica, the huge thick walled appendix.
2. Mucocele of the appendix, the occasional result of lumen obliteration, and rarely degenerating into malignancy.
3. Carcinoid tumor of the appendix, called by Aschoff¹⁰ "mucous membrane naevus," rarely showing metastases.
4. Gelatinous adenocarcinoma primary of the appendix; rapidly metastasizing.

The adenocarcinoma is of the gelatinous type and is the most common form found in all malignancies of the colon. The structure shows a scarcity of cells but an abundance of a gelatinous mucus.

It would be interesting to know just what pathologic picture was present fourteen months previous when the patient complained of indefinite pain in this area. At that time his symptoms disappeared upon correcting his constipation. Is it probable that he also had a mucocele following a lumen obliteration which degenerated into a malignancy? We can not prove or disprove this, but on careful examination of the removed specimen there were only solid tumor masses having a glassy appearance (the gelatinous structure).

It is probable that neither a mucocele nor a primary carcinoma nodule causes any pronounced symptoms and consequently no medical advice is sought. A rupture immediately precipitates an acute abdomen. In the carcinoid tumors⁸ the symptoms are those of an interstitial appendicitis of the chronic type.

The first authentic case of primary carcinoma

of the appendix is reported by A. Beger¹ in 1882. In a splendid article he recites the details of his case.

In a forty-seven-year-old man a "boil" appeared on the skin surface in the right inguinal region. This was opened and drained of an odor-

and speaks of it as resembling an amputation neuroma of peripheral nerves. In these cases Hasegawa could demonstrate in serial sections that the argentaffin cells separate themselves from the columnar cells of the Lieberkühn crypts and sink into the deeper parts where they are con-

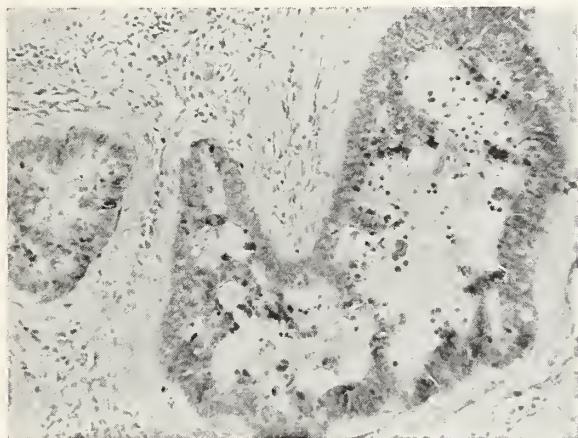

Fig. 2. Microscopic appearance of the gelatinous adenocarcinoma of the appendix.

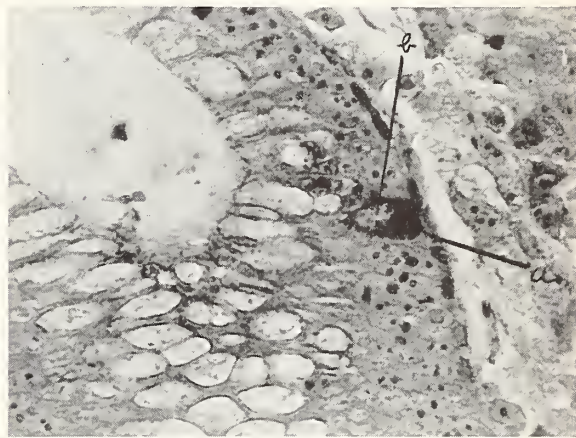

Fig. 3. Base of a Lieberkuhn crypt. (a) Argentaffin cell. (b) Its nucleus.

less pus with no gas or fecal material. Three and one-half years later the patient was operated upon under chloroform anesthesia with salicylic spray used for asepsis. This proved to be a carcinoma of the tip of the appendix, which had grown into the abdominal wall and had burrowed through the fascia and appeared as a raised "boil" on the skin surface. As the drained "boil" had not healed, a biopsy was made and a diagnosis was made of adeno-carcinoma of the bowel and correctly estimated as that of the appendix. This then is the only case on record where carcinoma of the appendix has been diagnosed before operation.

Hasegawa² states that the process of growth of the carcinoid is very slow and thinks most likely in the great majority of cases these tumors begin developing in early youth.

In an elaborate article Hasegawa establishes the relation of the carcinoid tumor to the argentaffin cells of the Lieberkühn crypts, and also demonstrates the metastatic possibility of the carcinoid tumor. He found that in the inflammatory process of the appendix, whether mild or acute, in which obliteration of the lumen takes place there is a process going on of amputation of the sympathetic nerve so that a neuroma of the sympathetic nerve develops,

stantly found surrounding the sympathetic "amputation" neuroma. Scattered throughout these neuromata were found cells resembling ganglion cells but in them could be demonstrated the argentaffin granules.

So silver salts are taken up by the granules of: (1) the few scattered argentaffin cells found normally in between the goblet cells of Lieberkühn crypts; (2) the cells of the carcinoid tumor; and (3) the ganglion-like cells of the amputation neuroma.

Hasegawa developed the following staining technic: Small pieces of tissue of an appendix or of a carcinoid tumor are fixed in formalin, then thoroughly washed in running water. Now the tissue is placed in a 2 per cent solution of silver nitrate and incubated for twenty-four hours at 98.6. After a short period of washing in distilled water it is again placed in an incubator for twenty-four hours immersed in the following ammonium hydrate silver nitrate solution: To 10 c.c. of a 2 per cent solution of silver nitrate are added seven drops of a 10 per cent solution of either sodium or potassium hydrate and the resulting precipitate is dissolved by using dropwise, liquor ammonia. After a running water treatment the tissue is dehydrated, embedded in paraffin, sectioned thin (5 micron)

and mounted. It is to be noted that the outside sections are very black. Then follow the sections of proper impregnation and deeper insufficient silver will be found.

Argentaffin cells⁴ are common in the crypts of Lieberkühn of the duodenum and appendix, infrequent in the jejunum, ileum and colon, and occasionally may be found in the stomach. Rarely are they found among the cells of the villi.

The argentaffin cell adheres closely to the basement membrane, is bottle shaped with the narrow part of the cell to the lumen. These cells may pass down through the limiting membrane of the lamin propria into the connective tissue. They are found singly or in groups and here they may become intimately connected with the nerves of the plexus of Meisner or form the carcinoid tumor.

There is no other special cell in the Lieberkühn crypt called the Paneth cell which is found only at the bottom of the crypt and only in the duodenum, jejunum and ileum. The Paneth cells have spherical nuclei and the cytoplasm at the lumen end has scattered large round secretory granules.

The argentaffin cells also have spherical nuclei, but have a fine compact mass of granules in the cytoplasm at the base. The granules of the Paneth cells respond to the chromaffin stains while the granules of the argentaffin cells respond to the silver stain.

The argentaffin cells make their first appearance in the fourth month of fetal life while the Paneth cells appear in the seventh month. The function of the granules of the argentaffin and the Paneth cells are not definitely known. Some histologists claim the Paneth cells are young goblet cells but if that were so we should also have the Paneth cell in the Lieberkühn crypts of the colon where they are definitely absent.

The interesting physiology of the intestinal glands and villi is that, besides producing digestive juices, there is a massive shedding of epithelium going on all the time. This requires a constant replacement, and the new cells develop in the bottom of the Lieberkühn crypts. So that the feces of a starving patient consist of the intestinal juices, mucus, bile and the desquamated epithelium.

Hasegawa quotes Masson who made this interesting observation: "Characteristically there are two types of cells in the carcinoid tumor,

one having vacuoles containing lipoids resembling the adrenal cortex and the other type having chromaffin granules resembling the cells of the adrenal medulla. With these characteristic likenesses in mind Masson named the growth "endocrine tumors of the appendix."⁴

Huebschman is quoted by Hasegawa in the declaration that the origin of the carcinoid cell is either from the Paneth cell or the argentaffin cell of Schmidt-Ciaccio.

Krompecher, who also is frequently quoted by Hasegawa, draws comparisons between the basal cell of the skin and the occasional cell found among the columnar epithelial cells of the intestinal or Lieberkühn glands as being also basal cells. He calls the tumors forming from these cells "Basaliom."

Scott⁶ records the age range from five to eighty-one years.

Vance⁹ reports that carcinoid has been reported in the literature as becoming malignant nine times.

The incidence of primary carcinoma in all appendices examined is 0.35 per cent, as reported by Selinger.⁷

The incidence of primary malignant tumors of the appendix varies in different large clinics. In large clinics about 1 per cent of carcinomata of the bowel occur in the appendix. Of all primary malignancies of the appendix, 10 per cent are carcinoma and 90 per cent are carcinoid.

In 1936, Rosenblatt and Robertson⁵ reported on 360 cases of primary carcinoma of the appendix. Rosenblatt, et al, report 0.2 to 0.5 per cent of all surgical appendices, as carcinomatous, while less than 0.5 per cent of all intestinal carcinomata are found primary in the appendix.

At St. Joseph's hospital, Saint Paul, from January 1, 1933, to September 1, 1939, the total number of appendices removed and studied were 3,692. Of this total number, our case is the only primary adenoma carcinoma of the appendix (0.027 per cent of all appendices studied). During this period there were eight cases of carcinoids reported or 0.216 per cent of all appendices studied.

Conclusions

1. Primary adenocarcinoma of the appendix is comparatively rare.
2. It is futile to attempt to make a preoperative diagnosis.

CASE REPORTS

3. If a rupture of the appendix occurs, metastases will be present within a year.

4. The similarity and difference between the adenocarcinoma and the carcinoid tumor is emphasized.

5. Other names for carcinoid tumors are: (a) mucous membrane nevus; (b) endocrine tumor of the appendix; (c) basaliom.

6. A case of primary adenocarcinoma is reported.

CASE REPORTS

THE TREATMENT OF MYASTHENIA GRAVIS WITH ORAL PROSTIGMINE* Report of a Case in a Patient with Congenital Hemolytic Jaundice

DAN. L. FINK, M.D., and ARTHUR J. MOSS, M.D.
Minneapolis, Minnesota

THE earliest description of myasthenia gravis was presented by Dr. Willis in 1685.²⁶ He said of "The Palsy" that "... motion fails wholly in part or member, but is performed weakly. . . . There is a scarcity of spirits so that on first arising in the morning they move their arms this way and that . . . but by noon, the store of spirits being spent, they are scarcely able to move." He describes a case in which the tongue was involved so that after talking for a time, the patient became mute for an hour or two. More accurate and precise descriptions of this condition were presented by several German investigators in the latter part of the 19th century, and by Wilks in England in 1877.²⁵

Since that time many have studied the etiology of myasthenia gravis. As a result, numerous theories have been propounded, placing the primary disturbance in the endocrine system, the nerves or the muscles.¹² Metabolic disturbances and chemical imbalance have been considered of significance.¹ The fact that thymomas are frequently found in cases of myasthenia gravis has led some investigators to believe that the underlying cause is of a neoplastic nature.¹⁰

The present status of the etiology is best presented by Pritchard, who found the nerve and muscle to be physiologically normal, but found that electrical stimulation of a nerve in myasthenia gravis gave a characteristic curve placing the defect at the myoneural junction.¹⁶ He believes, together with many others, that acetylcholine plays an important rôle in the transmission of impulses across the myoneural junction. In myasthenia gravis, it is believed this chemical is diminished

by the overactivity of the choline-esterase present in the blood.^{6,15,16} Even this theory has been refuted by recent experimental work in Germany.⁹

Correspondingly, extracts of the ovaries, hypophysis and tuber cinereum have been used in the treatment of myasthenia gravis, but without success. Strychnine, adrenalin and parathormone have been tried; some have used calcium, presuming the mineral metabolism to be at fault.¹² Extirpation of thymic tumors has also been advocated as a therapeutic measure.¹⁰ Ephedrine^{7,14} was used with supposedly good results in some instances and more recently glycocholl has been advocated.³ All these substances failed to control the disease to any great extent and reportedly good results in many instances were apparently due to spontaneous remissions of the condition.

In 1934, Walker presented her method of therapy.²⁴ In a letter to the editor of the *Lancet* she said that because myasthenia gravis had been thought to be due to a curare-like poisoning of the myoneural junction, she thought it would be well to try the effect of physostigmine, a partial antagonist of curare, in the treatment of the disease. Her attempt in a single case of myasthenia gravis gave gratifying results. Later, she reported on the successful use of prostigmine, a similar, though less toxic, drug.^{13,23} The co-relationship of curare and prostigmine in myasthenia gravis was later demonstrated.⁴

The use of prostigmine by mouth was introduced in 1935 by Everts, who found that in addition to being more readily administered, its effect was more prolonged and with fewer untoward reactions.⁸ Several investigators have felt that the use of prostigmine was

*From the University of Minnesota and Minneapolis General Hospital.

dangerous because of its toxic effects, and have advised against its oral administration until more is known of its fate in the gastro-intestinal tract.^{2,31} However, the men who have used it the most, notably Viets and Schwab and their co-workers, feel that in myasthenia gravis the toxic effects are not a serious hazard.^{19,20,21,22}

The drug to be administered by mouth is supplied in 15 mg. tablets and the dosage must be individualized to get the best therapeutic effect without injurious side effects.^{6,18,22} Its action is apparently enhanced by the addition of ephedrine as was recently shown by Viets and Schwab in a study of forty-four cases, in 41 of which ephedrine increased the effect of the prostigmine.²² Schafer used benzedrine as an adjunct.¹⁷

In the past twenty years the diagnosis of myasthenia gravis had been made but three times at the Minneapolis General Hospital. The first case was that of a patient who apparently had a spontaneous remission after symptomatic treatment only and has not been heard from since (thirteen years). The second patient expired before therapy could be instituted. The case presented here is the first to be treated with prostigmine at the Minneapolis General Hospital.

Case Report

Mrs. C. H., a thirty-four-year-old white woman, was admitted to the hospital on August 31, 1939, giving a history of progressive generalized weakness for three to four months and cough and fever for three days. For the preceding three months she had become progressively weaker. She seemed quite rested and was able to do her housework in the morning, but by evening she was "all tired out"; after walking a block she became so exhausted she had to stop and rest; after eating part of her meal, she had to use her hand to assist her jaw; and ptosis of her upper lids had become pronounced. For three days prior to admission, the patient had had fever with increasingly severe dyspnea, dysphagia, ptosis and cough, with inability to raise sputum.

Review of her past health revealed that the patient had congenital hemolytic jaundice, confirmed by laboratory studies; and that in January, 1938, after a severe, acute exacerbation of the jaundice, her spleen had been removed. She was seen in the Minneapolis General Hospital on two other occasions with findings of acute cholecystitis and cholelithiasis, but no mention of symptoms of myasthenia gravis was made until March, 1939, when it was noted only that "patient says she becomes very weak at the end of the day." In retrospect, the patient claimed to have had diplopia as early as November, 1938.

Physical examination revealed a critically ill patient almost moribund, very cyanotic and dyspneic with marked ptosis of both lids, dysphagia and dysarthria. Blood pressure was 120/70. A diagnosis of myasthenia gravis was made and at 2:40 A. M. 3 c.c. of 1:2000 solution of prostigmine methyl sulfate (1.5 mg.) and atrophine sulfate (gr. 1/150) was given intramuscularly. By 2:50 A. M. all the symptoms objectively and subjectively had either disappeared or had remarkably improved. She was able to cough and expectorate, to speak distinctly, to eat and drink, and her respirations became easier with disappearance of the cyanosis. The patient stated that she had not felt so strong for weeks.

Her temperature was 102° and there was evidence of consolidation in both lower lobes on physical examination and on x-ray study of the chest. No thymic enlargement could be demonstrated. Sulfapyridine therapy was started, the patient getting 4 gm. daily for five

days; and she was placed in an oxygen tent for twenty-four hours. By the seventh day her temperature was normal and remained so.

The effects of the prostigmine lasted until 8:00 A. M., at which time the symptoms had recurred and the same dose was repeated with the same startling results. She was then started on prostigmine bromide by mouth augmented with ephedrine hydrochloride. The dosage was 15 mg. every 2 hours from 8:30 A. M. to 10:30 P. M. with ephedrine hydrochloride gr. $\frac{3}{8}$ given at 7:30 A. M., 10:30 A. M., 4:30 P. M. and 8:30 P. M.

For the next few days it was necessary to augment the oral medication with the intramuscular drug on several occasions. By September 6, 1939, the signs and symptoms had almost entirely disappeared and the patient was up and about the ward. The dosage was then gradually reduced so that by September 21, 1939, she was taking but 30 mg. of prostigmine bromide daily together with four doses of ephedrine hydrochloride. However, on the dosage the patient developed diplopia, dysarthria and dysphagia; while on 3 tablets daily these symptoms disappeared again.

Laboratory studies revealed a normal urine, a hemoglobin level of 78 per cent, and white blood count of 37,500. Blood calcium was 11.5 mg. and phosphorus was 4.6 mg. Plasma chlorides were 276 mg. per 100 c.c. The blood Wassermann test was negative; the icterus index was 12. The average red blood cell diameter was 7.2 micra, and increased fragility of the red blood cells could be demonstrated. Urine chlorides were 2.04 gm./100 c.c. Sputum on admission revealed type 28 pneumococcus. Basal metabolic rate, electrocardiogram and spinal fluid were all normal.

The patient was discharged on September 23, 1939, asymptomatic, taking 15 mg. of prostigmine bromide at 10:30 A. M., 4:30 and 8:30 P. M. together with 1 capsule of ephedrine hydrochloride (gr. $\frac{3}{8}$) each time. Since then she has been followed in the Out-Patient Department and when last seen, three months after admission, she had gained fifteen pounds in weight and was free from symptoms. On our suggestion she discontinued the drug on one occasion with prompt recurrence of the syndrome.

Conclusions

A case of myasthenia gravis is reported in which prostigmine bromide by mouth combined with ephedrine hydrochloride is being used effectively.

The case is further of interest because of the history of congenital hemolytic jaundice and splenectomy. The congenital hemolytic jaundice preceded the myasthenia gravis.

HISTAMINASE IN THE TREATMENT OF URTICARIA OF PREGNANCY

J. S. BLUMENTHAL, M.D.

Minneapolis, Minnesota

THE use of histaminase in the treatment and prevention of allergic signs and symptoms has received a great deal of attention recently. The theory is that the release of histamine in the tissues is the immediate cause of the phenomena of allergy. The result of treatment as well as the theoretical basis for it has been reported with varying results in the literature. Best¹ showed that lung and other tissues when suspended in saline solution and incubated in the presence of toluene at 37 C caused the disappearance of natural or added histamine. Best and McHenry² also noted that there appeared to be a marked relation between histamine shock and anaphylactic shock. The substance which produced the disappearance of histamine is thermolabile and in 1930, Best and McHenry³ suggested the name histaminase. They stated, however, "Since it has not been established that histamine is the causative agent in any pathological condition there would be no obvious clinical application of histaminase, even if it should be established that the ability of an organism to inactivate histamine can be increased by administration of the enzyme." Laymon and Cummings⁴ in a recent publication of a presentation before the Society for Investigative Dermatology came to the conclusion that histaminase is apparently of value in some cases of allergy, though they could not attest to any specificity. Dr. C. W. Laymon, in a personal communication, states that he is himself convinced that histaminase is very useful in many cases of urticaria where other methods have failed. Miller and Piness,⁵ on the other hand, in a later publication, came to the conclusion after treating forty-two allergic patients including twenty-eight with urticaria, that histaminase failed to give unequivocal evidence that this enzyme was responsible for the relief or prevention of any signs or symptoms of which the patients complained.

Karady and Browne⁴ in 1939, however, recorded a successful attempt to neutralize the action of histamine in the guinea pig by using histaminase (Winthrop).

In the case presented here, the histaminase used was that manufactured by the Winthrop Chemical Company and called by them "Torantil." The product is dispensed in tablets and is said to be derived from hog's kidney, the unit of activity being "the amount which will inactivate one mg. of histamine hydrochloride during incubation at 37.5 C. for twenty-four hours." These tablets containing five units each are to be administered before meals and with one glass of water. The usual dose recommended is from five to ten units three to four times daily.

The patient presented here is a white woman, thirty-one years old, whose last menstrual period was July 26, 1939, and who therefore was due to deliver about May 2, 1940. She is a primipara, 5 feet 4 inches in height and her usual weight has been 112 pounds. She gave no history of any previous skin abnormality. She has a history of a mild degree of hyperthyroidism which had been treated by x-ray with apparently good results so that she has no symptoms referable to her goiter at present. Her basal metabolism has been normal for several years. She had taken iodine occasionally because she said it made her feel better and she had continued to take a few drops of Lugol's solution at times, throughout her pregnancy. There is no past history of allergy of any type and she had never had any skin lesions. Her family history is negative except for a history of a twin pregnancy by her mother's sister.

The patient's physical condition when first seen was good and that of a normal pregnancy although the possibility of twins was suggested due to the large size of the uterus. Her weight was 133 pounds, blood pressure was 120/80, her pulse rate 90, fetal heart rate 140. Urine was normal. Hgb. 90, r.b.c. 4,200,000, w.b.c. 7,000, Wassermann negative. Measurements were normal.

The pregnancy was uneventful in all respects until February 17, 1940, when a small area of redness developed about the vulva with a very annoying itch. The itching increased very rapidly and the urticaria spread until it covered the whole body. Elimination diets, stopping of iodine, starch baths, ultraviolet ray, anti pruritics of any and all kinds and intravenous sodium thiosulphate were tried and to no avail. Sedatives, in-

HISTORY OF MEDICINE IN MINNESOTA

DISEASES OF THE DAKOTA INDIANS*

By THOMAS S. WILLIAMSON, M.D.

(Continued from the October issue.)

During those years I saw several cases of croup, one of which proved fatal; but I do not remember to have seen a well marked case of it among Indians since. Influenza was endemic every winter, generally beginning very soon after those who had been away hunting and living on animal food returned and began to mingle with those who remained in the neighborhood and subsisted almost entirely on corn and potatoes. As there was always much feasting at such times, I at first attributed it entirely to over eating, and still think this may have had something of a causative nature, but those who made no change in their diet at such times did not escape. I observed that all persons connected with the mission, i.e., white persons from the States, were exempt from this influenza the first winter and generally had it lighter than others the second; after which they suffered about the same as the others. I am not aware that the disease ever proved directly fatal there, but it induced other diseases that did.

Except from this influenza, which seldom prevailed for more than a month at a time, the Indians, notwithstanding their scant clothing, suffered much less from what are usually called colds than white people, and this I think was owing to their scant diet.

Almost every year of my residence in Minnesota I have seen several cases of paludal disease, but during the first ten years of my residence at Lac qui Parle I saw only one such in that region which proved fatal. This, like most of the others, had its origin in the swamps of the lower Minnesota and Mississippi. Little Crow, afterwards so infamous, visited Lac qui Parle in the spring and took with him on his return to the village below Saint Paul (i.e., where it now stands) a young woman who returned to her parents during the summer and soon after was taken down with remittant fever. I was called to see her and had no doubts as to my ability to administer such medicine as would, with the blessing of God, remove the disease—but I could not conscientiously do this while the conjurers were pow wowing over her; and a young man to whom her younger sister had been given as a fee for doing this refused to give way to me—so she died, as I expected she would under such treatment.

The summers of 1845 and 1846 were warmer than any for a long time previous, in Minnesota, and hence there was a great increase in such diseases as are caused by decaying vegetable matter. During the autumn of 1845 many of the children suffered from cholera infantum, dysentery and fever; and during the following winter several aged persons died of intermittent fever; these I suppose might have recovered under proper treatment, but I had little quinine and it was impossible to get more; they also lacked animal food and good nursing, as their friends were, most of them, absent on their fall hunt.

In the autumn of 1846 there was more sickness and more deaths from the same cause, but how many I cannot say as I saw but a small part of the sick; for during this same autumn at the request of the Indians of Little Crow's village and

their agent I removed from Lac qui Parle to their village, a few miles below Saint Pauls. I have been thus particular as to the Indians at Lac qui Parle, for two reasons: first, notwithstanding the great lapse of time I have a much clearer remembrance of their condition, sicknesses and deaths, than at a later period; second, I had an opportunity of studying them at that time in their primitive condition, living without bread, pork or salt, such as has occurred to few physicians, and is not likely ever to occur again.

Notwithstanding the prevalence of scrofula and much suffering from want of food and clothing, if it had not been for violent deaths they would have increased in numbers nearly as fast as our own white population. I saw at times many of the Indians of the plains who subsisted at most times entirely on buffalo meat, they generally appeared real healthy with the exception of sore eyes. Scrofula is certainly less prevalent among them than among such as subsist almost exclusively on vegetable food, and until the buffalo began to fail they were increasing rapidly, in spite of the occasional ravages of small pox and measles.

I will here mention some of the causes of phthisis among the Dakotas; I have already mentioned scrofula, and alluded to the principal cause of that, hence it is not necessary to say more about that disease. Next is over exertion in order to obtain a subsistence. It has been often said and most people believe that the Indians lead a very easy, lazy life; but this is far from true. From the time I came to Minnesota until twenty-one years ago the Indians of this State depended for a subsistence chiefly on hunting; though most of them raised some corn, which, at certain seasons of the year, was the principal, and sometimes the only, food. Hunting may be very pleasant to those men who engage in it only for recreation, but it is hard and unpleasant as work. Near Lac qui Parle there were few or no deer and the principal animal food was wild fowl, which were obtained chiefly in the fall and spring when the water was little above the freezing point, and the hunter after walking from one to twenty miles to a sheet of water where ducks were plenty waded in among the tall grass and stood in water often knee- and sometimes waist-deep for hours to get a fair chance at a good flock. His ammunition cost him so much he could not afford to shoot at fowls on the wing or at long range, for each charge of his gun cost him at least as much as the amount for which one duck would sell. If he were so fortunate as to shoot his game without wading, still in most cases in order to get it he must wade into deep water and sometimes swim; and when it was secured he frequently had to carry it ten or fifteen miles over a bleak prairie, with all his clothes, except his blanket, wet, and often stiff with frost. A few deer were killed during the summer within ten to twenty miles of the villages on the Mississippi and lower Minnesota, but each of them usually cost many days' walking through thickets. The principal deer hunt was in autumn and early winter, when from fifty to one hundred families went together, for smaller parties would be cut off by their enemies. In such expeditions, besides their clothing, bedding, wooden dishes, each woman's work-bag, and children unable to walk, it was necessary to carry for each family a skin tent weighing from forty to one hundred pounds, an iron kettle for boiling their food, an ax, a hoe for leveling the ground where the tent is to stand, and some food, as not unfrequently no game was killed for a day or two. The country to be hunted over and the place for the next encampment having been determined on the night before, as soon as it is light hunters start, each carrying his gun, ammunition, apparatus for making fire, knife and a small hatchet. The mistress of the family packs and binds in bundles the tent and its contents assigning to each member of the family his portion of what is to be carried, taking

the heaviest burden herself, unless the family owns a horse, in which case that takes the largest share, and she the next, each still carrying something. Many families had no horse and in those the burden of each woman in middle life did not average less than 100 pounds, and sometimes much more; this was usually carried from four to ten miles a day, averaging about six. Sometimes when a wide prairie without a camping place was reached, or a scare from enemies occurred, their loads were carried from twenty to thirty miles in a day and part of the night, and this through woods or the long grass of the prairies.

You will not think it strange that such taxing of the muscles and nerves should bring on phthisis, sometimes by mere exhaustion, but oftener by causing hemorrhage from the lungs.

It was supposed and said by persons casually passing through the Indian country that the men had a much easier time than the women, and it is true that, as is the case among civilized people who labor for subsistence, the men had more time to rest than their wives, that is, were oftener idle. In hunting, however, the toil of the men was more exhausting than that of the women. The deer hunter was often unsuccessful after having run forty or fifty miles without a road or having tasted food, while if successful in killing a deer it was generally after chasing it many long miles; and, being obliged to bring in the whole carcass, his load was frequently much heavier and he had farther to carry it than any of the women.

Cases of hemoptysis were more frequent among men and more of them died from diseased lungs than the women. The life of those who subsist on buffalo was very different as they had many horses, but among them, too, the young men often suffered severely, first in finding the buffalo, and next in killing them. As their clothing is made almost entirely of buffalo skin, which is too stiff to allow of free motion of the parts it covers, they were accustomed to chase the buffalo on horseback, even in the coldest weather of winter, with their arms and all the body above the belt entirely naked. These dwellers on the prairie when near buffalo were generally fine and healthy, but when they could find none of these animals suffered even more from starvation than the other Dakotas. This suffering from lack of sufficient food is another cause of phthisis.

Having assigned the causes of the prevalence of this disease among the Indians, I might here close my already long communication, but will mention some other facts which will be interesting to you.

As above mentioned, I moved to Kaposia, an Indian village six miles by the river below Saint Pauls, in the autumn of 1846. During the winter I was called to see several genuine cases of ague, and a much larger number of abnormal cases of paludal disease; and here I will state that this disease which used to be called bilious fever is much less regular in form in Minnesota than it was in Ohio when I practiced there. Usually there is much less of what is called fever, that is of heat and arterial action and often the chill or sweating stage is scarcely perceptible; so that, though readily recognizable by persons familiar with it, even regular physicians who know it merely from description in books are very liable to mistake it for some other disease. Since I have ceased to practice medicine I have seen several instances of this, two of which proved fatal, as appeared to me, in consequence of this mistake. The summer of 1847 also was unusually warm and cases of paludal disease were numerous, both among whites and Indians in the country near Fort Snelling. The Dakotas suffered most because, like our British ancestors, for security against their enemies they had made their villages in the midst of swamps, and also because they lacked food. Government usually

gave them their flour and pork in the month of June, but that year it was withheld for a month or two, and many of them died in consequence. In health they could have subsisted on roots, chiefly of sagittaria, obtained from swamps, and on wild ducks, pigeons and fish. But the stomach of the sick rejected fish and pigeons; and it often happened that when a man, after wading in swamps for hours, returned with ducks, or a woman with roots, he or she would fall down in a chill. The food brought home was speedily prepared, but the bringer, in a chill or fever, could take no portion of it then, and before the fever was gone and appetite had returned some hungry child had eaten all the food.

I suppose a majority of the Indians were more or less affected with the disease, and about one in thirty died of it. Many more would have died but for food given them by their white neighbors, and probably four-fifths of those that died might have been saved by proper food and medicine. Subsequent summers were cooler, more healthy sites were selected for some of the villages the next year, and there was less of the disease, and subsequently but little.

Some years later these lower Sioux, as they were called, suffered severely from whooping cough in the spring and early summer. To the children who were brought to me soon after the attack, I gave small doses of tartar emetic for the first two weeks, keeping their stomachs a little irritable so that when the cough came on severely they would vomit a little. Later in the disease when they became feverish or the stomach so irritable as to reject necessary food, I gave laxatives, and of those thus treated I think not one died. At other villages the mortality was considerable. I was taken to see the sick after more than twenty had died, out of a population of about 400. On examining the little sufferers it was manifest they were perishing for lack of nutriment; and on inquiry I found that the whole village had for some time been subsisting solely on fish, and whenever a paroxysm of coughing came on they vomited what had been eaten. Medicine could do but little for them, so I told the chief to call together his principal men, told them all to look at the sick children and gave them a severe scolding for letting the children starve. When they pleaded poverty as an excuse I told them to send all the young men immediately to hunt deer, and for the older ones to go to their traders and get corn, flour and sugar for the children. They did as I directed and very few died afterwards.

Similar treatment was less successful when the disease prevailed in winter, because it was impossible to keep the patient comfortably warm.

DAKOTA MEDICINE*

By REV. THOMAS S. WILLIAMSON

AMONG the Dakotas, as among other heathen races, the offices of physician and priest were, for the most part, united in the same person. This being the case, it is not strange that their pathology should be shaped by their ideas of the spiritual world. Supposing every object, artificial as well as natural, to be the habitation of a spirit capable of hurting or helping them, and that all diseases were caused by some one or more of these spirits taking possession of a part or the whole of the body of the patient, to determine the name and nature of the spirit causing the trouble was regarded as the first business of the physician or *con-*

*From "Tah-Koo Wah-Kan; or The Gospel Among the Dakotas," by Stephen R. Riggs, 1869, p. 435.

jurer, as we usually call the medicine man of the aborigines of our country. This he attempted, not only by observing the symptoms, but by incantations addressed to the spirit or spirits which were the special objects of his worship, and expected on that account to befriend him.

The second business of the medicine man was to drive out the intruding spirit. This was attempted by all kinds of horrid noises and gestures, not omitting to call upon his god or gods for assistance. He also, in most cases, applied his mouth to the skin of the patient near the diseased part, and, after sucking for some time with all his might, would put his mouth in water kept in a vessel usually made of bark for that purpose, and blow into the water the phlegm, mucus, or blood, which he pretended to have drawn from the seat of the disease through the skin; but in most cases they doubtless came from his own mouth or throat. In many cases he would also introduce through his mouth into the water a small pebble or shell, which he would show as evidence that he had extracted the offending cause of the disease through the skin. As in this work, by shrieking, screaming, groaning, shaking his rattle, stamping and other threatening motions, the conjurer exerted all his strength, it was customary, even in cold weather, to divest himself of all clothing except his breechcloth, moccasins, and leggins; and the latter, instead of being bound about his legs, hung trailing from his ankles.

When medicines are administered, their efficacy is attributed to the god or spirit residing in the plant, rather than to any mechanical, chemical, or other power inherent in the medicine itself.

The number of practitioners is large, in some villages not less than one man in ten and one woman in thirty. Among them are to be found some of the shrewdest, strongest intellects, and a very large proportion of those who are only one step above idiots. A proper idiot I have never met among Indians, probably because such are left to perish in infancy; but the proportion of those who make an approach to idiocy is much greater among savages than among civilized people; and a large part of these are applied to in cases of sickness. Many of the conjurers are known as such by that peculiar cast of countenance which belongs to the spiritist of civilized nations; others have countenances strongly indicative of cunning and deceit. I have met two or three men among them of good, plain, common sense, and open, honest countenances. The most eminent of these, when on a certain occasion he came to me for medicine for a disease brought on by over exertion and exposure in the practice of their orgies, on being charged with deceiving his people, acknowledged the charge, and excused himself on the ground of his poverty and his need of the promised reward, and the number and urgency of those who applied to him to show them by his incantations how and when they might find and destroy their enemies.

There are a few individuals who give medicines without conjuring or invoking the aid of spirits. I have known one such who attained a deservedly high reputation among his own people and was sometimes called to practice among the whites. With intellectual and perceptive faculties strongly developed, and such knowledge of the powers of roots as is attainable among his people, naturally polite, and very observant of all those little things which contribute to the comfort of a patient, I have often thought he might have acquired fame and money among civilized men, if he had not justly preferred to live among his own people and do what he could for them.

The medicines used by the Dakotas were mostly roots, and their name for a physician, Pay-zhe-hoo-ta-we-chashta, Herb-root-man. They, however, used not only other parts of plants, but sometimes animal and mineral substances. In

general their medicines were all secret, the knowledge of them concealed as far as possible from each other, except in cases where large fees were paid by such as were not likely to become rivals in the same community, or where an individual not expecting to practice his profession much longer, owing to age or infirmity, might communicate to some descendant or other near relative the knowledge which he possessed. This disposition to conceal their knowledge, so prevalent among quacks, not less than the want of books, prevented the transmission and accumulation of knowledge; so that if any important discoveries were made, they were liable to perish with the discoverer.

With such false pathology and such hindrances to the transmission of knowledge, we could not expect that the sick would be much benefited by the medicine men. So far as I have had an opportunity of observing their practice in cases of fever and some other diseases, with very few exceptions, they did more harm than good. But I know of no way of accounting for the high value set on their services without supposing that, in many cases, they gave relief. My observation inclines me to think that this occurs especially in wounds and pains from local inflammation more frequently than we should expect from what has been said above.

The perceptive faculties among the Dakotas are far more acute than among civilized men. The successful medicine man, like the successful warrior, attains to the highest honor, and is more sure of getting property largely, than either the warrior or hunter; and thus his faculties are stimulated to the highest degree of activity; and having usually only one patient at a time he can observe more closely the effect of the medicine he uses. Some of this class are excellent nurses of the sick, and most attentive to all those thousand little things so conducive to the comfort of their patients. The family is removed from the tent, or the patient and tent from them; and the ground which constitutes the floor of the tent is carpeted, in summer, with ferns or other soft herbage, and scented with aromatic herbs, and, in seasons of the year when these cannot be obtained, with the best substitutes for them accessible. Some of the medicine men watch their patients very thoroughly, and to prevent noise exclude children, and in many cases women too, unless the nearest relatives.

They practice blood-letting, which with them is an operation generally performed with a sharp flint which serves very well for scarifying. When a vein is to be cut, the flint is made fast in a stick, which serves as a handle, and, like a fleam used in bleeding horses, it is driven in with a stroke. As this is a difficult operation, few attempt it; but local blood-letting is very common, the operator usually drawing the blood directly into his own mouth. Some, however, use a horn, or a part of one, applying the large end to the surface whence the blood is to be drawn, and taking the smaller end, which is perforated, into the mouth.

They attribute many of their diseases to bile, or "yellow water," as they call it, and for its removal use emetics, purgatives, and clysters. Most of them, however, freely acknowledge that none of the native remedies for certainty and safety equals those used for purging and puking by civilized men, since to secure vomiting the Dakota doctor is commonly obliged to tickle the throat with a feather.

For purging, the Dakotas who lived near the Mississippi, in common with their eastern neighbors, the Ojibwas, relied chiefly on the root of a tall and very handsome species of euphorbium which abounds on the prairies between Saint Paul and Red Wing. Coarsely powdered it is administered in small quantities, and it operates quickly and often severely. They say it is safe if used dry and the patient abstains entirely from drink until the operation is over, but very dangerous

if the patient drinks freely soon after taking it. The Ojibwa chief, Firm Earth, the predecessor and older brother of the first Hole-in-the-Day, who died near Fort Snelling in 1843, was said by his companions to have come to his end by drinking freely after taking a dose of this root. He died in a few minutes after walking about, and apparently from the effects of acrid poison. The plant is not found on the Upper Minnesota or farther west, and consequently I have had but few opportunities of witnessing its effects. The Indians who have not access to it, use various other plants, none of which appears to have much efficacy. The same may be said of those used as diuretics.

To promote appetite, especially after fevers, they used cranberries, preferring for this purpose the fruit of the tree cranberry, and sometimes substituted bitter aromatic roots.

Sweating in a small tent, over heated stones, was a frequent and perhaps their most efficacious remedy for the removal of disease. It was resorted to not only in cases of pain and sickness, but as an antidote or purifier by those who had killed any person, or otherwise contracted ceremonial uncleanness. The process is described elsewhere.

Contrary to what might be expected, many of them use anesthetics. I have frequently heard of persons reviving after being apparently dead, and seen several such who appeared very much as is common with those who are recovering from the effects of an excessive dose of opium, who nevertheless, I have good reason to believe, had not taken it. In consequence of the conjurers interfering with some of my own patients, I had an opportunity of observing one or two in the state of anesthesia. It is caused by making the person inhale the fumes of calamus roots, and some other substances, burnt on coals. Whether the effect is produced by the calamus or some of the other ingredients, or by the combination, I am unable to say. This state is sometimes produced for the purpose of allaying that extreme restlessness which attends some diseases, but chiefly, I suppose, that the practitioner may have the credit of restoring a dead person to life.

The Dakotas were far more successful in the practice of surgery than medicine. Their constant practice in cutting up animals slain in the chase, made many of them well acquainted with comparative anatomy. Yet their ignorance about the circulation of the blood caused them to lose patients, who might have been saved by a judicious use of bandages, or the entire removal of them. They use tents to keep open deep wounds or abscesses, and prepare good ones for the purpose from the inner bark of the slippery elm. They sometimes apply wet dressings to wounds or sores, and cover them with green leaves, either fresh or boiled; but not possessing the materials for making poultices, plasters, or cerates, they generally endeavor to dry up and scab over wounds and running sores. Sometimes they cover the raw surface with a paste made by chewing certain roots, bark, or leaves. At other times the medicine is reduced to a powder and dusted over the sore. A variety of substances are used for this purpose, among which none is more highly esteemed than the root of the *Asclepias tuberosa*, a species of milk-weed. This is also sometimes given internally.

To reduce swellings, especially those arising from sprains or bruises, they apply various stimulating vegetables, including tobacco. Among these they most value what they call *blue root*, a species of pyrethrum very common in the prairies of Minnesota and Dakota.

A few of them are skilful in the treatment of burns, but this is not generally the case. Commonly they apply oil or grease of some kind, when it is to be ob-

tained, and carefully conceal the knowledge of the other remedies they use. I once saw an excellent effect produced on a very extensive and severe burn, by covering the entire raw surface with the inner bark of the yellow, or, as it is called in Minnesota, the Norway pine. The bark had been shaved thin and made soft by beating it, and the inner mucilaginous surface applied, which allayed the pain and inflammation. I do not think any of the medicines of the shops could have a better effect.

When suffering from disease they will, with few exceptions, gladly avail themselves of the services and medicines of regularly educated physicians, and the conjurers not less willingly than others; although they endeavor to prevent others from doing so, claiming that their medicines are superior to the white man's.

FREE MEDICAL CARE

The man in the street may not understand how political medicine would lower the quality of medical care he receives but he certainly can understand taxes. And when he is told that the cost of such a program would amount to between 10 per cent and 15 per cent of the national payroll he can begin to see the joker in back of this promise of "free medical care."

During a recent session of the New York State Legislature, two bills were introduced which give us an idea of what we may expect if our busy propagandists succeed in foisting this scheme upon an American public deceived by false promises and unacquainted with the true facts.

These bills were alike in all essential details; both bills would have vested the control of medicine in a group composed predominately of laymen and entirely under political control. The medical representation provided would have been such a small minority as to have negligible power and although the bills provided for a professional advisory board, such a board would have had purely advisory powers with absolutely no authority to enforce its recommendations.

Of course nothing in this world is free and in the case of compulsory health insurance, the staggering bill would have to be met by the very people whom the bill is supposed to help. Although workers earning less than \$20 a week were promised complete medical care for only \$10 a year, the resulting deficit would have been made up by taxes on workers earning not much more. For example, salaries between \$20 and \$40 a week would be taxed up to \$41 a year; between \$40 and \$60, up to \$92 a year.

Even this would not be an intolerable load if it represented the entire cost, but the bills provided for a heavy tax upon the employers, which tax would of course have to be passed on to the workingmen either in the form of lower salary or in the form of higher prices for the commodities they manufactured, and then the deficit still remaining would be made up by general taxation, either direct or indirect, and everyone who is capable of any thinking at all understands that all taxes are ultimately paid by the man who works for a living.

President's Letter

OUR GREAT TASK

THE American method of practicing medicine has developed the greatest advances in medical science and knowledge and has brought these to a larger proportion of the entire country's population than ever before in history. Never before has the whole population of any country received such efficient medical care as this country now enjoys. All the recent discoveries, inventions, and new developments that can aid medical care are being utilized; in addition to this, continuous experiments are being conducted in the endeavor to discover better methods of fighting disease.

During the past quarter of a century changes in every phase of life and knowledge have taken place; these changes have been slow enough to be regarded as an evolution and people have been able to accustom themselves to the new conditions without too great difficulty. But with these changes new ideas have been disseminated which are revolutionary in character and which if put into effect would completely change the manner of living of entire groups of our population. Experimenters, dreamers, and radicals, each with his peculiar ideals and theories, offer their ideas in alluring and enticing style and each would revolutionize the world. Among these theories Compulsory Health Insurance under government control, or Socialized Medicine, as it is often called, has been presented, in the rosiest and most attractive manner possible by large and powerful groups. Those who advocate it are either misinformed, ignorant, or actuated by selfish and ulterior motives. They would tear down and utterly destroy our established American system of medical practice and substitute for it the European system.

Should such a change be accomplished, not only will progress in medical science and knowledge be greatly retarded, not only will the initiative and ambition of the physician to advance in skill and knowledge be removed, but the status of the physician will be greatly lowered, his work reduced to drudgery, and his chosen profession will offer him but a bare living. Worse than that his opportunity to be of the greatest service to his patients will be curtailed. All of these things have been said before; but they are so vital to the public welfare that they must be repeated.

Since time immemorial we have been taught that the physician should not enter into the field of politics, that medicine and politics cannot mix, that the bickerings of political life will ruin the practice and usefulness of any doctor, however learned and clever. But times and conditions have changed. One need but consider the proposed bills introduced into our various legislatures and in Congress, or read the speeches and addresses of men high in legislative and executive positions in our national government to realize that this threat is serious and imminent. The radio broadcasts sent out in the past two or three months by the Department of Interior in Washington show what is going on under Mr. Ickes' direction. With but little regard for truth and no thought of how impossible or wasteful their schemes would be, they would have the people believe that all the ills of humanity could be cured by political control of medical care.

Unless we physicians enlighten the people, politicians will soon force government control of medical care upon us. It is high time for us to act. We can no longer remain an inarticulate group. However distasteful and no matter how difficult it may be for us as individuals to enter into this struggle, we must each take an active and energetic part or we shall all lose. We have allowed ourselves to remain in obscurity too long; it is time for us, now, to express ourselves and to do it forcibly and effectively. We must take an active part in public affairs and we must let people know that medical matters are vital and important to them. If we wish to retain our American way of practicing medicine we must let the public know what the European system is like, what its results are and what they can expect from such a system. Every physician has friends and patients who trust him and who believe in his honesty. He must talk frankly to these people. The time has come when the medical profession must speak, not only in its own defense, but in the defense of the people who are easily misled to their own hurt. We should do this, not by argument or vituperation, but by calm statements of fact. As Dr. Andrew H. Smith told the New York Academy of Medicine: "The world has a right to know, and it is our duty to tell, just what progress we are making day by day, the steps by which results are obtained, the difficulties we meet, the uncertainties still to be cleared up, the problems which are pressing for solution." If we can gain the confidence of the public and help them to understand what it would mean to bring the European system to this country there would be no need for worry. To bring about this understanding is our great task.

HISTORICAL HIGHLIGHTS ON APPENDICITIS

AS Treves has well remarked, discussions
on the question of priority constitute the
most pitiable and petty items in the literature
of medicine. Any claim to priority in medi-
cine or surgery rests not upon the date of per-
formance but upon the date of publication
(Kelly). However, the credit for a new pro-
cedure should go not to the person who mere-
ly first did it or wrote about it, but to the
one who "put the idea across."

It seems incredible that the true nature of a
lesion so obvious to us now as appendicitis
should have been unrecognized for so long.
In 1753 Heister first demonstrated at necrop-
sy lesions occurring in the appendix. From

the time of Mestivier of France, who in 1759
first operated upon an appendiceal abscess, un-
til Fitz's paper in 1886, there were occasional
reports on appendicitis in the literature, stud-
ied with amazing detail and skill, but the ob-
servers failed to trace the true origin of the
disease. In 1827 Mélier, a French physician,
presented a clinical description of appendicitis.
However, Dupuytren, the leading French sur-
geon of the day, disagreed with some of Mé-
lier's statements and held him up to ridicule.
Mélier retracted his statements and, as a re-
sult, advancement in the knowledge of appen-
dicitis was held back for 50 years (Collins).
In 1880, Goldbeck and his school advanced the
theory that the primary disease lay in the ce-
cum and not the appendix. They advanced
the terms "pertyphilitis, epityphilitis and en-
dotyphilitis," which confused rather than clar-
ified the situation. While Addison, Bright
and Volz described the typical lesion in appen-
dicitis, the credit for recognizing the true
pathological nature of this disease belongs to
Fitz (1886) who also gave the disease its
name, appendicitis.

The surgery of appendicitis dates back about
a century. Excellent reviews have been given
by Collins and Kelly. According to Kelly the
earliest efforts of the surgeon in the treatment
of this disease consisted in opening a few ab-
scesses and then gradually making the in-
cision before the detection of fluctuation (Han-
cock, 1848; Willard Parker, 1867). With the
dawn of antiseptic surgery, a few surgeons
ventured to open the peritoneum, to straighten
out a kink of the appendix (Treves), to trim
off the edges of a fistula in the appendix
(Sands), and at last to remove the entire or-
gan (Krönlein, Morton, Sands). To Thomas
G. Morton of Philadelphia belongs the cred-
it for the first appendectomy, deliberately un-
dertaken with the diagnosis of acute appendi-
citis. In stressing the need for the early diag-
nosis and treatment of this disease, the names
of Fitz, Price, Morton, Fowler, McBurney,
Richardson, Morris, Murphy, Ochsner and
Deaver deserve mention. To McBurney more
than to any other surgeon belongs the cred-

it for crystallizing our ideas regarding the treatment of this disease. His paper entitled "Experiences with Early Operative Interference in Cases of Disease of the Vermiform Appendix", published in the New York Medical Journal for December 21, 1889, is a classic in the treatment of acute appendicitis. The subsequent years have not brought any important changes in his ideas of treatment.

It is interesting to note the cause of death of some of the investigators of the problem of appendicitis. Fowler died from peritonitis following a ruptured appendix. McDowell, who did the first successful ovariectomy in this country, also died from this disease. Price and Treves died of peritonitis; Fitz succumbed following an operation for chronic gastric ulcer. The etiology of the peritonitis in the cases of Price and Treves is not clear, although Price is said to have had an infection involving the retroperitoneal lymph nodes. Parker, Murphy, Ochsner and McBurney died from various forms of cardiovascular disease, the first from cerebral hemorrhage and the latter three from coronary disease. Deaver died of an obscure anemia, the exact nature of which was not determined even at autopsy. T. G. Morton died of cholera. It is noteworthy that both his brother and a son died of ruptured appendicitis, upon both of whom Morton had urged in vain the attending surgeons to operate.

It may seem somewhat surprising that the mortality of appendicitis is higher by occupation among physicians and surgeons than it is in the population at large. Whitney found that, from the mortality statistics of the United States census, the death rate for gainfully employed men (whole group, between fifteen and sixty-four years) was 20.7 per 100,000. For physicians and surgeons the rate was 22.1. Similarly, Alvarez found that medical men delay longer than lay people in seeking treatment for cancer of the stomach.

At present, the problem of appendicitis is not one of lack of scientific knowledge, but rather one of applying that knowledge effectively. Physicians would do well to apply that knowledge to themselves as well as to their patients.

CHARLES E. REA, M. D.

A SAFE SAFETY PIN

THIS product, the result of the inventive genius of Dr. Woodard Colby of Saint Paul, is 'now being manufactured and will shortly be available for general distribution. For those who have had the opportunity to use this pin, its merits are most appealing. Its construction is simple and most ingenious. The outstanding feature is the manner in which the point is concealed, making it impossible to cause injury to infants in the ordinary use to which it is put and virtually harmless if swallowed. It is to be manufactured by the Minnesota Homecrafters, Inc., under a plan sponsored by the Minnesota Department of Education and the United States Government. The pin has received the unqualified endorsement of the Ramsey County Medical Society and the St. Louis County Medical Society and of many leading physicians, among them Dr. Bela Schick of New York, Dr. Walter Ramsey and Dr. H. P. Ritchie of Saint Paul and many others.

The plan of manufacture and distribution as at present undertaken is two-fold. First, it will place a much desired article on the open market and, second, it will provide gainful employment for a goodly number of handicapped individuals. That these workers are by no means unskilled is evidenced by the fact that out of seventy-five useful articles exhibited at the Minnesota State Fair last month prizes were awarded to sixty-three. At the Tri-State Fair they received prizes for twelve from a total of fifteen shown, at the Proctor Fair ten out of twelve and at the Hibbing Fair every one of eight articles exhibited received awards.

Miss Marion Medd, Supervisor of this Homecrafters' project, informs us that a teacher provided through the Works Projects Administration visits the participating persons once a week and instructs those capable of skilled craftsmanship in the production of wood and/or metal articles. These articles are such that they can be sold on their own merit entirely and not on a sentimental appeal. Miss Medd is of the opinion that the Colby Clasp is ideally suited to this purpose because it can be completed in the home and will furnish work and income to this deserving group.

JAMES TRENT CHRISTISON, M.D.

MEDICAL ECONOMICS

Edited by the Committee on Medical Economics
of the

Minnesota State Medical Association

W. F. Braasch, M.D., Chairman

THE BLIND GODDESS

These are truly hectic days. Never has our American life been involved in such confusion and uncertainty as confronts us today. In the midst of turmoil the medical profession alone goes on its way, carrying on its mission of combating disease in any form which presents itself, as it has done in ages past. Conformists when necessary, but never obstructionists. So now, as emergencies arise, we change our methods to support our country's needs, making any necessary sacrifice without hesitation. All we ask is to conduct our healing art as we know it should be done and without interference from those who are not one of us. And now our shield and protection, the American Medical Association, in the midst of its efforts to support the nation's defense, is assailed by the Federal Department of Justice for daring to defy its plans for political control of medicine.

Trial Postponed

Suddenly the political element reveals itself, announcing that the trial is postponed indefinitely. And so, possibly in response to the ringing editorial which appeared in the last issue of the *Journal of the American Medical Association* and which was broadcast in the public press, the ban was suddenly lifted, at least until after election.

One would think that the terrific cost entailed in our nation's defense would stop such impractical schemes, but such is not the case. How stealthily the campaign to socialize medicine proceeds is shown by a recent attempt, under the guise of defense, to put the medical care of five million young men in the deferred list under control of federal health agencies. We, in the ranks of the Minnesota State Medical Association, can take pride in being the first to voice our opposition to this insidious

plan which, if carried out, would eventually suppress the private practice of medicine.

Sword May Be Sharper

It is no wonder that the members of the American medical profession are intensely interested in the forthcoming election and are vigorously supporting those who uphold their principles. While the Damoclean sword has been temporarily sheathed, it may be sharper than ever after election. In the meantime, it behooves every one of us to use every ounce of influence with all of those with whom we come in contact and to do what we can to protect the public welfare and the future of medicine.

MINNESOTA FIRST

The Council of the Minnesota State Medical Association is the first among responsible, executive bodies of state medical associations to go on record in opposition to free medical service for the rehabilitation of draft registrants rejected for physical defects. At the same time (as noted elsewhere in these columns) the Council went on record against the offer of Wassermann tests for all Class 1 registrants and the consequent slowing up of the defense program.

The physicians of Minnesota and of the nation are making an impressive contribution to defense preparations. They will do more, if more is asked of them; but when a welter of utopian schemes for improvement of civilian health is hastily tossed by civilian health officials into the already complicated machinery for registration, examination and induction into service of drafted men, then the physicians who will be asked to bear the burden are entitled to protest.

And when these schemes, if put into effect,

would also plunge the country into an endless program of government medical care of civilians, the obligation of physicians to oppose them is obvious.

The resolution passed by the Council at a special meeting held October 16 in Saint Paul is as follows:

1. WHEREAS, the Surgeon General of the United States Public Health Service has requested that serological tests for syphilis be given to every man who registers under the Selective Service Act, October 16, 1940, and

WHEREAS, the advisability of making the test on this scale has been thoroughly discussed with public health authorities and syphilologists in Minnesota:

IT IS HEREBY RESOLVED by the Council of the Minnesota State Medical Association called in special session on October 5, 1940, that the request to examine in this manner all registrants is impractical and inadvisable, especially in view of the emergency of the situation and the short time available to prepare for such an undertaking, and

WHEREAS, the registrants assigned to Class 1 when inducted into military service will have a complete examination at the mobilization center including a serological test:

A. It was the opinion of the Council that it would be inadvisable to duplicate such examinations for these registrants who are assigned to Class 1.

B. Since the selection and induction of men into service at this time is distinctly a military and not a public health program, it was the opinion of the Council that the procedures entailed by the test would lay an additional heavy and unnecessary burden and expense on physicians and public health services.

C. In view of the lack of organization for the collecting, mailing and testing of the specimens collected, it seemed advisable to avoid interjecting any procedure or undertaking that would complicate or in any way slow up the efficiency of the draft machinery.

2. WHEREAS, the program of the Minnesota State Medical Association and the Minnesota State Board of Health is a comprehensive one in that it includes not only syphilis but all infectious diseases, and

WHEREAS, encouragement of prophylactic and preventive medicine is part of that program,

It was the further opinion of the Council that such prophylactic measures should include prevention of venereal diseases at home and in the communities around the cantonment

3. WHEREAS, all deferred registrants under the selective Service Act still retain their civilian status.

It was also the opinion of the Council that any special testing or rehabilitation of those deferred registrants with regard to disease or disability should be carried out by the private physician with free choice of physician and hospital, thus helping to relieve overburdened military and public health facilities.

NATIONAL HEALTH PROGRAM—1940

That the National Defense program will also involve a national health program on a completely new basis seems altogether likely from the report of the September 16 Conference of State and Provincial Health Officers in Washington which was printed in *Public Health Reports* of the United States Public Health Service for September 27.

The customary cautiousness of United States Public Health Service officials in the handling of ticklish new plans for medical service to civilians was abandoned at this conference. A bright new world was envisioned. In this world, hands of the Health Service were to be freed, at last, to wipe out syphilis in the United States, to correct the physical defects of youth before they reached draft age and to rehabilitate the unfit discovered by draft board examiners—all without troublesome interference.

State medicine? Government medical service? Meaningless words now, it seemed; outmoded bogies. The mere invocation of those magic words, "National Defense" was to be enough, henceforth, to lay such uneasy wraiths.

They Took It For Granted

The surgeons of the United States Public Health Service put the problems to the conference and took for granted the answers. Of course, the program was desirable. Of course, the health service was ready to supervise, to supply funds to carry on the work. . . .

Presumably the conference acquiesced, at least informally, in the proposals made to it, though the method of securing acquiescence may have been similar to the method understood to have been used to gain backing for the astonishing proposal to offer every man who registered on October 16 a free Wassermann test for syphilis. This last-named plan was proposed to the conference by Senior Surgeon O. C. Wenger, of the Health Service.

Committee No. 2 Approved

In this case, it is understood, the regular conference committee of venereal disease was consulted first. This committee refused, because of the obvious difficulties involved, to give its approval; but its action was not al-

lowed to dampen the general enthusiasm. Another committee was promptly appointed and this second, impromptu committee approved without question. It was the report of the substitute committee that was presented to the conference.

"Discussion (of this plan) brought out a number of practical points and administrative difficulties," the health service account acknowledges, "such as the magnitude of the task to be accomplished within a very short time; the inadequate number of technicians available to perform the tests; the insufficient stock of specimen tubes and the lack of proper storage facilities for specimens awaiting examination."

According to the report, the health officers seemed anxious to accomplish "all that might be done within the limits imposed by circumstances."

Rejected for Minnesota

Actually, a compromise proposal was made by which Class 1 registrants, only, might be offered a Wassermann test. This proposal was later brought by Dr. A. J. Chesley, Secretary State Board of Health, to the official attention of the Council of the Minnesota State Medical Association for advice as to the policy which should be followed in Minnesota. The action taken by the Council at a special meeting, held, on both proposals and also on the proposal to provide rehabilitation for "culls," rejected from service, because of physical condition, is printed in full elsewhere in these columns. It will be noted that the Council did not favor even the compromise plan for several reasons, chief among them being the fact that selection and induction of men is distinctly a military and not a public health program, that testing Class 1 registrants would duplicate tests that would be made as a matter of routine at the time selectees were inducted into the service and that the procedure would place an added and unnecessary burden upon examining physicians.

The plan for providing physical examinations and correction of remediable defects among youths enrolled for benefits under the National Youth Administration was presented for approval to the Conference and has also been broached for Minnesota beneficiaries by director Chester A. Lund of Minnesota.

Youth Plans to Be Discussed

Just how the plan will eventually be conducted—if it is conducted in Minnesota—has not yet been determined. An early meeting with the Minnesota State Medical Association's Committee on Low Income and Indigent Problems, of which Dr. W. A. Coventry of Duluth is chairman, had been arranged as this issue went to press. It is altogether probable, however, that the Youth Administration will try to insist upon letting this work to the contract basis. State health departments are lowest-physician bidder in each county, on a contract basis. State health departments are to be asked to be co-sponsors in this work.

Following is the resolution introduced and, at least informally, approved by the conference on the subject of rehabilitating the men disqualified for military service because of physical defects.

To Correct Defects

RESOLVED: That persons who are otherwise found to be satisfactory and available for induction into the land or naval forces of the United States for training and service as provided by the Selective Training and Service Act of 1940, but who are placed on a deferred status because of physical defects or ailments which are readily amenable to treatment and cure may, upon application to the Surgeon General of the United States Public Health Service, be considered for acceptance as beneficiaries of that service for correction of such physical defects or ailments.

The committee contemplated, according to the report, that the Surgeon General of the United States Public Health Service would use his discretion in determining facilities, institutions and personnel to be employed in such corrective work and that any non-governmental facilities that might be used would be reimbursed out of funds made available to the United States Public Health Service for the operation of a program of rehabilitation among eligible rejected men.

Surgeons Thanked

Health of industrial workers, health and welfare of civilian populations, special public health measures involved in mobilization and in regions surrounding cantonments, education and qualifications of personnel—all these received attention and discussion.

At the end, the conference adopted a mild and non-committal formal resolution of thanks to the representatives of the United States Public Health Service, requested their con-

tinued interest and coöperation and drew attention of civil and military defense authorities to the importance of public health problems in the nation's defense.

If they did not formally go on record in favor of each resolution as it was presented, they certainly did not voice any objections—at least no objections were reported in the United States Public Health Service publication. The reason was, of course, that the object of the conference was not a new health program; instead it was national defense. And what social dreams if properly interpreted, cannot be tethered to national defense?

MEDICAL INDUCTION BOARDS

Profiting by experience of 1917, every man accepted for military service under the Selective Service Act of 1940 will be given a careful final physical examination by an Induction Board of specialists before he is assigned to cantonments or camps for training.

Tentative selections for appointments to Minnesota's board have already been made by Army Medical officers in consultation with medical association officials. All boards are to be made up of three internists, one general surgeon, one orthopedic surgeon, two ophthalmologists, one otolaryngologist, one neuropsychiatrist, one clinical pathologist and one dentist, including probably both civilian specialists and reserve officers on temporary duty.

From nine to twelve of these boards will probably be needed for each corps area; but it is understood that only one will be needed for Minnesota and immediate vicinity. Headquarters for this board will be at Fort Snelling.

Service Temporary

Specialists selected will all be on temporary duty. They will probably serve for an estimated period of about a month following each selection of drafted men and they will probably be paid at the same rate of base pay as a major in the regular army, with allowances for travel and subsistence while on duty. Whether they will be required to be on duty for an entire eight-hour day or only for a part-time period each day had not yet been decided as this issue went to press.

"During mobilization," according to an editorial on the induction boards which appeared in a recent

Journal of the American Medical Association, "the usual flow of men will be from local selective service boards to induction stations for final examination and induction, then to reception centers for classification and other processing, then to organization, installations or replacement centers in which they are to serve.

"The induction station serves the same purpose as the recruiting station does in times of voluntary enlistment. Therefore recruiting stations, augmented as required, will be used as induction stations."

Arrangements for x-ray, laboratory or other special examinations will be made as requested by the chief of the board in local hospitals or clinics.

Well Qualified Men Needed

It is obvious that thoroughly qualified men are needed for this board and that the service may involve a very real sacrifice on the part of members willing to offer themselves.

The importance to the effectiveness of our armed forces and also to the welfare of the individual drafted man, of painstaking examinations at this critical point in the progress from selection to training assignment goes without saying. It is made clearer when experience in the World War is taken into account. From the moment that the drafted man arrives at his training camp he becomes the responsibility of the government and, by the same token, any aggravation of ailments which he is permitted, by oversight, to take with him from civilian life is likely to become the basis for endless claims for compensation in time to come.

PRIVILEGED COMMUNICATIONS

(Monthly editorial prepared by the Medical Advisory Committee.)

Due to recent cases which have been brought to the attention of the Medical Advisory Committee, it is necessary that we again stress the fact that meticulous records, both office and hospital, made at the time of rendering service and signed by the physician or surgeon in charge himself constitutes one of the surest defenses against malpractice litigation; also that additions to these original records, if necessary, should under all circumstances be made, if possible, by the original writer, or at least, read and initialed by him. If not, the name of the writer of such additions should appear in full on the record.

These records should then be carefully preserved and made available at all times to the maker of them, but their contents should be con-

sidered as confidential information and at no time should they be exposed to public perusal unless the law or the courts demand it.

If privileged communications obtained in the physician-patient status are required by insurance companies, governmental agencies or any other party, they should only be divulged when the request is made in writing and such request signed by the patient or his legal representative, the request to be filed with the record together with copy of the report submitted.

Careful attention to this will become more and more necessary as government and state authorities, as well as private institutions, demand a greater quantity of information from the members of our profession.

The giving out of privileged communications and confidential information without proper authorization can become a distressing incident in the life of a physician.

—B.J.B.

THANKS OF THE COUNCIL

Special thanks and appreciation were expressed by the Council at their fall meeting to the following:

To Dr. J. M. Armstrong of Saint Paul, long chairman of the Historical Committee, for his faithful service and distinguished contributions to the collection, editing and publishing of manuscripts of the committee now appearing in MINNESOTA MEDICINE under the title "History of Medicine in Minnesota." Dr. Armstrong recently retired from the active practice of medicine in Saint Paul.

To the Olmsted - Houston - Fillmore - Dodge County Medical Society and to Mr. R. R. Rosell, executive secretary of the Minnesota State Medical Association, and his staff for their successful conduct of the 87th annual meeting of the Association held at the Mayo Civic Auditorium in Rochester last April. The final report of that meeting presented to the Council showed a substantial profit which has been turned over to the general fund of the Association.

PRICE OF HEALTH

The statement that the medical or health bill for society is too large is but an expression of the reluctance of society to pay the price for good health, as well as an evidence of complete failure to place full value on man's greatest asset—good health.

—FRANCIS F. BORZELL, M. D., in
Pittsburgh Medical Bulletin,
October 26, 1940.

MINNESOTA STATE BOARD OF MEDICAL EXAMINERS

J. F. Du Bois, M.D., Secretary
Saint Paul, Minnesota

Itinerant Health Lecturer Pleads Guilty to Fraudulent Advertising and Practicing Healing Without a Basic Science Certificate

Re: State of Minnesota vs. Edward F. Marcell
Re: State of Minnesota vs. Guy Pearson

On October 5, 1940, Edward F. Marcell, fifty-three years of age, who gave Pasadena, California, as his home, entered a plea of guilty in the District Court of Morrison County, to an information charging him with the crime of practicing healing without a basic science certificate. The Honorable Don M. Cameron of Little Falls, Minnesota, Judge of the District Court, sentenced Marcell to pay a fine of \$400.00 plus costs of \$5.18, or to serve one year in the Morrison County Jail. Marcell paid the fine and costs. Marcell's brother-in-law, Guy Pearson, 31 years of age, of North Power, Oregon, pleaded guilty to assisting Marcell, and was sentenced by Judge Cameron, at the same time, to pay a fine of \$50.00 and costs of \$5.19, or to serve 90 days in the Morrison County Jail. Pearson paid the fine and costs.

Following a disposition of their cases in the District Court, Marcell and Pearson were arraigned before the Honorable Phil S. Randall, Judge of the Municipal Court of Little Falls, on a charge of fraudulent advertising. Both defendants pleaded guilty and each was sentenced by Judge Randall to pay a fine of \$100.00 and costs of \$3.10, or to serve ninety days in the Morrison County Jail. This sentence was suspended by Judge Randall because both defendants had paid their fines in the District Court, and upon the further condition that the defendants refrain from practicing healing in any manner in the State of Minnesota. The defendants are also to refrain from inserting any further advertisements in Minnesota papers, and in addition, they are to leave the State of Minnesota by October 15, 1940.

Marcell and Pearson arrived in the State of Minnesota about September 9, 1940, and proceeded to advertise a so-called exposé of devils, drugs and doctors at Detroit Lakes, Minnesota. They advertised a so-called health lecture for women only, following which a lecture was to be given for men only. The matter was called to the attention of the Minnesota State Board of Medical Examiners, but too late to apprehend the defendants at Detroit Lakes. Subsequently the defendants operated at Bemidji, Virginia and Little Falls, where they were arrested on October 4, 1940, following an investigation made by F. Manley Brist and Reginald M. Johnson on behalf of the Minnesota State Board of Medical Examiners, in cooperation with County Attorney Austin L. Grimes, Sheriff William J. Butcher and Deputy Sheriff Henry A. Smith. This investigation disclosed that the true purpose of inserting the advertisement was to secure prospective purchasers of a so-called health course which Marcell was selling at \$58.00 per patient. Marcell recommended this health course as a treatment for a multitude of human ailments and claimed that it consisted of various mineral preparations in capsule form. As a special inducement, the health course could be purchased for \$36.00 cash while Marcell was in Little Falls. The defendant's manner of operation, including the deceit practiced upon the public in the advertisement, and the numerous false statements made in the advertisement inserted in the Little Falls newspaper, stamp the defendants' activities as quackery. Both defendants readily admitted

Communication

that they had no medical training whatsoever. Marcell stated that he was in the commercial photography business for a number of years, and that in August 1939, his father died at Pasadena, California. He stated that his father had operated this so-called health course for many years.

The Minnesota State Board of Medical Examiners is very much pleased with the disposition made of these cases by Judge Cameron and Judge Randall. It, perhaps, is hardly necessary to point out that the imposition of a few stiff fines, such as were imposed in these cases, will go a long way toward stamping out this type of quackery. Minnesota has been comparatively free of this evil. Nevertheless, one or two other persons have operated in this State, and needless to say that other prosecutions are contemplated. The Minnesota State Board of Medical Examiners wishes to acknowledge the very prompt and efficient coöperation given in these cases by the local authorities, and particularly by County Attorney Grimes, Sheriff Butcher, and Deputy Sheriff Smith, all of Morrison County.

Minneapolis Woman Sentenced to Eight-Year Term at Hard Labor for Criminal Abortion

Re: State of Minnesota vs. Hattie Anderson.

On October 16, 1940, Mrs. Hattie Anderson, forty-five years of age, entered a plea of guilty to an information charging her with the crime of abortion. Due to the fact that the defendant had a previous conviction in 1933, for a similar offense, Mrs. Anderson was sentenced by the Honorable Paul S. Carroll, Judge of the District Court of Hennepin County, to a term of not to exceed eight years at hard labor in the Women's Reformatory at Shakopee.

Mrs. Anderson, who holds no license to practice any form of healing in the State of Minnesota, stated that she lived at Mound, Minnesota. On September 22, 1940, she performed a criminal abortion upon a twenty-one year old Wisconsin girl. The abortion was performed at Apartment 3, 89 Spruce Place, Minneapolis. Mrs. Anderson was paid \$25.00 for her services. The girl became critically ill and was taken to Deaconess Hospital where she died on Tuesday, October 8, 1940. Because of the fact that the case was promptly reported by the attending physicians to the Minnesota State Board of Medical Examiners, it was possible, with the coöperation of the Women's Bureau of the Minneapolis Police Department, to obtain a statement from the girl before she died. The defendant was immediately placed under arrest and taken to the Hospital where she was identified by the girl just a few hours prior to her death.

Mrs. Anderson had a previous conviction for a similar offense on April 11, 1933, on which date she entered a plea of guilty in the District Court of Hennepin County to an information charging her with the crime of abortion. She was sentenced at that time, to a term of not to exceed eighteen months in the Women's Reformatory, but was placed on probation. She violated her probation by performing a subsequent abortion, and on February 21, 1936, her stay of sentence was vacated by Judge Baldwin. Mrs. Anderson served fourteen months and eighteen days for that crime. In the instant case it was decided to charge the defendant with the crime of abortion rather than manslaughter, because of her previous conviction, the laws of the State of Minnesota providing that where a defendant has one previous conviction, the Court may double the sentence for a subsequent offense. Mrs. Anderson attempted to have the Court limit her sentence to four years, but Judge Carroll told her that she had been shown considerable leniency by the State of Minnesota when she was charged with the crime of abortion rather than manslaughter.

MINNESOTA MEDICINE
Saint Paul, Minnesota
Gentlemen:

Men of medical and dental professions should be on guard against an imposter who goes about "borrowing" money. He represents himself variously as a physician, a dentist, or a son of a physician (depending on whom he is striking for a loan), as practicing in various small towns of the state and giving various names (Dr. Claud Mays, Rush City, Minn. when he interviewed me).

His story varies but in the above interview he was on his way home, had his wife and baby with him and would I lend him two dollars (his request is usually from two to five dollars) to get home on and he would send it back to me the next day. He disappeared while I was telephoning to check up on him.

He has a great deal of information about physicians indicating that he may have a medical directory to consult. He rushes in, greets with a glad hand, speaks very rapidly and glibly and has been very successful in victimizing many physicians and dentists in Duluth on at least three occasions in the past two years. A man answering his description has also operated on the Iron Range as well as in Superior, Wis. A man also answering his description has gone from house to house in Duluth selling "reducing pills" "recommended by the doctors at Rochester, Minnesota." He asks \$1.50 down and the pills to be delivered in a week at which time the customer was to pay another \$1.50 for the bottle.

This man is short, perhaps 5 feet 4 to 6 inches. He is very stocky and heavily built, has dark hair, and a very round face with plump cheeks. My impression is that he had a scar on the right side of the forehead. He was dressed in a wrinkled faded blue or blue-green suit.

By being forewarned, quick action on the part of the intended victim and coöperation with local authorities may result in the arrest and conviction of this imposter.

Yours truly,
L. L. MERRIMAN, M.D.
923 Medical Arts Bldg.
Duluth, Minnesota
October 3, 1940.

THE GANG THAT RUNS THINGS

"Ah, what's the use?" said the enthusiastic young physician, "I tried to horn in here, but only busted my horn! There is a gang that runs this medical society, and outsiders have no more show than a snake has hips!"

The Past President, to whom this remark was directed, lighted an obese cigar with a red and gold life preserver around its midriff and then spoke:

"You are right, young man, and you are wrong," he said. "By this statement I mean that you are right about a 'gang' running the society. There's a 'gang' running every organization on earth. If there wasn't there wouldn't be any organization. On the other hand, you are wrong when you say you tried to horn in and couldn't. You did not go about it right. Any good guy who wants to horn into any gang has to know the password, and I will give it to you in strictest confidence. Those words are: 'What can I do to help?' Any man who will use those words will find himself as busy as a one-armed piano player with a bad case of hives!"

—Detroit Medical News.

OF GENERAL INTEREST

At Ruthton, Minnesota, Dr. Arthur F. Sether is a member of the village council.

* * *

Dr. W. R. Morrison of Billings, Montana, recently visited in Bemidji, Minnesota, where he practiced for eight years, from 1900 to 1908, before going to Billings.

* * *

Dr. Paul F. Dwan of Minneapolis, who is recuperating after a severe illness, will leave about December 1 with his family for Florida to spend the winter.

* * *

Dr. Myron O. Henry of Minneapolis was guest speaker at the Camp Release Medical Society meeting at Dawson, Minnesota, October 11. His subject was "Treatment of Fractures of the Upper Extremity."

* * *

Dr. H. S. Diehl and Dr. C. D. Creevy of the Medical School, represented the University of Minnesota at the meeting of the Association of American Medical Colleges at Ann Arbor, Michigan, October 28-30.

* * *

Dr. Seigfried C. G. Oeljen of Waseca has moved into his newly completed office building north of the court house. The building, which houses only his offices, is of brick and is 22x47 feet.

* * *

Dr. F. G. Gunlaugson, health officer of the Mankato district office of the Minnesota Department of Health and a first lieutenant in the medical reserve officers corps, has been called to active duty for the next year. He is stationed at Fort Snelling.

* * *

Dr. George Michael Jennings, chief surgeon at the Northern Pacific Beneficial Association Hospital in Missotla, Montana, and a graduate of the University of Minnesota Medical School '08, passed away October 16.

* * *

Dr. A. E. Hansen, assistant professor of pediatrics at the University of Minnesota Medical School, addressed the annual meeting of the Bryan Memorial Hospital in Lincoln, Nebraska, October 8, on the subject of "Rheumatic Fever."

* * *

The marriage of Dr. J. J. Stratte of Grand Forks, North Dakota, to Miss Irene Dille, took place September 30. Dr. Stratte, former Kittson County surgeon, in addition to his practice in Grand Forks, is associated with the Berlin-Griffin Clinic at Hallock, Minnesota.

Dr. George C. Kimmel, Mayo Foundation fellow, will become associated with the Interstate Clinic at Red Wing, January 1, it is announced. Graduated from the University of Minnesota Medical School in 1936, Dr. Kimmel took his internship at Temple University in Philadelphia.

* * *

Dr. Bernard Watson, who left the staff of the University of Minnesota Health Service and Medical School last spring to become associated with the Battle Creek Sanitarium at Battle Creek, Michigan, visited in Minneapolis in October, while in the state on a pheasant hunting trip.

* * *

Dr. and Mrs. George B. Weiser of New Ulm marked their fiftieth wedding anniversary, October 2. They were married in 1890 at Selinsgrove, Pennsylvania. Their son-in-law and daughter, Mr. and Mrs. C. T. Ekelund of Pontiac, Michigan, came to New Ulm for the celebration, at which the couple received the congratulations of their many friends.

* * *

Dr. Russell W. Morse of Minneapolis was installed as president of the Hennepin County Medical Society, October 8. He succeeds Dr. James A. Johnson. Plans for the year include sponsorship of a series of lectures for expectant mothers in connection with the adult education program of the YWCA. Lectures will be given each Friday morning.

* * *

Dr. A. C. Ivy of Chicago will give the annual E. Starr Judd lecture at the University of Minnesota Medical Amphitheatre, January 15, 1941, at 8:15 p. m. His subject is "The Mechanisms of Gastric Secretion."

Dr. Ivy is head of the Department of Physiology and Pharmacology at Northwestern University Medical School.

* * *

Dr. Hans E. Guloien of Fargo, North Dakota, has located in Willmar, Minnesota, opening offices there at 316 West Fifth Street.

A graduate of Rush Medical School, University of Chicago, in the Class of 1938, Dr. Guloien served his internship at St. Mary's Hospital in Duluth. Prior to coming to Willmar, he was resident surgeon at the Mary McClellan Hospital at Cambridge, New York.

* * *

A father and his son have become associated in the practice of medicine in Red Wing, Minnesota. Dr. L. E. Claydon, one of the oldest practicing physicians in

Goodhue county, and Dr. Donald R. Claydon have opened new offices at 324 Main Street. Also associated with them is Dr. E. M. Baldigo, a graduate of the University of Minnesota Medical School, who served his internship at Miller hospital in Saint Paul.

* * *

Dr. and Mrs. William M. Balfour of Rochester, New York, are the parents of a son, James McQuarrie Balfour, born August 26. Dr. Balfour, who is a research fellow in pathology at the University of Rochester Medical School, is the son of Dr. and Mrs. Donald C. Balfour of Rochester. Mrs. Balfour, the former Oane McQuarrie, is the daughter of Dr. and Mrs. Irvine McQuarrie of Minneapolis.

* * *

Dr. R. F. Pierson, licensed in Minnesota by reciprocity with Nebraska, has become associated with Dr. Henry C. Doms of Slayton, Minnesota. Dr. Pierson, who was graduated from the University of Nebraska in June, 1938, served one year as an intern at the Clarkson Hospital in Omaha, and six months at the Fairview Hospital in Minneapolis.

Dr. Pierson married Miss Maxine Steggs, a graduate of the Clarkson Hospital School of Nursing, April 7, 1940.

* * *

The University of Minnesota Medical School has instituted a required course in First-Aid for freshmen medical students. The one-quarter course, consisting of fourteen lectures and six practical demonstrations, was instituted because it was felt that it was pertinent to the preparedness program in event of an emergency. The University of Minnesota is one of the first medical schools in the country to include such a course for freshmen in the curriculum. Ordinarily, medical students do not receive any instructions in caring for emergencies until they are juniors and seniors.

* * *

Dr. Bertram S. Adams, president of the Minnesota State Medical Association, was honored by the Hibbing Elks Lodge and citizens of Hibbing for his civic service to the community and the state, October 22. The testimonial dinner, an outstanding event in north-eastern Minnesota, was the Elks' seventh annual honor night.

More than 400 men, many of them distinguished leaders of the medical and dental professions and of fraternal societies, attended the dinner. In addition to verbal tributes, there were scores of congratulatory telegrams and communications, among them one from Governor Harold E. Stassen and another from the employees of the Adams Hospital.

* * *

Dr. A. B. Stewart of Owatonna, "dean" of the medical and surgical profession of Steele County, was the

recipient of many congratulatory messages when he observed his seventy-seventh birth anniversary, September 23.

Born at Hume, New York, in 1863, Dr. Stewart has practiced in Owatonna since June, 1891. He has studied at hospitals and clinics in Vienna, and Edinburgh, and holds a fellowship in the American College of Surgeons. In 1918 he was given the rank of major in the U. S. Army and was chief of the medical staff at Fort Snelling.

* * *

Dr. B. T. Horton of Rochester addressed a meeting of the Tennessee Valley Postgraduate Medical Assembly in Knoxville, Tennessee, October 10. He presented two papers: "The Treatment of Peripheral Vascular Disease" and "Histamine in the Treatment of Specific Types of Headache." On October 14, he addressed a meeting of the Norfolk County Medical Society in Norfolk, Virginia, speaking on "The Treatment of Headaches and Vertigo with Histamine." From there he went to the University of Virginia in Charlottesville to speak before a meeting of the Virginia Neuropsychiatric Society.

* * *

When the fifteenth annual conference of the Association of Clinic Managers is conducted in Rochester, November 6, 7 and 8, the program will include an address of welcome by Dr. C. W. Mayo; an address, "The Value of Medical Statistical Research" by Dr. Joseph Berkson of Rochester; a talk on "Medico-military Preparedness" by Dr. Russell M. Wilder of Rochester, chairman of the Committee on Medicine in the Division of Medical Sciences of the National Research Council; and an address, "Air Conditioning: Its Use and Limitations in Clinics and Hospitals" by Dr. Charles Sheard of Rochester.

* * *

Three experiments, designed to engender and conserve energies and resourcefulness of the United States Army, are being carried on in the University of Minnesota physiological laboratories under the direction of Dr. Ancel Keys, professor of physiology. One of the projects has to do with the study of fatigue in soldiers in marching and field operations, and with means of reducing the fatigue and increasing ability to carry on maneuvers.

A second experiment concerns the prevention and treatment of wound shock, especially in emergencies arising on the battlefield; the third, with a study of heart and circulation under conditions of low oxygen supply, as found in planes flying at high altitudes.

* * *

Two Minnesota physicians were among the prize winners in the Abbott Camera Competition for Physicians, and two others received honorable mention.

Dr. Lawrence Berman of Saint Paul was one of the

fourth prize winners in the pictorial and general division with his entry, "Hilltop." Dr. Charles Heilman of Rochester and Dr. Ernest J. Losli of Minneapolis were among those who received honorable mention. Dr. A. J. Hertzog of Eau Claire, formerly of the University of Minnesota Medical School staff, won an honorable mention.

Dr. J. R. Sturre of Minneapolis won third prize in the division devoted to Gross Specimens and Photomicrographs.

* * *

Dr. Irvine McQuarrie, head of the Department of Pediatrics at the University of Minnesota Medical School, has returned from Rochester, New York, where he addressed two meetings. He spoke at the Rochester Academy of Medicine, October 15, his subject being "Medical Conditions in North China As Related to Military Invasion." On October 16 he addressed the Rochester Pediatrics Society on "Adrenal Tumors in Childhood."

Dr. McQuarrie on September 18 and 19 gave two lectures at the University of Iowa in Iowa City for a program on Maternal and Child Hygiene, sponsored by the State Board of Health. His subjects were "Anoxia and Asphyxia in the New Born" and "Common Diseases of the New Born Infant."

* * *

Physicians who are lecturing in the course, "Orientation to Practice," offered to seniors in the University of Minnesota Medical School, include: Dr. H. S. Diehl, "Opportunities In and Preparation for Practice"; Dr. A. W. Adson of Rochester, "Medical Licensure"; Dr. W. A. O'Brien, "Quackery, Fads, Cults and Patent Medicines"; Dr. F. J. Hirschboeck of Duluth, "The Ethics of the Practice of Medicine"; Dr. S. M. White, "The Management of the Public and Private Patient"; Dr. J. M. Hayes of Minneapolis, "Starting the Practice of Medicine"; Dr. B. J. Branton of Willmar, "Malpractice"; Dr. R. E. Scammon, "Medical Care of the Indigent and of Low Income Groups." Judge Paul Carroll of Minneapolis is lecturing on "The Physician in Court."

* * *

Representing the University of Minnesota at the American Public Health Association meeting in Detroit, Michigan, in October were: Dr. Ruth E. Boynton, director of the Students' Health Service; Dr. Ralph V. Ellis, associate professor of preventive medicine; Dr. Gaylord Anderson, head of the Department of Preventive Medicine and Public Health; Miss Mellicie Palmer, acting director of the course in Public Health Nursing; George O. Pier, assistant professor; and Miss Mary Parker.

Though he was unable to attend, Dr. W. A. O'Brien was honored at the banquet, October 10. He was among the former members of the Detroit Department of Health, who were awarded certificates of merit for the outstanding work they have done elsewhere. The awards were made by Dr. Henry F. Vaughn, director of the Department of Health of the city of Detroit.

The first annual Minnesota Medical Foundation Lecture will be presented at the University of Minnesota Medical School on Tuesday evening, November 12. Dr. Conrad A. Elvehjem, Professor and Head of the Department of Biochemistry, University of Wisconsin, will present the lecture, the title of which is "The Biochemistry of the Vitamin B Complex."

* * *

The University of Minnesota Board of Regents has accepted a gift of a collection of medical journals from Dr. Ivar Siversten of Minneapolis.

* * *

Dr. Morris Fishbein was principal speaker at the General Medical Faculty annual dinner meeting in the new Coffman Memorial Union on the University of Minnesota campus, October 4. He spoke on "Medical Writing" and "The Role of the Medical Profession in National Defense."

Dr. H. S. Diehl presided at the dinner, the program for which also included talks by Dr. James S. McCartney on the admission of students to the Medical School during the current year; a report by Dr. Erling S. Platou, president, on the development of the Minnesota Medical Foundation during its first year; a report by Dr. W. A. O'Brien on postgraduate medical courses during the past year; observations by Dr. Irvine McQuarrie on his recent visit in China, when he held a visiting professorship at the Peiping Union Medical College. Dr. Diehl reported on the organization of the United States General Hospital Unit No. 26.

* * *

The 1941 convention of the Interstate Post Graduate Medical Association of North America to be held in Minneapolis next October, is expected to bring 4,000 physicians and surgeons to that city.

The association recently concluded its 1940 assembly in Cleveland, Ohio. Speakers at the meeting, held from October 14 through 18, included several Minnesotans: Dr. Maurice B. Visscher, head of the physiology department at the University of Minnesota, whose subject was "Intestinal Absorption as a Clinical Physiological Problem"; Dr. Walter C. Alvarez of Rochester, who conducted a diagnostic clinic, "Puzzling Cases of Abdominal Pain"; Dr. Waltman Walters of Rochester, diagnostic clinic, "Surgery of the Pancreas"; Dr. Howard K. Gray of Rochester, address, "Cancer of the Stomach"; Dr. Charles W. Mayo of Rochester, address, "The Treatment of Vesico-Colonic Fistula"; Dr. Claude F. Dixon of Rochester, diagnostic clinic, "Diverticulitis"; Dr. Alfred W. Adson of Rochester, diagnostic clinic, "Surgical Treatment of Peripheral Vascular Disease"; Dr. William F. Braasch of Rochester, address, "Infections of the Urinary Tract"; Dr. John S. Lundy of Rochester, address, "Choice of Anesthesia."

Dr. William L. Benedict of Rochester gave the Schneider Foundation Eye Presentation. The subject of his address was "Relationship of Ophthalmology to Systemic Disease."

The first permanent board of trustees for the Minnesota Medical Foundation was elected at the organization's first annual meeting, October 25, in the new Coffman Memorial Union on the University campus.

Elected to the board of twelve members to serve terms of four years each were Dr. William W. Will of Bertha, Dr. Edwin J. Simons of Swanville, Dr. Lloyd H. Rutledge of Detroit Lakes; to serve three-year terms, Dr. Russell J. Moe of Duluth, Dr. Albert M. Snell of Rochester and Dr. Gordon C. MacRae of Duluth; two-year terms, Dr. Jennings C. Litzenberg, Dr. Owen H. Wangenstein and Dr. Cecil J. Watson of Minneapolis; and one-year terms, Dr. Erling S. Platou of Minneapolis, Dr. George A. Earl of St. Paul and Dr. Robert L. Wilder of Minneapolis.

Dr. Platou, president of the Foundation, presided at the meeting and reported on the program and development of the Foundation during the past year. Dr. Wilder gave the secretary's report, and Dr. Litzenberger, the treasurer's report. Reporting on membership expansion activities were Dr. Will, Dr. Moe and Dr. Olga Hansen. Dr. Maurice B. Visscher, editor of *The Bulletin of the Minnesota Medical Foundation*, reported on that publication.

Dr. Erling W. Hansen reported for the Nominating Committee.

* * *

Speakers at the twelfth annual meeting of the Medico-Military Inactive Status Training Unit in Rochester October 6-20, included besides members of the Mayo Clinic staff: Colonel Kent Nelson, MC USA, Medical Director R.O.T.C. University of Minnesota; Major F. B. Waweman, MC USA, Washington, D. C.; Lt. Comdr. Donald McCarthy, MC-O, USNR, Minneapolis; Lt. Albert R. Behnke, Jr., MC USN, Washington; Captain Andrew H. Davidson, MC USN, District Medical Officers 9th Naval District, Great Lakes, Illinois.

Also Lt. Col. Jarret M. Huddleston, MC USA, Fort Snelling, Minnesota; Colonel Monte Belot, Med. Res., Kansas City, Missouri; Comdr. John R. Poppen, MC USN, Bureau of Aeronautics, Navy Department, Washington, D. C.; D. R. Brimhall, Director of Research, C.A.A., Washington; Dr. H. S. Diehl of the University of Minnesota; Brig. Gen. John H. Hester, Inf. Executive for Reserve Affairs, War Department, Washington.

Also Colonel A. D. Tuttle of United Airways, Chicago; Lt. Herbert M. Bosch of the Minnesota State Board of Health, Minneapolis; Major James J. Morrow, Med. Res. of Austin; Lt. Comdr. R. H. Hunt, MC USN, Minneapolis; and Dr. Edward A. Dosey, Professor of Bio-Chemistry and Director of the Department, St. Louis University Medical School, St. Louis, Missouri.

The staff consisted of Dr. Donald C. Balfour, director of the Mayo Foundation; Col. Herbert C. Gibner, MC USA, Corps Surgeon, 7th Corps Area, Omaha; Captain Ernest W. Brown, MC USN, Senior Medical Officer, Navy Yard, New York; Col. Frederick L. Smith, Med. Res. USA, Rochester; and Captain Robert O. Pearman, Med. Res., St. Joseph, Missouri.

In Memoriam

John Rishmiller

Dr. John Rishmiller, Minneapolis surgeon for many years, passed away at the home of a nephew in Gibbon, October 15. He was seventy-four years old.

Dr. Rishmiller was chief surgeon of the Soo Line Railway in Minneapolis for a long period, but severed his connection several years ago when he retired from practice. He had made his home in Gibbon since last spring.

Dr. Rishmiller was vice president of the Hennepin County Medical Society in 1912.

Charles Alex Van Slyke

Dr. Charles Alex Van Slyke, one of the first ophthalmologists to practice in Saint Paul, died Sunday, July 21, 1940.

Dr. Van Slyke's father, William A. Van Slyke, came to Minnesota Territory in 1859, was active in politics, and is said to have been the father of the park system in Saint Paul.

Charles A. Van Slyke was born December 14, 1865. He received his education at the Franklin School and later attended Shattuck Military Academy at Faribault where he was a member of the football and baseball teams. In 1887 and 1888 he attended medical lectures at the Saint Paul Medical College and in 1889 at Cooper Medical College, San Francisco.

In the winter of 1890, Dr. Van Slyke made a trip to the South Sea Islands. He wrote a short description of the trip and made an interesting collection of shells from the islands.

Dr. Van Slyke received his medical diploma from the Medical School of the University of Minnesota in 1891. He spent part of the year 1892 in study abroad. Upon his return he studied during the years 1893 to 1895 at the New York Ophthalmic and Aural Institute. He was house officer at Knapp Hospital for Eye, Ear, Nose and Throat in 1894. He then returned to Saint Paul and began the practice of his specialty with his brother, Dr. Fred Van Slyke. He had offices in the Kendrick Building, Baltimore Block, Endicott Building and the Lowry Medical Arts Building. He was in active practice until 1936 when he sustained a cerebral accident. He later established an office at his residence. A second cerebral accident in 1940, followed by a hip fracture from a fall, proved fatal.

Dr. Van Slyke belonged to the Saint Paul Rod and Gun Club for many years and was president of that club in 1911. He was a member of the Royal Arch Masons for many years and was a thirty-second degree Mason and a Knight Templar. He was president of the Junior Pioneers in 1919. In early life he was a member of the Minnesota National Guard.

Dr. Van Slyke was a member of the Minnesota Academy of Ophthalmology, the Ramsey County Medical Society, the Minnesota State and American Medical Associations.

Dr. Van Slyke married Anna C. Perrior in Saint Paul, December 15, 1902. He is survived by his widow, a son, Charles Alex Van Slyke, Jr., of Milwaukee and a daughter Mrs. Ralph Coggeshall of Plainfield, New Jersey, a brother, Kenneth, of Saint Paul and a sister, Grace, of Saint James, Minnesota.

He had many loyal patients and friends.

—JAMES C. FERGUSON.

J. Thornwell Witherspoon

Dr. J. Thornwell Witherspoon, a member of the Hennepin County Medical Society and editor of *Modern Medicine*, passed away recently at the Norwalk Hospital in Norwalk, Connecticut.

He was a contributor to medical literature, having published more than fifty articles and many abstracts in leading gynecological and surgical journals. His latest medical textbook, "Clinical Pathological Gynecology," was published in 1939.

Born in New Orleans in 1900, he was graduated from Princeton University and spent two years at Oxford on a Rhodes scholarship. He received his M.D. degree at Johns Hopkins University.

Victor A. Young

Dr. Victor A. Young passed away August 20, 1940 at his home in West Duluth, Minnesota, after an illness of three years.

He was a native Minnesotan, born at Amor, Minnesota, April 21, 1875. In 1903 he received his M.D. degree at Hamline University. The year before his graduation he was married to Mary Alice Jones, a daughter of a pioneer physician, at Battle Lake, Minnesota. This companionship was interrupted by the death of Mrs. Young in February, 1930. The responsibility of two daughters and two sons fell on Dr. Young's shoulders. In August, 1935, he married Susan A. Isaacson of Fergus Falls, Minnesota, who together with his children survive him.

Dr. Young's first practice was at Scanlon, Minnesota, which, at that time, was a lively lumbering town. Here he remained for two years and then moved to Hankinson, North Dakota. In 1915 he located in West Duluth, Minnesota, and continued his practice there until his death.

Dr. Young will be remembered for his devotion to his work and his kind sympathy and understanding.

REPORTS and ANNOUNCEMENTS

MEDICAL BROADCAST FOR NOVEMBER

The Minnesota State Medical Association broadcasts weekly at 11:00 o'clock every Saturday morning over Station WCCO, Minneapolis, Station WLB, University of Minnesota, and KDAL, Duluth.

Speaker: William A. O'Brien, M.D., Professor of Preventive Medicine and Public Health, Medical School, University of Minnesota.

The program for the month will be as follows:

November 2—Eye Injuries

November 9—Glaucoma

November 16—The Cross-eyed Child

November 23—Cataracts

November 30—Children's Dentistry

UNIVERSITY OF CHICAGO POSTGRADUATE COURSES

The Department of Obstetrics and Gynecology of the University of Chicago and the Chicago Lying-in Hospital, through the coöperation of the Children's Bureau, U. S. Department of Labor and the Illinois State Department of Public Health, offers five postgraduate courses of four weeks each between January 6 and June 21. The beginning dates of each are: January 6, February 10, March 17, April 21, and May 26. All the members of the department and all services and units of the institution participate in the instruction. Only a limited number of postgraduate students are accepted for each period. A deposit of \$25.00 is required, of which \$10.00 is returned on completion of the course. All communications should be addressed to: Postgraduate Course, 5848 Drexel Avenue, Chicago, Illinois.

AMERICAN PUBLIC HEALTH ASSOCIATION

The registered attendance of the 69th Annual Meeting of the American Public Health Association and meetings of related organizations held in Detroit the week of October 7 was 3,187, second largest in the Association's history. Delegates came from every State in the Union, the District of Columbia, Alaska, Hawaii, Puerto Rico, Canada, Cuba, Mexico, Denmark, China and New Zealand.

The officers elected for the year 1940-1941 are as follows:

President: W. S. Leathers, M.D., Nashville, Tenn.

President-elect: John L. Rice, M.D., New York, N.Y.

Vice President: Robert D. Defries, M.D., Toronto, Can.

Vice President: Charles Edward Finlay, M.D., Havana, Cuba.

Vice President: Selskar Gunn, New York, N. Y.

Treasurer: Louis I. Dublin, Ph.D., New York, N. Y.

Chairman of Executive Board: Abel Wolman, Dr. Eng., Baltimore, Md.

Executive Secretary: Reginald M. Atwater, M.D., New York, N. Y.

A Committee on Public Health in the National Defense was appointed with the following personnel: W. S. Leathers, M.D., Chairman; Stanley H. Osborn, M.D.; Huntington Williams, M.D.; Abel Wolman, Dr. Eng.

Among the resolutions passed was one emphasizing the necessity for maintaining civilian health as essential in national defense and pledging the united support of members to the national defense and to the maintenance of health in a free people.

The 70th Annual Meeting will be held in Atlantic City, N. J., in October, 1941.

ALUMNI ASSOCIATION OF THE MAYO FOUNDATION

Dr. Porter P. Vinson of Richmond, Virginia, was elected president of the Alumni Association of the Mayo Foundation at its twenty-second annual meeting in Rochester last month.

Other officers are Dr. William H. Long of Fargo, North Dakota, first vice president; Dr. J. Blackford of Seattle, Washington, second vice president; Dr. Ernest L. Meland of Minneapolis, secretary. Dr. D. M. Masson of Rochester was re-elected associate secretary and treasurer. Dr. John M. Berkman of Rochester was elected to the board of governors.

Named to the advisory board for three-year terms were Dr. J. M. Culligan of St. Paul, Dr. George D. Mahon of Dallas, Texas, Dr. Robert W. McQuay of Toronto, Dr. Charles H. Leech of Lima, Ohio, and Dr. Lindon Seed of Chicago.

MINNESOTA PATHOLOGICAL SOCIETY

Two papers will be presented at the meeting of the Minnesota Pathological Society, November 19, at 8 p. m. in the amphitheater of the Institute of Anatomy at the University of Minnesota. Dr. R. G. Green will present a paper, "The Nature of Virus Infections," and Dr. John M. Adams, "Epidemic Virus Pneumonia in New-Born Infants."

WABASHA COUNTY MEDICAL SOCIETY

Dr. D. G. Mahle of Plainview was elected president of the Wabasha County Medical Society, succeeding Dr. E. W. Ellis of Elgin, at the society's annual meeting in Plainview, October 10.

Dr. Robert A. Glabe of Plainview was elected vice president, and Dr. W. F. Wilson of Lake City was re-elected secretary-treasurer. Dr. E. C. Bayley of Lake City was named a delegate to the State Association, and Dr. Ellis of Elgin was named alternate. The board of censors is composed of Dr. R. R. Hendrickson of Wabasha, chairman; Dr. Mahle, and Dr. W. J. Cochrane of Lake City.

The business session preceded a duck dinner, at which there were thirty-three guests. Following the dinner, there was a scientific session.

WEST CENTRAL MEDICAL SOCIETY

At the annual meeting of the West Central Medical Society held in Morris, October 9, Dr. F. W. Behmler of Morris was elected president, and Dr. Otto Bergan of Clinton, vice president. Dr. H. Linde of Cyrus was re-elected secretary-treasurer. Named as delegate to the State Association was Dr. C. I. Oliver of Graceville. Alternate is Dr. Charles Bolsta of Ortonville. Dr. N. F. Doleman of Tintah was elected censor for three years.

Dr. E. M. Elsey of Glenwood is the retiring president.

At the meeting a medical fee schedule was adopted by the society.

Dr. B. W. Jarvis of Lowry was accepted as a member of the society.

WOMEN'S AUXILIARY

MRS. A. C. BAKER, Fergus Falls, *President*

MRS. E. V. GOLTZ, 2259 Summit Avenue,
Saint Paul, *Publicity Chairman*

The first fall board meeting of the Women's Auxiliary of the Minnesota State Medical Association was held Friday morning, October 4, in the Center for Continuation Study at the University of Minnesota. Mrs. M. A. Nicholson, state president, presided. Following the business meeting, luncheon was served. Mrs. Wm. B. Roberts of Minneapolis was the social chairman for the day.

It was gratifying to have a splendid attendance. Considerable enthusiasm was shown and an eagerness for the new season's work. Members of the board were guests of the Hennepin County Auxiliary at the open meeting and tea held at the home of Mrs. J. F. Curtin on West Lake Boulevard, following the board meeting.

On Monday, September 30, Mrs. J. J. Ryan of Saint Paul was hostess at an informal breakfast in honor of the national president, Mrs. V. E. Holcombe, who was passing through Saint Paul.

Sincerest sympathy is extended to Dr. Richard R. Cranmer of Minneapolis in the recent death of Mrs. Cranmer who had endeared herself to members of the Auxiliary. Her untimely death, occurring after several weeks of illness, has been a blow not only to her own Hennepin Auxiliary, but to the state board as well. She was a most enthusiastic Auxiliary worker and was also active in the P.E.O. and other organizations.

Mower County Auxiliary recently held its first meeting which was followed by luncheon with twelve members present.

Washington County Auxiliary reports the election of new officers as follows: Mrs. F. M. McCarten, president; Mrs. Gertrude Stevens of Lake Elmo, vice president, and Mrs. C. H. Sherman of Bayport, secretary and treasurer. There were eleven members present at the meeting which was held at the home of Mrs. Landeen.

BOOK REVIEWS

Books listed here become the property of the Ramsey, Hennepin and St. Louis County Medical libraries when reviewed. Members, however, are urged to write reviews of any or every recent book which may be of interest to physicians.

OBSTETRICS IN GENERAL PRACTICE. J. P. Greenhill, B.S., M.D., F.A.C.S. Professor of Obstetrics and Gynecology, Loyola University Medical School, Chicago; Professor of Gynecology, Cook County Graduate School of Medicine; Attending Gynecologist, Cook County Hospital; co-editor Year Book of Obstetrics and Gynecology; author of Office Gynecology. 448 pages. Illus. Price, \$3.50, cloth. Chicago: Year Book Publishers, 1940.

VITAMIN THERAPY IN GENERAL PRACTICE. Edgar S. Gordon, M.D., M.A. Associate in Medicine and Instructor in Physiological Chemistry, University of Wisconsin; and Elmer L. Sevringhaus, M.D., F. A. C.P. Professor of Medicine, University of Wisconsin, editor Department of Endocrinology, Year Book of Neurology, Psychiatry and Endocrinology. 258 pages. Illus. Price, \$2.75, cloth. Chicago: Year Book Publishers, 1940.

THE 1940 YEAR BOOK OF PUBLIC HEALTH. Edited by J. C. Geiger, M.D., Dr.P.H. Director of Public Health, City and County of San Francisco; Clinical Professor of Epidemiology, University of California. 560 pages. Illus. Price, \$3.00, cloth. Chicago: Year Book Publishers, 1940.

METHODS FOR DIAGNOSTIC BACTERIOLOGY. A Complete Guide for the Isolation and Identification of Pathogenic Bacteria for Medical Bacteriology Laboratories. Isabelle G. Schaub, A.B., Assistant in Bacteriology, Department of Pathology and Bacteriology, Johns Hopkins University School of Medicine; and M. Kathleen Foley, A.B., Bacteriologist in Charge of the Diagnostic Bacteriological Laboratory of the Medical Clinic, the Johns Hopkins Hospital, Baltimore. 313 pages. Priced, \$3.00, cloth. St. Louis: C. V. Mosby Co., 1940.

THE PRACTICE OF MEDICINE. Third Edition. Jonathan Campbell Meakins, M.D., LL.D. Professor of Medicine and Director Department of Medicine, McGill University; Physician-in-Chief, Royal Victoria Hospital, Montreal; Formerly Professor of Therapeutics and Clinical Medicine, University of Edinburgh, etc. 1,430 pages. Illus. Price, \$10.00, cloth. St. Louis: C. V. Mosby Co., 1940.

BACILLARY AND RICKETTSIAL INFECTIONS—Acute and Chronic. William H. Holmes. Professor of Medicine, Northwestern University Medical School; Chairman Department of Medicine, Passavant Memorial Hospital, Chicago. 676 pages. Price, \$6.00, cloth. New York: The MacMillan Co., 1940.

SYNOPSIS OF MATERIA MEDICA, TOXICOLOGY AND PHARMACOLOGY. For Students and Practitioners of Medicine. Forrest Ramon Davison, B.A., M.Sc., Ph.D., M.B. Assistant Professor of Pharmacology in the School of Medicine, University of Arkansas. 633 pages. Illus. Price, \$5.00, flexible binding. St. Louis: C. V. Mosby Co., 1940.

A TREATISE ON MEDICOLEGAL OPHTHALMOLOGY. By Albert C. Snell, M.D. Lecturer in Ophthalmology, School of Medicine and Dentistry, University of Rochester; Consultant in Ophthalmology, Strong Memorial Hospital and Rochester General Hospital; Ophthalmologist Park Avenue Hospital, Rochester, N. Y., etc. 312 pages. Illus. Price, cloth, \$6.00. St. Louis: C. V. Mosby Co., 1940.

A TEXTBOOK OF MEDICINE BY AMERICAN AUTHORS. Edited by Russell L. Cecil, Professor of Clinical Medicine, Cornell University Medical College. Associate Editor for Diseases of the Nervous System, Foster Kennedy, Professor of Clinical Neurology, Cornell University Medical College. 5th Edition. Philadelphia and London: W. B. Saunders Co. 1940. Price \$9.50.

Previous editions of the textbook have rightly earned great popularity, especially among younger members of the profession. The fifth edition, which has just appeared, contains a number of new articles on subjects not covered in previous editions and a number of rewritten articles on subjects previously covered. Other articles have been brought up-to-date and new illustrations have been added.

On the proper assumption that no one individual can know or present in a textbook all that is known in the field of medicine, the editor has obtained the services of some 130 teachers of medicine in university medical colleges who have written on various subjects of particular interest to them, and the result is a particularly fine volume for the undergraduate medical student or the medical practitioner. This method of textbook writing obviously adds to the up-to-dateness of a volume and that applies to the present volume. The editors are to be congratulated.

C. B. D.

CLINICAL HEART DISEASE. Samuel A. Levine, M.D., F.A.C.P., Assistant Professor of Medicine, Harvard Medical School. Second Edition. 495 pages. Illus. Price \$6.00. W. B. Saunders Company, 1940.

Levine's second edition of his "Clinical Heart Disease" is a book written by a clinician for clinicians. It is a clear, concise monograph on modern cardiology. This is no treatise on cardiac physiology, nor does it contain unnecessary pages of references. It is a book which reflects years of experience in cardiology, and it gives to the reader the practical results of the author's knowledge. The book is well written and easy to read. Levine's monograph is highly recommended both for students and practicing physicians.

M. J. SHAPIRO, M.D.

SYMPTOMS OF VISCERAL DISEASE. F. M. Pottenger, A.M., M.D., LL.D., F.A.C.P. 5th edition. 442 pages. Illus. Price \$5.00. St. Louis: C. V. Mosby Co., 1938.

The author is one of the real pioneers in a fundamental and consistently neglected field. In some teaching institutions his approach to the character of disease is almost heresy. His broad view axiomatically precedes the opening chapter in these words: "There is a patient who has the disease as well as the disease which has the patient."

Dr. Pottenger is a chronic abstainer from the evils of dogma and the empiric modus operandi. He is a sincere champion of the constructive evolution of medical practice. This is evidenced by one sentence in his

introduction to this edition: "Nearly every chapter has been partially or wholly rewritten." Those of us, whose privilege it is to know him, understand this to convey his consistent dissatisfaction with our limitations. He remains dissatisfied with such routine practice as considering a case complete by virtue of an accepted diagnostic name and, arbitrarily given, more or less effective accepted therapy. He cares more for the physiologic bedrock than the nominally polished but meaningless superstructure.

For simple illustration, some are appeased by such a term as "nervous stomach." He would like to know where the nervousness originates and how it operates. Is it central, sympathetic, parasympathetic, endocrine, humeral, or what, and if so, why?

Through all the areas and systems of the body this insatiable curiosity stalks. His answers are by no means complete or wholly adequate (nor are anyone's), but his search could be a source of stimulation to anyone with a will or a desire to pursue truth or allow a well deserved vacation to his suppressed analytic intellect.

ROBERT LYMAN NELSON, M.D.

OPERATIVE SURGERY. J. Shelton Horsley, M.D., LL.D., F.A.C.S., Attending Surgeon, St. Elizabeth's Hospital, Richmond, Va., and Isaac A. Bigger, M.D., Professor of Surgery, Medical College of Virginia, Surgeon-in-chief, Medical College of Virginia Hospitals, Richmond, Va. Fifth Edition. 2 Volumes. 1,567 pages. Illustrated by Helen Lorraine. Price \$18.00. St. Louis: C. V. Mosby Company, 1940.

A two-volume work which covers the operative procedures of the authors and collaborators is not an attempt to include all surgical operations, but is rather to a considerable extent a record of the author's personal experiences.

Among the new procedures described are ligation of the patent ductus arteriosus, segmental pneumonectomy, and extrapleural pneumothorax. Segmental pneumonectomy is a recent development in the surgical treatment of bronchiectasis and extrapleural pneumothorax appears to have a distinct place in the surgical treatment of pulmonary tuberculosis. The chapter on peritonitis in which the pathology, symptoms and treatment of the various types of peritonitis are considered is of great interest.

Blood banking, the use of Mueller's solution and Elman and Weiner's method of giving amino acids for protein replacement are described. Clute's incision is given for exposing the diaphragm, the terminal esophagus, and the cardiac end of the stomach. A new tube gastrostomy is described which may be used as a substitute for the intranasal Jutte or Levine tube.

The treatment of appendicitis is considered in great detail, and the most recent statistics are given.

Operations for lesions of the intravertebral discs and hypertrophy of the ligamentum flavum are described and illustrated, as also is the treatment for bronchial asthma by division of the sympathetic and parasympathetic nerves in the root of the lung.

The section of plastic surgery is especially well il-

lustrated. Operations for webbed fingers, the repair of harelip and cleft palate deformities, descriptions of pharyngoplasty, operation for ptosis of the eyelids, operations for rhinophyma, and the tubed pedicle flaps are described and illustrated.

In the section on orthopedics the new technic for nailing intracapsular fractures of the hip, a bone peg for ununited fractures of the carpal scaphoid, Schanz's osteotomy, McMurray's osteotomy, Stein's operation for hallux valgus, a new operation for hammer toe, operations to equalize the length of the lower extremities, Ober's fasciotomy for sciatica, an operation for unstable knee, Smith-Peterson's incision for exposure of the hip, Campbell's new shelf operation at the hip, and a new operation for acromioclavicular dislocation are described.

Gynecologic surgery is not touched upon in this work.

H. J. PRENDERGAST, M.D.

NEW AND NON-OFFICIAL REMEDIES, 1940. Containing descriptions of the articles which stand accepted by the Council on Pharmacy and Chemistry of the American Medical Association on Jan. 1, 1940. Cloth. Price, postpaid, \$1.50. pp. 656-LXVIII. Chicago: American Medical Association, 1940.

Each year a revised list of the articles which stand accepted by the Council on Pharmacy and Chemistry of the American Medical Association as of January first is published in book form under the title of "New and Non-official Remedies." The book contains the descriptions of acceptable proprietary substances and their preparations, proprietary mixtures if they have originality or other important qualities, important non-proprietary non-official articles, simple pharmaceutical preparations, and other articles which require retention in the book.

A list of articles and brands accepted by the Council, but not described, is included in the book to cover simple preparations or mixtures of official articles (U.S.P. or N.F.) marketed under descriptive, non-proprietary names for which only established claims are made. Diagnostic reagents which are not used in or on the human body, and protein diagnostic preparations are not included in New and Non-official Remedies unless the determination of the status of these products by the Council has been requested by the distributor: If such products are found to be marketed in accordance with the Council's rules, they may be included in the list of undescribed, but acceptable articles.

New and Non-official Remedies is a practical and condensed text of pharmacology and therapeutics; it contains scientifically elaborated standards for all accepted non-official drugs; its Index to Distributors is a list of manufacturers, a large number of whose products have met the Council's high standards; its Bibliographical Index is a storehouse of references to reports which have been made mainly on unaccepted and unacceptable drugs; its prefatory material contains the

Council's "Rules," a time-tested and reliable set of basic principles for the furtherance of scientific and rational medicine.

A supplement to the annual volume of New and Non-official Remedies is published twice a year to bring up to date such current revisions and additions as have been necessary since its last publication. Every product included in the book is subject to the official rules of the Council. The comments to rules are changed occasionally by way of clarifying interpretation to insure fair consideration of all submitted preparations as new standards are recognized. Such constant and critical consideration of its contents provides the physician with a valuable reference list of acceptable new preparations on which to base his selection for use in treatment according to the established current practices of the profession.

The 1940 New and Non-official Remedies, of course, contains the revisions which appeared in the supplements for the 1939 edition, and continues the plan of grouping together articles having similar composition or action under a general discussion. These discussions have undergone considerable revision in the 1940 edition. Further revision of statements regarding the actions, uses, dosage, composition, purity, identity, strength or physical properties of many of the articles has also been necessary in some cases. Noteworthy re-

visions are those of the chapter on Liver and Stomach Preparations, radically rewritten and including a statement of requirements suggested by findings of the Anti-Anemia Preparations Advisory Board of the U. S. Pharmacopeia; the subsection Tuberculin, entirely rewritten to conform to newer knowledge in this field; and the chapter Allergenic Protein Preparations, the name of which has been changed to Allergenic Preparations. Minor but relatively important revisions are found in the articles: Bismuth Compounds, Serums and Vaccines, and Vitamins and Vitamin Preparations for Prophylactic and Therapeutic Use.

The indices of the new volume of New and Non-official Remedies are of the same order and plan as in previous editions. A general index lists accepted articles, including those not described. This is followed by an index to distributors in which appear all the Council accepted articles listed under their respective manufacturers. Finally, a bibliographical index is added for listing proprietary and unofficial articles not included in N.N.R. This includes references to the Council publications concerning each such article as has appeared in *The Journal of the A.M.A.*, *Reports of the Council on Pharmacy and Chemistry*, *Propaganda for Reform*, Vols. 1 and 2, or *Reports of the A.M.A. Chemical Laboratory*.

CASE REPORT

HISTAMINASE IN THE TREATMENT OF URTECARIA OF PREGNANCY

(Continued from page 797)

cluding phenobarbital, bromides, nembutal were used in large doses to alleviate the marked distress of the patient who, by this time, was getting very desperate. The condition became so severe that therapeutic abortion was seriously considered as the patient's mental condition was steadily deteriorating and the skin was one mass of urticaria wheels and excoriations.

On March 11, 1940, histaminase was tried. Ten units were given with water four times a day before meals. Within twenty-four hours the skin became quite clear and the itching a great deal alleviated though not entirely gone. By keeping on this regime, a fair amount of comfort could be obtained. On March 27, 1940, the patient had a painless hemorrhage. A diagnosis of placenta previa was made and a cesarean section was performed by Dr. A. Hoaglund. Twin girls were delivered without complications and a central placenta

previa was found. Immediately after delivery, the urticaria and itching disappeared entirely though the histaminase was discontinued just previous to operation.

Comment

A case is reported of urticaria of pregnancy which was apparently helped by histaminase after all other means tried had failed to give any relief.

THE INDICATIONS FOR EXCRETORY UROGRAPHY*

B. H. NICHOLS, M.D.
Cleveland, Ohio

I CONSIDER it a great honor to present the Carman Lecture for the Radiological Society of Minnesota, especially when I recall the list of distinguished roentgenologists who have preceded me in delivering this lecture.

It was my good fortune and great pleasure to have known Dr. Carman intimately for a number of years. He was a great roentgenologist and clinician with a kindly, unselfish spirit. He was always willing to give any information he had which would be useful to his fellow practitioners and helpful to humanity. This great compassion and tolerance exemplified the character of Dr. Carman. He was a pioneer in radiology and contributed greatly to its success and development by his teachings and writings. It is with some timidity that I address you on "The Indications for Excretory Urography," for I feel that it will not be of sufficient quality to represent the man in whose name this lecture was founded.

The development of a media which can be introduced into the body and excreted by the kidneys greatly simplifies the diagnosis of diseases involving the urinary tract. Excretory urography makes possible the correct diagnosis and treatment of lesions which heretofore have not been diagnosed, or have been allowed to reach an advanced stage of development before their nature was determined. This examination can be carried out wherever a roentgenologist is available, which I believe is the case in the majority of hospitals in the United States.

The urinary tract frequently is the seat of disease without definite evidence of abnormal

changes. With symptoms closely resembling diseases of other organs, it becomes necessary to be "kidney minded." Abnormal changes in the urinary tract as a cause of symptoms must be excluded before surgical intervention, particularly in those cases without a clear-cut chain of symptoms of the disease for which operation seems indicated. Because of the complex structure of the sympathetic nervous system, fibers from the upper ureters, for instance, may refer pain to the gall bladder or colon. If a stone in the upper ureter moves further down the ureter, the reflex mechanism may transmit impulses to the appendix, ovaries and other organs. Many patients have been submitted to appendectomy when the correct diagnosis was found to have been a ureteral calculus or intermittent hydronephrosis.

A short history of the development of excretory urography may be of interest. Retrograde pyelography, or the visualization of the kidneys by the introduction of opaque media through a catheter, was introduced by von Lichtenberg in 1904, at which time he acted as the guinea pig for this experiment. Soon after, he realized the possibility of making such an examination by the introduction of the media into the blood stream. However, no practical application was developed until 1923, when Rowntree demonstrated excretory urography with the use of sodium iodide solution. When it was found, however, that this was not the ideal media for such an examination, von Lichtenberg's laboratories again began the study of media with urea bases and the combination of iodine, known as the selectan groups, and uroselectan was finally perfected by von Lichtenberg and Swick. Since

*From The Cleveland Clinic, Carman Memorial Lecture delivered at the annual meeting of the Minnesota State Medical Association, Rochester, Minnesota, April, 1940.

that time other preparations, particularly skiodan and diodrast, have been used extensively and have produced practical results.

The application of these preparations in excre-

stricted during this time. The patients are not instructed to retain bladder urine which we think has some influence on the kidney function. This is the technic used in the routine examination.

Fig. 1. Woman, aged thirty. Soreness in the right upper quadrant for six to eight years. A mass the size of a grapefruit was palpated on the right side. No hematuria. Nephrectomy was performed, and the pathological diagnosis was hypernephroma. The patient was well eight years without recurrence.

Fig. 2. Man, aged forty-seven. Intermittent pain in upper left quadrant for five years which was relieved by lying down. Excretory urogram shows hydronephrosis of the left kidney. A plastic operation on the stricture of the upper ureter relieved symptoms. Subsequent nephrectomy was necessary, however, because of the recurrence of symptoms.

tory urography has varied greatly. After the introduction of the media into the blood stream, many attempts were made to block the ureters artificially, to place the patient in a Trendelenburg position, or to dehydrate the patient. Such procedures were attempts to produce results similar to retrograde pyelography, which is applicable only in a very limited number of cases, especially when a retrograde pyelogram cannot be done.

By excretory urography, we are able to demonstrate anomalies and actual pathological changes in the kidney pelvis and ureters. A study of the dynamics of the kidneys and ureters and the determination of the kidney function can be made with a fair degree of accuracy.

It is practical not to interfere with the natural functions of the patient, but to introduce the dye into the vein and make the initial examination of the urinary tract within the first five minutes. A second examination is made in fifteen minutes, and a third film is made in thirty minutes. The last film is made one hour after the injection of the dye. The patient's activity has not been re-

We are convinced that only by constant repetition of the technic of examination in case after case is it possible to estimate accurately the dynamics and the function of the kidneys and ureters. This standard method of examination is not so important as is the constant repetition of whichever method is adopted. If the patient has disturbed function, films are made at two and three-hour periods, which helps greatly in determining the pathology present. This method has been well described in "The Clinical Value of the Delayed Urogram," presented by Dr. Braasch at a recent meeting of the American Association of Genito-Urinary Surgeons.

The following are contra-indications for such an examination: (1) Advanced renal dysfunction; (2) advanced cardiac decompensation; and (3) allergy to iodide salt. Sensitivity to iodide is probably the most important contra-indication for the use of intravenous dye in excretory urography as some deaths due to an allergic reaction to iodides have been reported recently. A history of allergy is important, and a preliminary

test for allergic reaction should be made before the dye is introduced.

Urography is indicated: (1) In cases of advanced prostatic disease where cystoscopy is im-

plantations; (6) in the presence of vesical fistula, ureteral fistula, or vesical diverticulosis; and (7) in the presence of a stone in the ureter or kidney. If used when indicated, excretory urog-

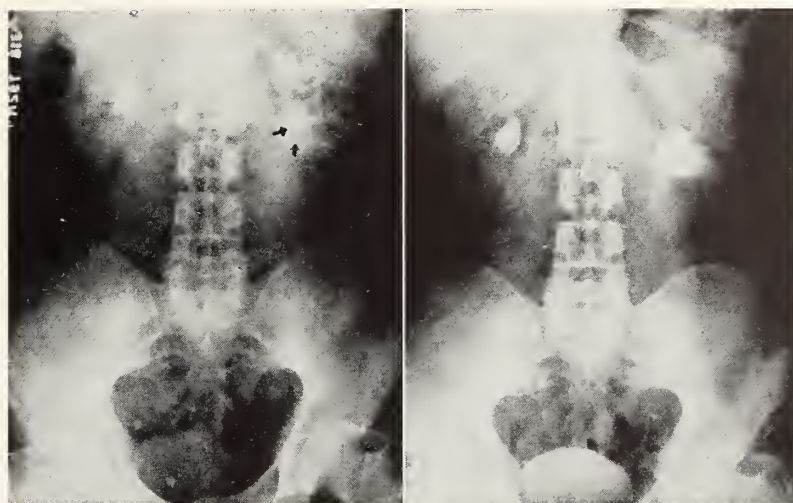

Fig. 3. *A.* Man, aged fifty-two. Recent accident to thorax and costal cartilage. A few red blood cells were found in the urine. The excretory urogram shows two non-opaque stones in the five-minute excretion from the right kidney. *B.* Thirty-minute excretory urogram obscures the stones. Pyelogram also obscured the stones.

practicable or impossible and the study of delayed function is of great help to the surgeon; (2) in cases in which it is impossible to catheterize the ureters; (3) in young patients and in the aged; (4) in the presence of hydronephrosis, nephroptosis, trauma to the kidney or ureters, and congenital anomalies; (5) in ureteral trans-

raphy makes possible the accurate diagnosis of a large group of urological diseases.

In a great majority of cases of a palpable mass in the abdomen (Fig. 1), it is possible to determine by excretory urography whether or not the kidney is involved. If the kidney is normal, the mass must be accounted for by other path-

ologic changes. Such an examination may reveal a ptosed or ectopic kidney, a tumor in the kidney, or a large hydronephrosis, all of which usually can be visualized on the excretory urogram. In-

Fig. 5. Woman, aged forty-two. A stone was removed from the ureter in 1934. Excretory urogram three years later shows a marked hydronephrosis on the right side.

termittent pain in the abdomen which may simulate gall-bladder disease or duodenal ulcer is frequently encountered and may offer a difficult diagnostic problem. Such atypical attacks of colic are often due to a mild, intermittent hydronephrosis, which may be determined best by an excretory urogram (Fig. 2). If the disease is only moderate in degree, a retrograde pyelogram may not always determine the presence of a hydronephrosis. However, kidney retention after the one-hour period may be indicated on the excretory urogram.

When roentgen examinations of the colon show no disease, symptoms referable to the colon may be due to a stone in the ureter, an opaque or nonopaque stone in the kidney, or any lesion of the kidney which may produce referred pain to the colon. Frequently, the primary lesion for a nodular infiltration in the chest cannot be determined. If the masses are large, a hypernephroma of the kidney should be considered. A destructive lesion in the bone might be a metastatic hypernephroma, and an excretory urogram in most instances will determine the presence or absence of such a lesion. The same pro-

cedure also applies to the determination of the etiological factors in an obscure anemia.

A large group of our patients with definite lesions of the kidney have had a normal urine, and the above group of cases are assumed to have been free from definite urinary symptoms.

As hematuria and pus in the urine are due to pathologic change in the urinary tract, an excretory urogram may be of help in locating the disease. However, such obviously urological cases should be referred to the urological department for cystoscopy. Excretory urography may be indicated in back pain of obscure etiology. A nonopaque stone in the kidney, a ureteral stone, a tumor of the kidney, or hydronephrosis occasionally may be the cause of such an attack of pain. The varying degrees of density of the excretory urogram from concentration of the opaque media in the pelvis (Fig. 3 A and B), will often reveal on the five minute film a stone which might be obscured entirely after one-half or one hour intervals. Likewise, the stone may be obscured by retrograde pyelography.

If the ureter is not completely blocked with the resultant nonfunctioning of the kidney, stones in the ureters (Fig. 4 A and B) are studied best by an excretory urogram. Such an examination determines whether or not the kidney is functioning, and the degree of such function. By this method, it is possible to determine the extent of damage to the corresponding kidney when the ureter contains a stone and is partially obstructed. From the patient's standpoint, the excretory urogram determines whether the physician may procrastinate, or whether the stone should be removed immediately. However, this problem should be decided by the urologist. In the presence of a stone or stones in the kidney, excretory urography to determine the presence of intermittent obstruction, or the amount of kidney damage (Fig. 5), will indicate whether or not it is advisable to delay treatment of such a condition.

Excretory urography during pregnancy may determine the cause of backache and other obscure symptoms. In such cases, the usual excretory urograms are made in the first hour period, to be followed by a film two hours after the introduction of the dye. This method will determine the degree of ureteral dilatation which often accompanies pregnancy, and may demonstrate a

marked degree of hydronephrosis in one or the other kidney.

In children with frequent urination, an early excretory urogram may reveal congenital diseases in the urinary tract. Proper treatment in an early stage may entirely relieve their symptoms and often save their lives. Likewise, large tumor masses in the abdomen in children may be located by an excretory urogram. The procedure for excretory urography in infants as described last year by Nesbit and Douglas¹ has been a great help in some diagnostic problems in children.

The purpose of this discussion has been to show some of the important procedures for the diagnosis of obscure clinical symptoms by examination of the urinary tract with excretory

urography. However, this carries with it a great deal of responsibility, and, in undertaking the interpretation of such examinations, the roentgenologist should have a wide knowledge of the pathologic changes found in diseases of the urinary tract which are demonstrable on the roentgenogram, as it is obvious that error in diagnosis may be worse than any attempt at such an examination. When properly evaluated, however, excretory urography constitutes one of the most valuable procedures in modern clinical diagnosis.

ENDOCRINE DISTURBANCES IN RELATION TO SKIN DISEASES*

FRANCIS W. LYNCH, M.D.

Clinical Associate Professor, University of Minnesota
Saint Paul, Minnesota

ENDOCRINE disturbances exert a powerful influence on the skin and its appendages and the cutaneous changes afford considerable diagnostic aid in many of the classical endocrinopathies. A review of these diseases will point out most of the important endocrine influences on the skin.

In both hypersecretion and hyposecretion of the thyroid gland and adrenal gland, the function and structure of the skin are disturbed. A dry, coarse skin and brittle nails are observed even in mild hypothyroidism and in well developed myxedema the thickened skin is still more diagnostic. In contrast, in hyperthyroidism the skin is moist and fine. Diffuse alopecia may be found in both conditions. In adrenal cortical hypofunction (Addison's disease) hyperpigmentation is almost always present and is often the most striking sign, while with overactivity of the adrenal cortex the skin may be red, dry and coarse and in some cases acne and hirsutism are prominent features of the disease. Acromegalic individuals present coarse hirsutism and pigmentary changes associated with a dry, thickened

skin showing hypertrophy of both epithelial and mesenchymal elements, occasionally manifested by the appearance of cutis verticis gyrata. In Cushing's syndrome (basophilic adenoma of the pituitary) hirsutism, acne and striae are characteristic features. Simmond's disease, resulting from loss of function of the pituitary gland, is associated with a dry skin and loss of hair. Disturbed sexual function is also observed with gonadal and adrenal cortical tumors and hirsutism may be an early sign of such disturbance. Similar characteristics are associated with tumors of the thymus or pineal body where the general overdevelopment of the body results in premature pubescence.

Analysis of these classical endocrine disturbances shows that most of the cutaneous anatomic structures and functions are directly influenced by endocrine associations. The endocrine influence on pigmentation is of the greatest importance, the adrenals having undoubted dominance over pigment production while the pigmentary changes evident in thyroid, ovarian and pituitary disease are probably due to the influence of these organs on the adrenal glands. Direct pituitary influence on pigment production in man has not been proved, though in cold-blooded vertebrates

*From the Division of Dermatology, the Medical School, University of Minnesota, Dr. H. E. Michelson, Director.

Special lecture delivered before the second annual meeting of the American Academy of Dermatology and Syphilology, Philadelphia, November 8, 1939.

the secretion of the intermediate portion of the pituitary gland has been clearly shown to influence the functional erythro-, melano-, and xanthophores.

That the character, growth and distribution of hair are more influenced by the endocrines than by any other factor may also be deduced by analysis of the classic endocrinopathies. Clinical observation and experimental studies suggest that the texture of the hair is controlled mostly by thyroid function, growth is chiefly subject to the pituitary gland and the distribution of hair is a result of gonadal activity.

Endocrine influence on the skin is by no means limited to the direct relations already enumerated. The general growth and development of the body are influenced and perhaps dominated by the pineal and the thymus. Metabolic activity is subject to thyroid function, the pituitary gland regulates water balance in the tissues and influences the metabolism of carbohydrates and lipoids, while final mastery of carbohydrate metabolism is given to the pancreas. If recent work on pancreatic hormones can be accepted then cutaneous lipoidoses and perhaps psoriasis can be related with the endocrines. The blood platelets and possibly other elements of the blood are influenced by the cyclic changes of menstruation. When one reviews these actions of the endocrine glands on the functions of the general tissues of the body, one is amazed that even more cutaneous diseases do not exhibit a closer association with endocrine disturbances.

The skin is directly influenced by vitamin deficiencies but also indirectly through their action on the gonads and possibly on other glands.⁸ A number of cutaneous diseases are characterized by sensitivity to light and endocrine disturbances are probably related to this type of sensitivity.⁵ Cutaneous hypersensitivity, in a broader sense, accounts for a large share of dermatologic conditions and the association between allergy and endocrinopathy has possibilities that have not yet been explored. That some interrelationship is present can not be doubted; hyperthyroidism is known to exaggerate allergic symptoms and estrogenic activity apparently decreases allergic tendencies.⁷

In the group of diseases which Becker regards as neurodermatoses there are many signs of endocrine activity; of these, the lowered blood pressure, vascular dilation or constriction and

emotional changes are most significant. The lowered metabolic rate is further evidence of such association. Both the central nervous system and the autonomic system are subject to hormonal influence and it is evident that perception of pain and itching are not free from endocrine control.

To review briefly, endocrine disturbances relate to skin diseases in a variety of ways. Specific influence of a number of the glands of internal secretion is manifested obviously in the classic examples of endocrine disease. Under less pathologic conditions there is nearly complete control over many cutaneous functions, especially hair growth and pigment production and all the tissues are influenced by the endocrine relation to water balance, metabolism, avitaminosis and allergy.

Clinical observation of numerous cutaneous diseases shows that the integument is affected even further. The spontaneous regression of ringworm of the scalp at puberty, the development of striæ in pregnancy and the herpetic and urticarial eruptions of pregnancy cannot be easily explained by the mechanism so far described. In other diseases the association may be less obvious but no less important.

Since the hormones act on all tissues, one might expect endocrine influence in those cutaneous diseases which are essentially systemic. Detailed discussion is of doubtful value because so little is yet known but syphilis is one disease which is without doubt influenced by the endocrines. The difference in the course of syphilis in the sexes and the favorable influence of pregnancy are well established clinical observations. In experimental studies a number of endocrine influences have been noted. As reviewed recently by Kemp⁴ one finds: (1) a more severe course in male animals; (2) a favorable influence through pregnancy; (3) the course modified favorably by administration of theelin; and (4) castration resulting in a less severe course. The importance of these observations is very evident but the instability of this knowledge is underscored in the next pages of the same journal, where Hu³ reports contradictory results after castration.

In contrast with the endocrine influence on systemic disease, an extensive systemic disease may influence the glands of internal secretion. Generalized exfoliative dermatitis exerts such a

general systemic influence and in association with this disturbance a number of endocrine abnormalities have been demonstrated. It has been suggested that these abnormalities might be the cause of the cutaneous involvement² but it appears more likely that they may be the result of the extensive disturbance of the functions of the skin.

Dermatoses Affected by the Endocrine Glands

We come now to a consideration of those dermatoses influenced by endocrine activity. It may be well to classify them into: (1) those essentially endocrine in nature; (2) those diseases where endocrine influence is obvious though other factors may be equally or more important; and (3) the cutaneous diseases where endocrine disturbance is probably or possibly of importance.

Among the cutaneous changes which are essentially endocrine are all those processes associated with the classic endocrinopathies which were enumerated at the beginning of this paper. There are in addition the more circumscribed lesions which occasionally serve as diagnostic aids in diabetes and thyroid disease. In necrobiosis lipoidica diabetorum, as in diabetic xanthomatosis, the cutaneous lesions do not result directly from endocrine influence but rather indirectly through the disturbance in nutritional metabolism (hyperlipemia). Localized myxedema is less easily explained. The characteristic nodules and plaques on the lower legs are associated with clinical hyperthyroidism but in a few cases having a more generalized distribution, the administration of thyroid substance has been followed by improvement.

There is some doubt as to the propriety of listing acanthosis nigricans as essentially endocrine, but the cutaneous as well as systemic changes are somewhat comparable with those of Addison's disease. Chromaffin tissue insufficiency is demonstrable in both conditions, but in Addison's disease the cortical hypofunction is more evident. Hemochromatosis shows resemblance to both these diseases. Though the pigment is not of cutaneous origin its deposition in the skin is often a diagnostic aid and the presence of diabetes justifies placing this condition with those having endocrine significance.

That there is a relation between the endocrines and hypertrichosis is almost certain, though in

the mild examples the endocrine abnormality may not be easily demonstrable. In more severe cases of hypertrichosis it is common to obtain a history of menstrual abnormality or thyroid disease present at the onset even if not evident at the time of examination. Certainly one should never employ electrolysis until a complete history and examination have indicated that a pituitary, ovarian or adrenal tumor is not present.

The association between the endocrines and the loss of hair is not so clear. Certainly there is no adequate proof of such a relationship in alopecia areata or in the "hereditary" type of baldness. Therapy with pituitary gland extracts failed to live up to expectations. There remains a possibility that baldness is an hereditary trait associated with some type of mild endocrine dysphrophy.

A number of rather vague and indefinite dermatoses are associated with the menses and thought to be more common when menstrual disturbances are present. It is possible that many such cases in the older literature were unrecognized examples of dermatitis medicamentosa resulting from the repeated use of analgesics or antispasmodics. The characteristic menstrual dermatoses have a tendency to occur on the face or the extremities and in many cases their urticarial or eczematous appearance suggests an allergic mechanism. The reports of clinical studies of attempts at desensitization have not been very convincing.¹ The occasional occurrence of menstrual purpura may result from the cyclic changes noted in the blood (low platelet counts) or from changes in the permeability of the cutaneous vessels.

The endocrine changes taking place at the menopause are so extensive and so variable in degree and duration that one would expect more numerous cutaneous changes to accompany them. "Hot flashes" and edema are commonly met with but are not of dermatologic interest. Pruritus is occasionally observed. Other cutaneous diseases are often aggravated at or just before the menopause but perhaps the only dermatosis characteristic of this period is keratoderma climacterium, often associated with obesity, arthritis and hypertension. The circumscribed hyperkeratotic papules on the palms and soles bear some resemblance to the keratotic changes seen in acromegaly and in hypothyroidism. The

administration of thyroid medication is reported to have a favorable action in some cases; theelin should also be given a trial.

Kraurosis vulvæ and the somewhat comparable conditions in the male appear to have a distinct relationship with the menopause and other sexual changes, though endocrine therapy is usually unsuccessful. The physiologic atrophy of the external genitalia which normally follows the menopause should not be confused with kraurosis though it doubtless has been so confused, particularly in cases where pruritus or leukoplakia were also present.

The relation of endocrine disturbances to anal and genital pruritus is far from clear. There is no doubt that the changes associated with the menopause are of importance in many cases of vulvar pruritus but in only a few cases does complete relief follow the use of endocrine therapy by injection or inunction. The general pruritus accompanying the structural and functional changes of senile skin is endocrine in a general sense though both local and systemic therapy have been of little avail.

A number of cutaneous changes are associated with pregnancy. Hyperpigmentation (linea nigra) and striae are normal accompaniments and the chloasma of pregnancy is common; the latter usually disappears within a few weeks after termination of the pregnancy. Multiple small sessile or pedunculated fibromas occasionally develop during pregnancy and usually regress or disappear on its termination. Localized or generalized telangiectases or angiomas are rare accompaniments of pregnancy. Urticaria and herpes gestationis are not common and should probably be regarded as manifestations of a toxemia. The urticaria of pregnancy may be mild and transitory but in a few cases it is extensive and the pruritus may be uncontrollable. Herpes gestationis so closely resembles dermatitis herpetiformis that many observers regard them as identical. Even in the more common herpetiform dermatitis, there is frequent association with the menses or some distinct endocrine abnormality.

There must be a relationship between endocrine disturbances and the several seborrheic states. Between acne and endocrine function there is an association but there is little evidence as to its nature. Endocrine therapy for acne has been particularly disappointing when ap-

plied routinely, though thyroid substance, estrogens, and occasionally ovarian extract, are beneficial in selected cases. There appears to be some relation between rosacea, menses and the menopause but endocrine therapy is unsatisfactory. Extensive chronic seborrheic dermatitis is not infrequently associated with endocrine disturbances but it is not known whether the relationship is causal or whether there is merely a common association with some other underlying factor.

The structure and activity of the apocrine glands are surely influenced by hormones and Fox-Fordyce disease and suppurative hidradenitis are thus subject to endocrine relations. To what extent they may be regarded as endocrine disturbances remains unanswered.

Since dryness of the skin is often a sign of endocrine disturbance, it is only natural that ichthyosis should have been suspected of a similar association. Careful study of such cases fails to demonstrate any relationship and the results of endocrine therapy are usually unsatisfactory.

Pityriasis rubra pilaris and epidermolysis bullosa may also be mentioned as having an hereditary influence and are thought by some to be of endocrine etiology, though there is little proof and the results of endocrine therapy are unsatisfactory. Vitiligo is now in a similar category but it is more possible that future studies may demonstrate some endocrine dysfunction associated with this pigmentary abnormality.

Scleroderma has long been suspected of endocrine significance and not rarely it is reported in association with one or several endocrine dysfunctions. The administration of thyroid substances and in some cases the use of estrogenic or pituitary extracts appears to be followed by improvement. The experimental studies which suggested a relationship with the parathyroid glands have not been supported by further evidence but future study may clarify this distressing disturbance.

In connection with the parathyroid glands, one must mention calcinosis because these glands have so great an influence on calcium and phosphorus metabolism. In the majority of cases of calcinosis cutis the condition seems to be a local degenerative change rather than a systemic disease; in the few cases where it is a result of systemic disturbance, it has been impossible to incriminate the parathyroid glands. There is some evidence that impetigo herpetiformis is

associated with parathyroid deficiency and responds to therapy with parathyroid extract.

Through the autonomic nervous system the adrenal glands and possibly other endocrine structures have a considerable effect on the vascular supply of the skin and on numerous dermatoses, particularly those of the face and extremities. It is certain that the following conditions are thus modified or even given predisposition: livedo, acrocyanosis, erythema induratum and various forms of pernio. There is some evidence that acrodynia is closely associated with adrenal cortical disturbance.

There are undoubtedly numerous additional dermatoses where endocrine influences might be suspected of playing a part, but I have attempted to confine my discussion to those where such relationship seems evident though not necessarily proved. In considering this group of cutaneous diseases, it would be strange if subsequent advances in knowledge should not find me mistaken in many of my judgments.

Therapy

In spite of the many examples of endocrine relation to cutaneous disease the dermatologist needs little knowledge of endocrine therapeutics. In the cutaneous disturbances associated with the classical endocrinopathies, dermatologic assistance is chiefly diagnostic.

In the specific dermatoses known to be related to the glands of internal secretion, the endocrine disturbance is rarely amenable to therapy. In most of the dermatoses associated with pregnancy few would yet be bold enough to introduce endocrine therapy. My opinion as to the relative unimportance of hormonal therapy in acne has been expressed elsewhere;⁶ in the great majority of cases of acne, rosacea or seborrhea, treatment by other means is more successful; in the few cases with demonstrable endocrine abnormality, thyroid substance, ovarian extracts, estrogenic or possibly even androgenic agents may be successful.

It is with the menstrual dermatoses that endocrine therapy may soon have its greatest application but present chemical and biologic methods of study usually fail to demonstrate the exact nature of the underlying disturbance. In those cases with additional clinical evidence it is less difficult to select the proper therapeutic agents.

If some dermatologists do not agree that ther-

apy should be left to the endocrinologists, it may be well to recall the dermatologic attitude toward the indiscriminate application of antisyphilitic drugs in years past. During the stage of development of therapeutic modalities as powerful and yet as little understood as some endocrine substances, it is best that the indications, dosage and technic be developed among one group of clinicians, later to be applied by all practitioners, as is now true with antisyphilitic agents. Endocrine therapy is becoming increasingly more rational and it is not unreasonable to hope that by the time the true association between numerous dermatoses and endocrine disturbance has been demonstrated, the proper application of therapy will not be difficult. In the meantime, the haphazard application of endocrine therapy is of little help to the patient and certainly no aid to the progress of dermatology.

Summary

Since almost every type of endocrine disturbance has some visible effect on the skin and the normal character of the skin is dependent to a large degree upon a normal endocrine system, one would expect numerous dermatoses to be closely allied with endocrine disturbance. In practice a close alliance is seldom demonstrable, though in a number of cutaneous diseases there is a distinct endocrine influence. The very large number of dermatoses whose cause and pathogenesis are unknown leaves the possibility that some may be essentially endocrine but there are only a few where this appears likely. Although it is possible that more numerous chemical and biologic studies might demonstrate such a relationship, it seems more likely that newer methods of study must first be developed.

A more rapid advance in knowledge of the obscure actions of endocrines on the skin is delayed by the expense connected with experimental work in this field and by the lack of dermatologists capable of doing this work. There is slight consolation with less rapid advances in that there will be fewer errors requiring correction later. The irregular and frequently inexplicable course in even the better known endocrine disorders should make one suspicious and not too enthusiastic in observations on the course or the treatment of individuals or small groups of patients with dermatologic disorders of doubtful endocrine significance. Reports un-

accompanied by chemical or biologic studies must be reviewed in a most critical light. In connection with the favorable reports on the use of estrogenic agents in numerous dermatoses and with desensitization in acne and "menstrual dermatoses," critical analysis and confirmation should precede general acceptance and application.

MATERNAL MORTALITY AND FORCEPS DELIVERIES

FRANK A. LA BRECK, M.D.

Eau Claire, Wisconsin

IN THE delivery of obstetrical patients, efforts are continually being made to combat infections at their source. Rectal examinations in the course of labor and locating the heart beat to diagnose the position of the fetal head are replacing vaginal examinations of former days. Other measures to insure antisepsis and asepsis include sterile draping of the patient, a ten-minute scrubbing period before putting on sterile gloves and gowns, and the wearing of masks over the nose and mouth by nurses, interns and the attending physician.

And yet, little emphasis is placed upon such a potential source of maternal infection as the application of obstetrical forceps. In 1931, at the White House Conference, Plass³ reported that, in a series of 145,812 obstetrical cases, forceps were used in 17.9 per cent. Not only is infection introduced by the operator's hands or the instrument itself, but the forceps traumatizes the mucosa and musculature of the generative canal, and thus reduces the blood supply and vitality of the tissues, creating an ideal culture medium.

One application of the forceps may carry infection into the vaginal tract and uterus. Additional applications multiply the likelihood of infection. Yet, De Lee,² in the latest edition of his book on "Obstetrics," describes a method of rotating the head from an occiput posterior to an occiput anterior position, 180 degrees, through forceps manipulations in which four separate applications are required. Vedder⁵ advocates the use of the Kielland forceps for such a maneuver.

But in the method he advises, the forceps are re-applied for each three to five degrees of rotation accomplished, thus necessitating between 30 and 60 different applications of the forceps.

Certain factors, such as pelvic types and different presentations of the fetus make the use of forceps imperative. For instance, in the android and anthropoid types of pelvis, Caldwell¹ and his associates found it necessary to reverse the Scanzoni maneuver and rotate the occiput anterior presentation to the occiput posterior position by forceps manipulations. This occurred in 23.2 per cent of their series of 215 cases.

These two types of pelvis have compensatory space posteriorly, the anterior part of the inlet being narrow. A small baby frequently will come through. But, if it passes the inlet in the posterior position, difficulty in rotation usually occurs. Consequently, when these pelvic types are recognized, the operator will find delivery of the head with forceps in the persistent posterior position the method of choice.

Furthermore, it is mechanically wrong to attempt the rotation of the fetal head from a wide diameter through a narrow one. This principle holds true in the delivery of the aftercoming head of a version and breech extraction. Hence, if it is possible, it is logical to rotate the head to an occiput posterior position in the inlet itself in order to deliver the head with the occiput posterior. Titus,⁴ in his latest book on obstetrics, advocates this procedure in the delivery of the android and anthropoid types of pelvis.

Moreover, the application of any of the forceps now in use, all of which have a fixed pelvic curve, does not allow the head to flex, extend or rotate during traction on the forceps. As a result, unnatural relations occur in the birth canal during traction with forceps. Both trauma to the baby's head and to the mucosa and musculature of the generative tract result.

With these basic and other corroborative facts in mind, the author felt there was adequate cause for continued study and improvement of all known methods of forceps usage and construction. Broadly, the question presenting itself was, "How might forceps be designed and used in order to reduce maternal, natal and neonatal deaths?" Infection and reapplication of forceps seemed the principal criteria from which arose the problem, "What are the requirements in forceps design?"

Since delivery by forceps occasions unnatural relationships between the passenger and the passage, it is the task of the designer to have forceps made in such a way that they comply as closely as possible with the natural factors which effect birth. In this connection, two essentials must be kept in mind. In the first place, it is best for both mother and child to terminate any forceps delivery as quickly and simply as possible. Secondly, as is true for all operative instruments, absolute asepsis is requisite.

On these premises, the technical problem may be summarized in the following points:

1. Rotation of the child's head should be unrestricted by the operator's grip on the forceps handle. This might be avoided by a universal joint.

2. Movement of the head in the longitudinal axis of the birth canal requires a flexible forceps to avoid injury.

3. Pressure of the blades on the head should be reduced to a minimum. The head, while in the forceps, should be free to flex, extend and rotate during traction.

4. The usual stiff bond between the head of the child and the operator's hand should be eliminated by a full universal joint.

5. Reapplication of forceps should be reduced to a minimum, which it would be by inclusion of a universal joint.

6. Simple construction, safety of manipulation and absolute asepsis are imperative.

7. The forceps blade should automatically change its pelvic curve during any rotary movement in order to follow the curve of the bony pelvis.

8. It should be an all-purpose forceps incorporating ease of application and axis traction.

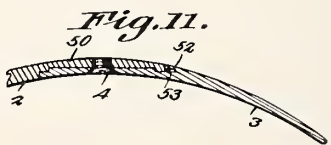

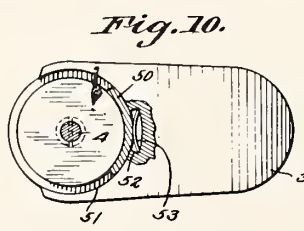

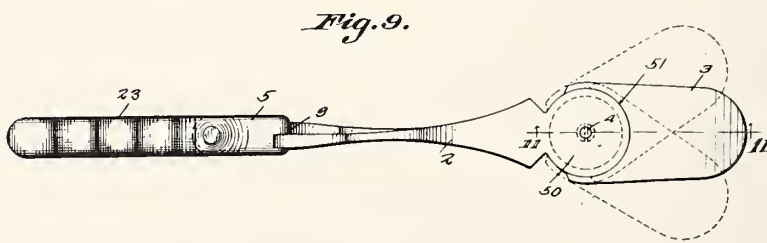

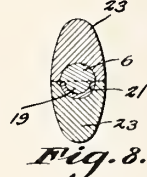

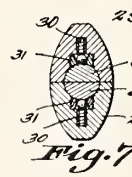

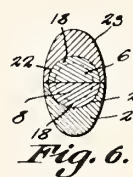

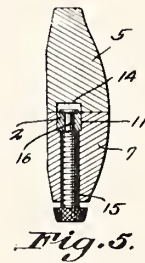

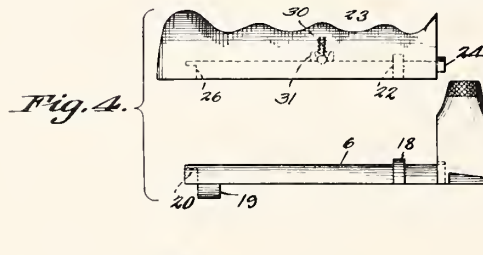

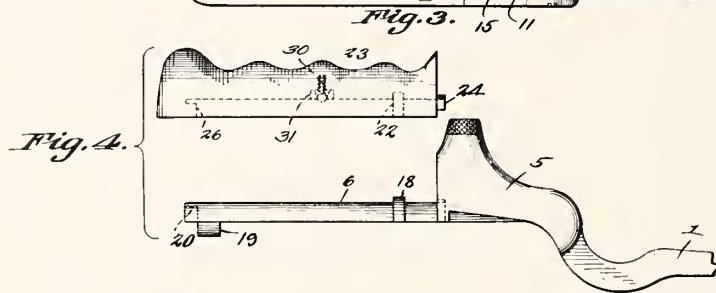

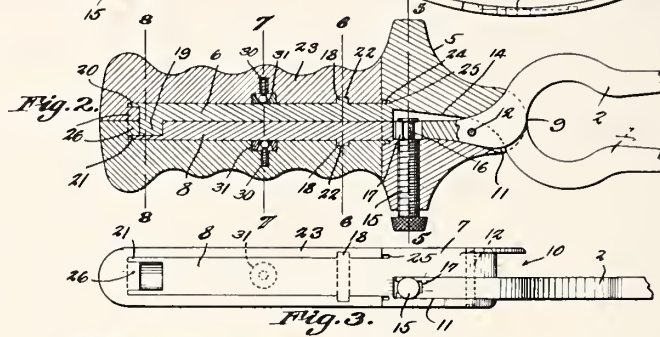

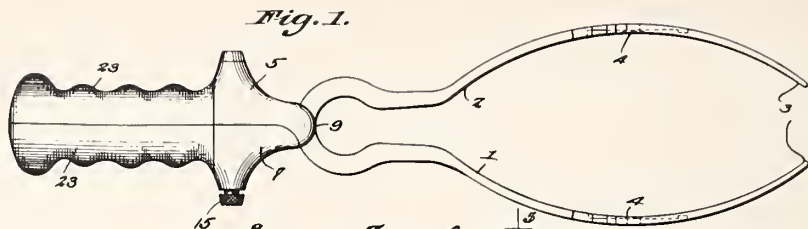

9. It should give equal dilation of all parts of the vaginal canal during traction, thus preventing deep muscular tears into the rectum.

10. By avoiding the necessity of reapplication, it should eliminate reversion of the head to its original position during rotation.

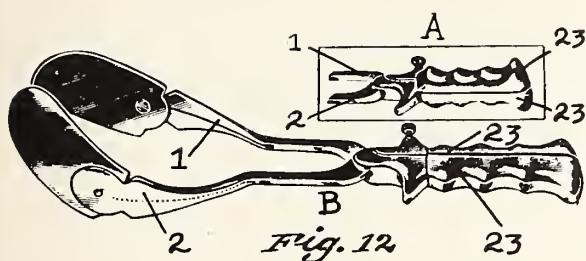

Among previously designed forceps, there is not one which solves the problem of flexion, extension and rotation of the child's head in such a manner that the entirely unhindered, yet powerful work of pulling can take place. This fact is most obvious in the forceps that have been most practical and applicable. Actually, in the most common case in which delivery with the aid of forceps is necessary, the head must rotate and the entire forceps must rotate with it. There is also no provision for flexion or extension of the head with the ordinary forceps.

With most forceps, if the operator resists the rotary tendency, the head, due to the pressure exerted upon it by the walls of the birth canal, must turn within the blades. If the physician rotates the forceps now in use, the head is injured by the blades and the soft parts of the birth canal are torn. These damages might result, even though the head is held in the forceps in the seemingly correct position. When the pelvis is normal, the forceps case may progress satisfactorily. But, if there is a deformed pelvis, the ill-effects of a so-called normal position become obvious.

Then, too, if the blades of the forceps serve only to hold the head tight or firm, as in the so-called axis traction forceps in which the handles are locked in a position by a screw and wing bolt while a special traction handle is attached to the blades, the head has more room for rotation. In this manner, it is easy to secure rotation despite the addition of extra metal arms which are awkward, difficult to apply and now seldom used. If, however, the physician holds the traction handle tightly, he hinders rotation, even though it is easier to follow the natural movement of the head with this instrument than with ordinary forceps. The one advantage of the old axis traction forceps is that by separating the pulling

mechanism from the clamping mechanism, the side pressure of the blades is reduced to a minimum. With the ordinary forceps, such as the Simpson or De Lee type, the attendant must

clamp the head with the handles while, at the same time, pulling them. It can be seen that even in the hands of the most expert, it is inescapable that the head will be compressed more than is really desired, due to the need for keeping a firm grip in the forceps.

With these criteria for the ideal forceps and the faults or disadvantages of other forceps in mind, the author has designed a new forceps, the primary object of which is reduction of fetal, maternal and neonatal mortality. These new forceps resemble De Lee's modification of the Simpson forceps. They are as easily applied, and the blades, being thinner, will occupy less space in the birth canal. The possibilities of free rotation, flexion and extension of the head, as well as the insertion of an elastic mechanism for the purpose of overcoming the friction of the head, is the goal sought.

In the Drawings

Figure 1 shows in top plan, a pair of obstetrical forceps constructed in accordance with the invention.

Figure 2 is a longitudinal section wherein parts appear in elevation.

Figure 3 is a plan view showing one member of the forceps, parts being broken away.

Figure 4 is a composite elevation showing one of the lever members of the forceps, and its grip, in spaced relation to each other.

Figures 5, 6, 7, and 8 are cross sections taken, respectively, on the lines 5—5, 6—6, 7—7, and 8—8 of Figure 2.

Figure 9 is a side elevation illustrating different positions which the blades may assume during the rotation of the head from occipital posterior to occipital anterior position, or vice versa.

Figure 10 is an elevation of one blade, wherein parts are broken away.

Figure 11 is a section on the line 11—11 of Figure 9.

Figure 12B shows position and grooves of blade locks that slide in shanks No. 1 and No. 2 for locking and releasing blades.

The forceps illustrated comprises levers 1 and 2, terminating in circular, disklike heads 50, received in correspondingly shaped recess 51 formed in blades 3, the blades and the heads being connected by pivot elements 4, for swinging movement in a direction at right angles to that in which the levers open and close. The blades are capable of assuming the positions shown in Figure 9, to facilitate (flexion, extension and) rotation of the head of the infant from occipital posterior position to occipital anterior, or vice versa. An undercut recess 52 is formed in each blade 3, and receives a bowed brake spring 53, bearing in its intermediate portion on the edge of the lever head 50 and preventing too free a movement of the blade under conditions well understood by those skilled in the art.

The lever 1 merges integrally into an enlarged body 5, having a rearwardly-extended, semi-cylindrical shank 6. A body 7 for the lever 2 is provided, and has a semi-cylindrical shank 8, corresponding to the shank 6 of the body 5. The levers 1 and 2 cross, as shown at 9, the bodies 5 and 7 of the respective levers being notched at their ends, as shown at 10, each to receive the other lever, a detachable fulcrum connection between the levers thus being afforded, as is common in the art.

The lever 2 can have relative movement, at the will of an operator with respect to the body 7, to produce opening and closing movement of the lever 2 with respect to the lever 1. This opening and closing movement is not to be confused with the opening and closing movement which the levers have at their place 9 of crossing.

The body 7 is supplied with a longitudinal recess 11, receiving the rear end of the lever 2, the lever being connected with the body, at a point intermediate the ends of the lever, and near the rear end of the lever, by a fulcrum element 12. The body 5 of the lever 1 is supplied with an internal recess 14, which, receiving the rear end of the lever 2, permits opening and closing movement of the lever 2 with respect to the lever 1, on the fulcrum pin 12. An adjusting member 15, such as a screw, is threaded into the body 7 of the lever 2, transversely thereof, the screw being provided at its inner end with a reduced neck 16, rotatably received in a notch or opening 17, formed in the rear end of the lever 2.

On their outer surfaces, the shank 6 of the lever 1 and the shank 8 of the lever 2 are supplied with transverse ribs 18, located adjacent to the respective bodies 5 and 7. On its inner or flat side, the shank 6 has a transverse, laterally projecting semi-cylindrical boss 19, and to the rear of the boss, the shank 6 is provided with a semi-cylindrical, trough-shaped flange 20. At the rear end, the shank 8 of the lever 2 is provided with a correspondingly shaped flange 21, receiving the boss 19 on the shank 6 of the lever 1.

On the shanks 6 and 8, grips 23 are mounted for rotation, transversely of the shanks, the grips having transverse grooves 22 which receive the ribs 18 of the shanks. At its forward end, each grip 23 is sup-

plied with a semi-cylindrical, trough-shaped, longitudinally-projecting flange 24, the flanges being received in correspondingly shaped grooves 25 in the rear ends of the bodies 5 and 7. Near their rear ends, the grips 23 have longitudinally extended, semi-cylindrical projections 26, the projection 26 of one grip being received within the flange 20 of the shank 6, and the projection of the other grip being received within the flange 21 of the other grip 7.

In order to prevent the grips 23 from turning too readily on the shanks 6 and 8, spring-pressed brake pins 30 are mounted for reciprocation in the grips, transversely thereof, the pins having rounded heads adapted to bear on the outer surfaces of the parts 6 and 8, the heads of the pins working through the conical bores of bushings 31, threaded into the grips.

By advancing or retracting the screw 15, the lever 2 can be adjusted in or out on its pivotal mounting 12, with respect to the lever 1, and the forceps, therefore, can be adjusted readily to the size of the head of the infant to be delivered. The grip structure 23-23 can rotate readily on the shanks 6 and 8, and thus the head has freedom to rotate within the pelvis, the head being permitted, automatically, to find the largest pelvic diameter. The device presents a structure wherein a full universal joint movement is possible. The rotary movement of the grips 23 may be regulated by exerting more or less transverse pressure upon them. The mounting of the grips 23 on the shanks 6 and 8 is such that by separating the shanks and rotating the grips, they can be taken off readily, thereby making it possible for the instrument to be taken apart and sterilized.

It will be noted, referring to Figure 12A, for instance, that if the trough-shaped grips 23 are rotated through an angle of 90 degrees, the grips will hold the forceps against opening. The physician, therefore, has within easy control a means whereby the forceps may be locked in position, against spreading.

These forceps may well be considered as new in both principle and design. The swivel, or ball joint bilaterally frees the head from any hindrance traceable to rotation, flexion or extension due to pull of the operator. The head can gradually and fully turn automatically to conform with the diameters of the birth canal in spite of the direction of the pull exerted upon it. Rotation of the head is due to the pressure of the soft portions of the pelvis, especially posteriorly. Rotation, then, is nature's attempt to adjust the fetal head to the compensatory space in the pelvis. It is possible to prevent any hindrance to the free rotation, flexion or extension of the head by the use of the new forceps. Thus, these forceps enable the replacement or substitution of natural labor powers by a forceps operation made to conform as closely as possible with natural conditions.

Most outstanding among the advantages of the new forceps is the fact that it is especially adapted to manipulate one of the abnormal positions, the occiput posterior position to occiput anterior position, or vice versa, when indicated. This is accomplished by rotating the head 180 degrees, if necessary, with but one forceps application. While this rotating movement is in progress, the blades automatically turn themselves to accommodate to the new pelvic position and to the pelvic curve. Delivery can be completed without changing the first application of the forceps or removing them. The fact that a second application of the forceps is not required during or after rotation, should minimize the chances of infections and trauma.

A lock is provided in the shanks to hold the forceps blades in a fixed position. This can be released by the operator after application of the forceps, thus allowing automatic free movement of the blades and the head during rotation and delivery.

An adjustment screw in the right handle can be set after application to a large head to prevent injury to the head from complete closure of the handles. One quarter turn of the outer handle 23, right or left, locks the blades on the head.

The new blades are designed to fit the head, and, consequently, all curves are cephalic. The blades automatically adjust themselves to the pelvic curve when necessary. This contingency is provided for by the joint near the center of the blades, which assists the blades automatically to adjust themselves to the pelvic curve during the movement of rotating the head from occiput posterior to occiput anterior position for delivery.

The author wishes to express his appreciation to the following obstetricians who have accepted the new forceps for trial and given time and effort in the various stages of its development: Drs. Paul Titus, N. J. Eastman, John W. Harris, A. H. Lahmann, H. H. Cummings, J. B. De Lee, Wm. Dieckmann, Fred L. Adair, R. M. Grier, Wm. E. Caldwell, H. C. Maloy, Hugh J. Tunstead, A. B. Hunt, and R. D. Mussey.

THE CARE OF PATIENTS PRECEDING GASTRIC OPERATIONS*

NORMAN H. BAKER, M.D.

Fergus Falls, Minnesota

PATIENTS with gastric lesions should receive individualized preparation for operation. They usually have a long story of trouble and their lesion is chronic. They are usually past middle age before they require operation, they have been on restricted diets for a considerable length of time and may be suffering from the effects of inadequate intake or assimilation of food. All of these factors can make them quite dejected, a feeling which a growling pain in their midst does little to dispel.

Patients should be placed in a hospital for a time prior to any gastric operation, excepting in the presence of perforation. They should spend at least four days to a week in the hospital. During this period much can be done to correct difficulties which constitute in a large measure the dangers of the operation.

This brief review will be confined to pre-operative measures indicated for common surgical lesions such as chronic ulcers, polypi, and malignant tumors. Patients with other lesions or complicating illnesses may require further preparation. An excellent source of information on this subject is "The Stomach and Duodenum" by Eusterman and Balfour.

Patients otherwise in good condition without stomach retention and without anemia, require no special pre-operative treatment. They frequently are anxious and discouraged. They need rest, relief from pain and want encouragement. One can go a long way to relieve anxiety and to encourage these people by emphasizing a friendly interest. Proper attention to details which may not be important to the surgeon but are to the patient, an explanation to the patient of the course of the disease which has led up to the present need for operation, a careful description of the proposed surgical procedure without dwelling too much on the matter of malignancy or dangers and complications of the operation, will almost certainly produce a happier state of mind. The ulcer patients should be kept reasonably free from pain, should have rest even though opiates be required during this preparatory stage.

Operation on gastric ulcers which are thought to be benign is not resorted to until reasonable intensive medical treatment has failed to produce healing. What constitutes intensive medical treatment must necessarily vary with the individual and the lesion. We have no criteria or combination of symptoms and findings which tell us absolutely whether a gastric ulcer is benign or malignant. Hence we do not have the freedom to spend unlimited time hoping for medical cure.

That nutritional disorders are associated with gastric lesions is frequently evidenced by loss of weight, anemia and dehydration. These disturbances faults should be corrected as far as possible. Many patients are incapable of ingesting or assimilating sufficient food prior to operation, but their nutrition can almost always be improved. Aside from obvious nutritional disorders, we now have proof that individuals with gastric lesions are prone to develop less obvious disturbances due to vitamin deficiencies and insufficient plasma protein. Holman has found that 44% of all free clinic patients in San Francisco, where citrus fruits should be abundant, were deficient in vitamin C and 14% were on the borderline of scurvy. One suspects it may be a higher figure in Minnesota. Ingals and Warren found 90% of their ulcer patients had low ascorbutic acid values in the blood. Evidently ulcer patients are prone to develop this deficiency either because of faulty diets, improper absorption of vitamins, increased destruction of the vitamins, or a combination of these factors. One primary effect on the body of low ascorbutic acid blood values is an inability to manufacture and maintain certain intercellular substances including all non-epithelial cementing substances. It has been proven that wound healing is poor in scorbutic animals.

Anker and Graham found the cause of death to be peritonitis in sixteen of fifty-one patients who died after operations upon the stomach. In twelve of these the bacterial leakage at the site of anastomosis followed an almost complete absence of fibrous tissue response along the suture line. All of which strongly suggests that adequate vitamin C may provide the "missing link" in certain unexplained surgical failures.

*Read before the annual meeting of the Minnesota State Medical Association, Rochester, Minnesota, April 23, 1940.

Holman further found that one half of his clinic patients showed vitamin A deficiency by the Hecht apparatus for stark adaptation. One effect of vitamin A deficiency is on the epithelial tissues, and we need not elaborate on the importance of healthy epithelium in surgical patients.

Vitamin B deficiency is difficult to measure but can cause atonic and weakened gastric musculature.

So it seems, then, that the pre-operative diet should include an abundance of vitamins. One satisfactory method of including this, is the daily administration of haliver oil, two capsules three times a day, four oranges and two lemons with the addition of the entire vitamin B complex in some form during the preoperative period.

Of late years evidence has accumulated that successful healing is dependent in some degree, at least, on sufficient plasma protein. Ravdin in particular has emphasized the resulting edematous stomach and disrupting wounds associated with lack of sufficient protein. Hence, we should attempt to raise the protein level to 7.5 gm. per 100 c.c. of blood before operation is undertaken. If the patient cannot ingest sufficient food, transfusion with whole blood is an effective means of increasing plasma protein.

Gastric retention is a frequent complication of these lesions and demands effective measures for control during the preoperative period. Eusterman outlines the signs and symptoms of retention as follows: "The outstanding features that denote need of treatment are dehydration, low output of urine, low blood pressure, shock-like prostration, high non-protein nitrogen content of the blood, low plasma chloride, enhanced CO_2 combining power of the plasma and in extreme cases tetany."

He further states as to the treatment: "In the management of gastric retention, feedings are given every two hours commencing at 6 A.M. and ending at 8 P. M. Each feeding consists of 200 c.c. of concentrated semi-solid carbohydrate food." Excluded from these foods are alcohol, meat broths, meat extracts and plain milk. Aspiration should be done three or four times daily before feedings, the frequency depending on the distress and amount of retention. At least 1,000 calories should be given daily. Many patients will be able to take more food and will require less frequent aspiration. As much food as possible for the patient to handle should be given

and the fluid intake should maintain the urinary output above 1200 c.c. per twenty-four hours. Certain patients will not tolerate sufficient food or fluid in this way and fluids must be given parenterally.

Occasionally, retention produces intoxication which may be very severe and may even result in tetany. Should intoxication be severe and tetany threaten, 5 c.c. of 10 per cent calcium chloride solution should be given intravenously, followed by glucose in saline. McVicar has shown how the poor condition of the patient with retention intoxication parallels the increase in blood urea, increase in CO_2 combining power of the plasma and a decrease in blood chlorides. The treatment consists of the administration of glucose and saline, combined with the measures previously outlined to relieve retention, until these factors approach normal.

The loss of weight and strength which accompany gastric retention frequently cannot be entirely replaced prior to operation. However, adequate fluid balance and reserve glycogen can be obtained, and intoxication controlled and the condition of the gastric wall improved by these measures.

Frequently these people have secondary anemia of varying degree. Sometimes this will require transfusion before operation. It is surprising, however, how well these patients with low hemoglobin values stand operation. Usually the effect of transfusion is more beneficial after the operation than before.

Occasionally repeated severe hemorrhage from a gastric lesion brings up the question of emergency surgical intervention to control the bleeding. This is always a grave situation and the matter of surgical treatment is, to say the least, debatable. Fortunately, with starvation, strict bed rest, and the use of opiates, the bleeding usually stops. Then the surgery, if indicated, can be delayed until a more favorable time.

Perforating lesions of the stomach may be subacute or "walled off" or a "slow leak." Usually these should be promptly attacked by surgical means as there is little hope that they will improve otherwise. Aspiration of stomach contents, continuous nasal suction drainage and the administration of fluids are indicated, prior to operation. If the perforation is old and considerable soiling with peritonitis has made the patient critically ill, the method used by Wangenstein of con-

tinuous aspiration, parenteral administration of fluids and subsequent drainage of the abscesses is probably safer than immediate intervention.

Acute perforation of a gastric lesion does not allow any time for preparatory treatment. Here of all places, procrastination, the desire to "make sure," the administration of fluids may cause a loss of time which more than any other factor is fatal. Aspiration of the stomach should be

done but lavage may well spread the contamination through the perforation.

Principles which apply to all surgical preparations should be followed in preparing for surgery on the stomach. High protein content in the pre-operative as well as the postoperative diet aids the healing of tissues. The mouth and upper respiratory tract should be cared for and be as free from infection as possible.

PRE-OPERATIVE PREPARATION OF THE DIABETIC PATIENT*

ARCHIE H. BEARD, M.D.

Minneapolis, Minnesota

THE diabetic patient should not be denied operative procedures because of his diabetes. He is a safe surgical risk if properly treated. Therefore, he should be allowed not only life-saving operations but those needed to make his life more comfortable. If it is a chronically infected gallbladder or appendix or hernia or relaxed perineum that needs to be repaired, there is no reason for denying such a procedure. It should be remembered that if infection is present, the diabetic condition becomes more severe, and in such instances, coma is more likely to occur. Therefore, in either chronic or acute conditions, we need to give the diabetic patient the same consideration as a normal person.

From the physician's standpoint once the diabetes is recognized the problem of treatment becomes more simplified. It is the unrecognized case that is found after surgical interference that has given the tragedy to this disease. The fault rests with the physician, and any normal surgical procedure should not be undertaken until after a complete urinalysis has been made. Remember that the patient may not be aware of his condition. This is true especially of elderly patients who have developed diabetes. Approximately one-third of the patients entering a large New York hospital were found to have diabetes for the first time when entered for a surgical condition. Only in severe infections is the treated surgical diabetic liable to die of his diabetes. It is rare for death to occur in the uncomplicated

case. However, anyone with a disturbed carbohydrate and, in turn, a disturbed fat metabolism can have a serious prognosis. It is for this reason that the coöperation between the medical and the surgical service must be very close, and the internist and the surgeon should have his definite duties assigned. Probably in a large institution the best method is to have one individual from the medical staff and one individual from the surgical staff responsible for the treatment. All cases fall into the following classifications:

1. Those in which the time of operation can be scheduled at a convenient hour.
2. Those in which the time of operation cannot be delayed, and the medical attendant must make every minute count.

Today it is generally agreed that the treatment of diabetes should be under medical management, that the best pre-operative and post-operative care is vitally important, and that, unless an emergency exists, two to three weeks should be spent in preparation for operation. In this period postoperative acidosis can be controlled completely. Each patient can be standardized on an individual diet with the necessary amount of insulin to keep acidosis and glycosuria under control. Today many cases can be controlled with only protamine zinc insulin, one injection being sufficient to cover all but slight glycosuria (one to two hours after one of the three meals). The patient in the first group should have a careful study of his cardiovascular system during this period including an

*Presented at the annual meeting of the Minnesota State Medical Association, Rochester, Minnesota, April 23, 1940.

electrocardiogram, frequent blood pressure readings, and x-ray of the chest for any cardiac or lung pathology. The ideal time for operation should be determined by blood sugar studies. Probably a blood sugar of 140 to 170 mgs. per 100 c.c. of blood is the ideal level depending upon whether the individual is young or old. In the elderly individual do not attempt to keep the blood sugar at too low a normal level because of possible cardiac embarrassment. The following rules apply to this group:

1. The amount of glucose in the diet and the total amount of daily insulin should be determined.

2. Approximately three hours before operation, one-third of the total glucose (as determined above) should be given by mouth in liquid form only. If regular insulin is used, probably one-third of the regular amount (as determined above) should be given. If protamine zinc insulin is used, allow approximately one-half or two-thirds of the total amount of daily injections. Following this procedure, it probably is safer to return to regular insulin until the patient has recovered.

3. The urine should be examined for sugar and acid bodies approximately two hours after the operation and every two hours for the next forty-eight hours.

4. Blood sugar determinations should be made about three hours and again twelve and twenty-four hours after the operation, even though the urine is free from sugar. In that way early hypoglycemia can be determined. If acid bodies are found in the urine, a carbon dioxide combining power determination should be made at this time.

5. The remaining glucose of the daily diet in the form of liquids (as determined previously) is to be administered in three equal amounts during the next twenty-four hours. If the patient is conscious and has no nausea and no vomiting, the carbohydrates may be given by mouth. Otherwise necessary food and fluids may be given intravenously, e.g., 5 per cent glucose in normal saline.

6. The amount of fluid and saline to be used depends upon the patient's general condition. If no acidosis is present, probably 3,000 c.c. will be sufficient, but if acidosis does develop it may be necessary to give as high as 5,000 c.c. to 8,000 c.c. (Observation for pulmonary edema always should be made.)

7. Twenty-four hours after the operation, place the patient on a liquid diet which can be changed gradually to semi-solid and solid food during convalescence according to the surgeon's instructions. For abdominal operations (especially of the gastro-intestinal tract), this probably cannot be done so readily. Fluid by intravenous and subcutaneous routes may be used.

8. Blood sugar determinations and urinalyses should be continued each day until the patient is established on his previous amount of insulin and his pre-operative diet.

The above group is fairly easy to treat, and the patient's progress usually is uneventful from a diabetic standpoint.

The next group of diabetic patients, however, must be carefully observed. It is in these individuals we find our diabetic tragedies, and only by careful hourly observations can dangers be eliminated. At times the patient enters the hospital in acidosis or coma, and the problem at first is a medical one. An operation may be necessary, but the surgeon hesitates to operate until the acidosis is under control. As a rule the person in this classification usually has an acute condition which may demand surgery as soon as possible. The patient usually has a septic temperature. During the time the internist is attempting to control the acidosis, the surgeon must be finding the cause of the fever and attempting, if possible, to give any pre-operative care that is necessary. During this pre-operative period, blood sugar determinations, carbon dioxide combining power determinations, blood urea nitrogens, and blood chlorides, as well as hourly urinalyses and complete blood counts should be made. Many individuals with the diagnosis of diabetic coma are unconscious from some other cause at the time of admission to the hospital, and many cases of coma are sent to the hospital under other diagnoses. The most frequent error made in a diabetic patient is to accept a diagnosis of an acute abdominal condition because of fever, nausea and vomiting, and localized abdominal pain and rigidity. These individuals may even be found to have a high white count. At times it is a problem to decide if the patient has diabetic coma with appendicitis. We all have seen individuals a few hours after operation who were operated on with two little scientific data. In turn it is not uncommon for the surgeon and the internist to meet over this type of abdominal condition. It is only after all available data can be obtained that the proper treatment can be instituted. Whatever diagnosis is made, the acidosis and coma must be treated first, and if the internist can be given a few hours the final results will be more encouraging. Whatever the cause of the acute condition, the diabetic must be treated first for acidosis. These patients often are dehydrated and in shock, and means must be taken toward clearing up the acidosis. This in turn will combat the state of shock the patient may have from his acute infection.

Only after the first urinalysis and the above blood studies have been made should insulin be used. Remember even though the patient has been known to be using protamine zinc insulin in the past, regular insulin should be used at this time in order to more rapidly relieve the acidosis. The treatment of diabetic coma is, first, to combat the dehydration, and, second, to treat the acidosis. At this time we may not be able to eliminate the glycosuria before the patient is to be taken to the operating room. However, glycosuria itself is never the cause of death in these individuals, but the amount of acidosis and shock are in direct proportion to our mortality.

In the treatment of coma the immediate need is fluid and sodium. Insulin does not exhibit its complete effect until body fluid has been restored. The treatment should be as follows:

1. The patient should have absolute rest in bed. It is advisable to have a special nurse.
2. The patient's body warmth should be maintained with blankets and hot water bottles.
3. Catheterization of the bladder probably will be necessary especially if the patient is unconscious and cannot cooperate. In this case a retention catheter should be inserted. This is not advised by all clinics, and there is some question as to whether or not it is a logical step. At the University of Minnesota Hospitals we have found that it gives us a great deal more information about the patient during the time he is unconscious and when the urine needs to be examined more frequently. The urine should be examined for diacetic acid and sugar every one-half to one hour depending upon the severity of the case.
4. Lavage of the stomach may be necessary. At times sodium bicarbonate solution may be used.
5. The lower bowel should be cleansed with an enema.
6. Fluids should be administered through all avenues. Normal saline should be given by proctoclysis and hypodermoclysis. Today sodium bicarbonate still is used in the treatment, but it should never be used subcutaneously because of the possibility of sloughing of tissue. The fluid intake and output should be measured and recorded. The fluid intake should be between 5,000 c.c. to 8,000 c.c. in twenty-four hours. Care should be taken that the patient does not develop pulmonary edema. The chest should be auscultated at intervals to determine whether this is occurring. Extrarenal uremia, which will be mentioned under prognosis, occurs as a severe complication of coma. This is due to severe dehydration, which may effect the kidneys so adversely that anuria persists even after adequate fluids have been given. Hypertonic saline or glucose may aid in reestablishing the flow of urine. After the patient has developed consciousness, fluids may be forced by mouth. Clear broth with a liberal amount of salt may be given—also tea, coffee, and water.

7. Glucose should be given in some form by mouth if the patient is conscious; if the patient is unconscious it should be given intravenously or by rectum. Generally 5 per cent glucose in normal saline is used. Hypodermoclysis of glucose is not advised in the treatment of diabetics because of the danger of infection.

8. The use of insulin depends upon the presence and the amount of glucose in the urine. A suggested routine in cases of mild acidosis is to give 40 units of insulin at once, and to follow the urine every hour as long as it is positive for sugar. Forty units can be repeated hourly as long as the reaction is four plus. Usually at the end of two to four hours the amount of insulin must be reduced to possibly 30 units, then 20 and then 10, depending upon whether the test is three plus to two plus (yellow-orange) or one plus to a trace (green). Usually one administers 100 grams of glucose intravenously (in saline solution) for every 100 units of insulin used. This is unnecessary at the outset of treatment in most cases, but it should be begun as soon as the blood sugar has come down below 0.30 per cent or before the urine sugar has become small in amount or negative. This particularly is true when ketone bodies still are present in the urine. In severe acidosis the urine should be examined every one-half to one hour for diacetic acid and glucose depending upon the length of the coma, the height of the blood sugar, and the Van Slyke determination. Usually it is necessary to allow a retention catheter to remain in place until plenty of fluids have been given and the patient has become conscious and cooperative. Another method of using insulin in acidosis is to give 1 unit of regular insulin per kilogram body weight for the first dose, following the urine every half hour until reduction with Benedict's solution is green or until the blood sugar has reached 0.20 per cent. The treatment should be continued until the acidosis has disappeared.

9. Ephedrine or adrenalin should be given for stimulation. Blood transfusion may be of aid if the degree of shock appears to be critical.

10. Alkalies should be administered. Sodium chloride is much needed in acidosis due to dehydration and vomiting. The large amounts of fluid which are given, as mentioned above, serve to reduce acidosis by eliminating ketone bodies. In order to combat the acidosis more directly, sodium bicarbonate or sodium lactate may be given intravenously. It is advisable to give 25 grams of pure sodium bicarbonate solution in 500 c.c. of distilled water allowing one-half hour for this procedure. The bicarbonate is not sterilized, but it is simply dissolved in sterile distilled water. The molar sodium R-lactate solution, which was introduced by Hartmann and bears his name, generally is used intravenously, but it can be used subcutaneously or intraperitoneally if necessary.

The prognosis of this type of case depends upon the blood findings. After reviewing the laboratory methods mentioned above, we can give,

more or less, a prognosis with the following information in mind:

1. A blood glucose of 500 mgs. per 100 c.c. of blood or higher offers a serious prognosis. The higher the blood sugar climbs, the more grave is the prognosis.

2. A Van Slyke (or CO_2 combining power of plasma) below 30 volumes per cent is of serious significance; if it is below 20, it is in a very dangerous zone.

3. A urea nitrogen which is definitely increased is of dangerous significance. High urea nitrogens are accompanied by lowered blood chlorides. These are the result of dehydration, nausea, and vomiting, and are spoken of as extra renal factors in the production of uremia. Marked hemoconcentration occurs, which is one of the most important actual causes of death. In addition the venous and arterial pressures fall. The patient may go into shock, and with this there may be anuria or marked oliguria. In other words, the lesion is not in the kidney.

4. A high leukocyte count and abdominal pain (many times suggesting the diagnosis of appendicitis), also, are serious factors. A leukocyte count of 25,000 to 50,000 is not infrequent in diabetic coma.

5. A patient in acidosis and coma with any of the high figures mentioned above and having fever is critically ill and a favorable prognosis must be withheld.

The choice of anesthesia, although not directly under the medical management, is of great im-

portance. It must be emphasized that among the general anesthetics, nitrous oxide and ethylene frequently are used. Cyclopropane has been used successfully, but ether is more or less disapproved except for narcosis of short duration. Nitrous oxide and oxygen are unsatisfactory for extensive abdominal operations because they give no adequate relaxation. Therefore, ether must be used in certain periods during anesthesia. Spinal anesthesia can be used in operations on the lower extremities and perineum.

In conclusion I want to emphasize the necessity of carefully observing the urine and blood sugar during the post-operative period. When the patient is unconscious and perspiring, it must be remembered that this may be due to hypoglycemia. Convulsions do not always occur in this stage. The alert physician will never be misinformed during this period if he relies entirely on the blood sugar studies. If the urine is not watched carefully, the patient may be treated for coma when he really should not receive any more insulin. This is true especially if protamine insulin is used. Remember the most prominent symptoms of protamine hypoglycemia are nausea, vomiting, headache, and dizziness.

PRE-OPERATIVE CARE IN SURGERY OF THE BILIARY TRACT

E. MENDELSSOHN JONES, M.D.

Saint Paul, Minnesota

LORD Berkley Moynihan often emphasized the fact that the most important person at any operative procedure is the patient. I am certain that this sentiment is reflected in the marked decrease in mortality and morbidity in some of the more serious surgical problems now treated so much more satisfactorily. There is also no doubt that the increasing amount of care and thought now given the preparation of surgical patients plays a major role in the achievement of more satisfactory results.

Cutting points out the three-fold aim of pre-operative care:

1. The establishment of a full and complete pre-operative diagnosis.

2. The minimizing of the risk incident to the contemplated procedure as such, especially by attention to the stabilization of metabolism, selec-

tion of the optimum time or operation, and the correction of such associated morbid conditions as are amenable to medical or minor surgical therapy.

3. The prophylactic treatment of postoperative complications.

When considering an elective operation, adequate time may be used in proper pre-operative preparation, but in the acute cases, one must carry out this preparation rapidly, and administer surgical aid despite possible complicating conditions.

I wish to mention a few things requiring attention in the preparation of a patient for any elective surgical procedure. Oral sepsis is frequently present, and no patient should be allowed to undergo an elective operation until this condition is carefully treated by thorough brushing

of the teeth and the use of a suitable mouthwash.

Mild respiratory infections are frequently the forerunners of severe postoperative complications, and when one such is present, the operation should be postponed until all signs of infection have disappeared.

The overweight patient is nearly always a bad surgical risk, and in an elective case should be placed on a reducing regime before being subjected to an operation. The risk in such cases is great because they often present technical difficulties and are more subject to cardiac and pulmonary complications.

In the aged, elective surgery should be undertaken only after careful balancing of the maximum possible benefit against the operative risk. Mason states that surgery which in younger persons is definitely necessary may prove only meddlesome in the aged. The pre-operative examination in the aged patient may show the various systems functioning efficiently enough, but doing so under low reserve, and the added burden of a surgical procedure is often enough to upset the balance, resulting in cardiac or renal failure. It is, therefore, necessary in the aged patient to be very careful to obtain as accurate an evaluation as possible regarding the renal and cardiac functions when considering any major surgical procedure.

Coronary disease may present a clinical picture very similar to that of gallbladder disturbance, and when this is suggested, a careful differentiation should be attempted. It may be possible to rule out one or the other, but not infrequently both conditions are present. The surgeon may thus have to perform a surgical operation in spite of the combined pathological change, but he is well guarded in his prognosis if he is cognizant of the exact problem with which he is confronted.

Close co-operation between the medical and surgical services should be carried out at all times in dealing with bad risk surgical cases. When gallbladder disease is complicated by jaundice, renal impairment is frequently encountered, calling for careful medical treatment before any major surgical procedure is attempted. This practice also applies when there is an accompanying diabetes, and because of pre-operative and postoperative supervision that is now given, the diabetic patient undergoes operations very well.

The choice of anesthetic is of great importance, particularly when one is dealing with a poor

risk. The many valuable additions and refinements in anesthesia produced in the past few years have been a great aid to the surgeon. It is very comforting to have a trained anesthetist with whom the surgeon may consult and plan the anesthesia as carefully as he plans the operation. There can be no doubt that the improved mortality figures in the more serious surgical procedures is due to improvement in anesthesia, as well as better co-operation between the anesthetist and the surgeon.

In surgery of the biliary tract, we may encounter acute and chronic conditions of the gallbladder with various complications. In every case of biliary disease there is more or less hepatic damage, and in the more severe cases it is frequently accompanied by dehydration. When jaundice is present, there is also a hemorrhagic tendency.

Recent work done at the New York Post-Graduate Hospital shows that the mortality in patients with acute cholecystitis is 15.6 per cent if operation is performed within six hours after admission. If the patient is given twenty-four hours of pre-operative preparation, the mortality is but 7.4 percent.

This emphasis dramatically the importance of thorough pre-operative preparation. It has been found that intravenous administration of five percent dextrose or glucose in normal saline solution affords a satisfactory means of supplying the needed carbohydrates to support hepatic damage, and the saline solution furnishes chlorides and fluids to overcome dehydration that may be present.

There are many surgeons who do not operate upon patients with acute cholecystitis unless the indications point to a rapid progression of the disease, suggesting a possible perforation. When this course is followed, more time is given for pre-operative preparation. The clinical course of the disease is carefully observed to determine the progress of the infection, and this is usually aided by repeated white blood counts. It has been our experience that the white cell count does not give a satisfactory indication as to the extent of the pathologic change present, and we are now relying more on the sedimentation rate for this information.

Usually cases of chronic cholecystitis presenting themselves for surgical care are in the class of patients known as "good surgical risks." How-

ever, one must bear in mind that these patients have some hepatic damage, and should be given a three to seven day pre-operative preparation. They should be given a diet high in carbohydrates and low in protein and fat, but of high caloric value. It is well to remember that cases of chronic cholecystitis having had previous attacks of acute cholecystitis may present a more serious problem and call for a more guarded prognosis.

When there is a history of gallbladder disease of long standing, there is a greater possibility of stones being present in the common duct, thus increasing the operative risk.

Jaundice accompanying either acute or chronic cholecystitis increases the morbidity and mortality rates nearly one hundred per cent. These factors must all be borne in mind when preparing a patient for such types of biliary surgery.

When jaundice is present, it is necessary to combat the hemorrhagic tendency so often present. It has been shown by several observers that the hemorrhagic tendency associated with obstructive jaundice is due to a lack of prothrombin in the blood plasma. The administration of vitamin K in addition to bile salts has been found to be most efficacious in dealing with this condition.

If the prothrombin clotting time is normal, two to six gelatin capsules each containing 200 mg. of alfalfa concentrate and one or two grams of animal bile salts, administered by mouth, is an adequate daily dose. When the prothrombin clotting time is prolonged, the dosage must be increased and continued until the prothrombin clotting time is normal. At the Ancker Hospital, we have been using Kagalin which is a synthetic vitamin K. Satisfactory results have been obtained with a dose of 2 mg. of Kagalin plus 5 grams of bile salts, four times a day.

It is often difficult to choose the advantageous

time to operate on a patient with jaundice, and it is not wise to depend on clinical grounds alone in deciding the course of the jaundice. The study of the serum bilirubin is a sensitive index to the degree and course of the jaundice, and should be depended upon rather than the appearance of the patient. If the jaundice is increasing, operation should be delayed until the patient becomes adjusted to the higher level. If it is stationary, the final decision must be made on the basis of the other clinical factors present. These patients are in the group of bad risks, and are the ones calling for all the support that can possibly be given before any surgical procedure is undertaken.

In this way, the postoperative complications will be fewer, and the mortality and morbidity rates will be kept at a reasonable low level.

It is our experience that blood transfusions are of great benefit in the pre-operative and postoperative case of patients subjected to biliary surgery. Oftentimes, it is well to give the blood pre-operatively and to have additional blood available for immediate administration should the necessity arise.

I again wish to emphasize the fact that close co-operation between the medical and surgical services is imperative in dealing with the more severe types of cases that are encountered in biliary surgery, and also to repeat Sir Berkley Moy-nihan's saying that the most important person at any operative procedure is the patient himself.

PORTAL OF ENTRY IN TUBERCULOSIS

A consideration of the portal of entry in tuberculosis brings out the following points: (1) Although alimentary infection is less common than respiratory, it is by no means a negligible factor, especially in children, quite apart from milk-borne disease; (2) in respiratory transmission, the sleeping accommodation is probably the most important single factor; (3) apart from the dust hazard industries, we still know very little about the risks of infection outside the home; (4) both alimentary and respiratory mass infections probably occur in the presence of the advanced case.—S. ROODHOUSE GLOYNE, M.D., *Tubercle*, Feb., 1940.

DIAGNOSIS OF TUMORS OF THE BREAST*

E. T. BELL, M.D.

Minneapolis, Minnesota

A CONVENIENT approach to the diagnosis of tumors of the breast is a consideration of the clinical features of the individual case. These are shown schematically in the following outlines:

I. Single Tumor

1. Adherent: Scirrhus carcinoma—95 per cent; fat necrosis; mastitis.
2. Non-adherent: Deeply-placed scirrhus; medullary or gelatinous; cystic disease; fibro-adenoma.

1. *Adherent Tumors.*—In the case of a single tumor in the breast the most important observation to make is whether or not it is adherent to the skin or deep fascia. The great majority of adherent tumors are malignant, but in rare instances an adherent growth proves to be fat necrosis or mastitis. Palpable axillary lymph-nodes strengthen the diagnosis of malignancy. Unless the diagnosis is obvious one should remove the lump and examine it before proceeding with the radical operation.

2. *Non-adherent Tumors.*—When a tumor is definitely not adherent there is an even chance that it is benign; in young women the majority are benign, in older women most of these are malignant. It is to be remembered that carcinoma is quite rare before the age of twenty-five years and very rare before the twentieth year. Deeply placed scirrhus carcinomas are not adherent and medullary carcinomas, having no fibrous tissue, do not adhere. Tumors that are unusually movable are apt to be fibro-adenomas. Cystic disease frequently appears as a single non-adherent tumor.

In this group it is imperative that the tumor be removed and examined before the operation is decided upon. An aspiration biopsy may be made if one is reasonably sure the growth is a cyst.

II. Multiple Tumors

Multiple tumors in one or both breasts are malignant when adherent and nearly always benign when non-adherent. A carcinoma that has spread through the breast assumes the form of multiple adherent masses. In rare instances a

medullary or gelatinous carcinoma appears as non-adherent masses.

Non-adherent multiple tumors usually represent cystic disease, but rarely they may be fibro-adenomas. It is usually satisfactory to remove the most conspicuous mass for microscopic examination. If cystic disease is found no further operation is indicated.

III. Single or Multiple Ill-Defined Non-Adherent Masses

These usually represent uneven involution of the breast. After repeated pregnancies some lobules do not regress as much as others. Varying proportions of fibrous tissue in different parts may also give the impression of tumors. A clinical diagnosis can usually be made and operation is seldom indicated.

IV. Acute Carcinoma

This is a highly malignant carcinoma which produces diffuse induration of the breast with adhesion to the skin. The appearances are those of an acute inflammation. There is redness, tenderness and local heat and the patient may have a low fever. This is an incurable tumor and a better palliative result is obtained by radiation.

V. Mastitis

1. *Mastitis of Puberty.*—In either boys or girls near puberty there may develop a tender indurated area in the breast. The mass is small and circular and the nipple is in its center. This is a mild self-limited process and requires only local protective treatment.

2. *Exudative Mastitis.*—These are inflammatory lesions that develop usually during lactation or pregnancy. They exhibit the characteristic features of inflammation and are treated accordingly.

3. *Chronic Fibrous Mastitis.*—Masses of fibrous tissue sometimes develop in the breast. They may have a patchy distribution or the entire breast may be converted into a firm mass. It is called fibrous mastitis but there are really no evidences of true inflammation.

*Read at the annual meeting of the Minnesota State Medical Association, Rochester, Minnesota, April 24, 1940.

In the male breast the most frequent cause of a mass is chronic fibrous mastitis. It often develops in young men.

VI. Discharge from the Nipple

1. *With a Palpable Tumor.*—Whenever a palpable tumor is found it should be removed and examined. It may prove to be a papilloma or a carcinoma.

2. *Without a Palpable Tumor.*—In these cases the discharge may be bloody or serous. When the breast is removed a small duct papilloma may be found but more often there is merely a cyst com-

municating with a large duct. There is a sharp difference of opinion as to the proper treatment of this group. I have followed several patients with a serous discharge for some years, one as long as twelve years. Malignancy has not developed.

In the diagnosis of cystic disease of the breast it is important to distinguish the adenomatous type from carcinoma. If one examines sections of the breast under low magnification benign lesions always show a definite lobulation. Under high magnification these adenomatous areas appear malignant. Adenocystic disease is neither a cancer nor a precancerous lesion.

TREATMENT OF CARCINOMA OF THE BREAST*

MAX W. ALBERTS, M.D., F.A.C.S.

Saint Paul, Minnesota

CARCINOMA of the breast because of its location and, as a rule, its early discovery, should be one of the most satisfactory malignant conditions that the surgeon is called upon to treat. But confusion has arisen in the minds of medical men as to the advice to be given a patient after cancer of the breast has been diagnosed because of the great variety of opinions regarding this subject which have appeared during the past few years. Treatment of carcinoma of the breast as elsewhere in the body predicates if possible the removal or destruction of all the cancer cells.

As in the treatment of any disease, the most important point is of course the diagnosis. All physicians are more or less familiar with the cardinal signs of malignancy, and after such a condition has been diagnosed the physician must determine the best method of attack, the one which will give the greatest promise of cure to the patient. Three methods are at our disposal when we plan such an attack: radical surgery, the use of deep x-ray therapy, and radium. The first question in the surgeon's mind is, can the lesion be treated surgically or is it obviously inoperable due to marked extension of the growth. Marked extension makes operation impractical because there is no doubt that it, in an inoper-

able situation, causes much greater harm than good.

Some years ago, Handley laid down a group of contra-indications for the operation of malignancy of the breast, and these contra-indications hold true to a great extent at the present time. Handley's contra-indications were: (1) if the primary growth has become attached to the bony thorax; (2) in the presence of subcutaneous nodules or skin infiltration situated more than two inches from the primary growth known as cancer en-cuirasse; (3) if there is a fixed growth in the axilla adherent to the thoracic wall; (4) if there is a marked edema of the arm; (5) if the supraclavicular glands are enlarged and fixed; (6) if there is evidence of visceral or bone metastases; (7) in the presence of some incurable constitutional disease, such as diabetes or tuberculosis, which is likely to be fatal in a few years; and (8) in the acute fulminating type of carcinoma.

Most of these contra-indications to operation can of course be recognized clinically and through the use of x-rays, and it is often surprising what an x-ray study will show in the presence of what appears to be a perfectly operable lesion. A case in mind demonstrates this.

A woman, aged fifty-two, with a small tumor located in the upper and outer quadrant of the left breast, which she stated had been present for about four

*Read at the annual meeting of the Minnesota State Medical Association, Rochester, Minnesota, April 24, 1940.

months, presented herself for examination. Palpation convinced us that the tumor, which was about the size of a small walnut, was malignant, and as has been our routine practice before operation is advised, a roentgenogram of the chest, and this revealed no evidence of metastases, so a radical operation was performed two days later. At that time, the growth was found to be a small scirrhous carcinoma with no evidence of glandular involvement in the axilla. Three weeks after the operation, she complained of severe pain in the back, and an x-ray study revealed the dorsal vertebrae to be studded with metastatic lesions.

As a result of this experience, our patients now have a film of the spine as well as a flat plate of the chest prior to operation.

Statistics vary a great deal in regard to the so-called cure of carcinoma of the breast by operative procedure because of certain definite factors. Following Handley's advice, some surgeons do not consider a lesion operable where nodes can be palpated in the axilla, while other surgeons attempt to operate upon these patients more or less routinely. The percentage of operative cure in this group will be somewhat lessened. It has been our policy, despite the fact that nodules can be palpated in the axilla, to advise operative interference, because very often the palpable nodules are not malignant but rather the result of some inflammatory change. It is the grade of malignancy or another as yet undetermined factor, which causes some tumors to metastasize a great deal sooner than others. Each of us has had experience illustrating this fact, and I wish to cite two rather striking cases in point.

The first is that of a woman, who at the present time is seventy-two years of age. I saw her first in 1926 because of a fractured arm. She was in the hospital for the fracture, and the interne in his routine examination discovered a tumor in her right breast. Examination of the tumor, at that time, revealed it to be about 2 centimeters in diameter, hard, and fixed to the skin. She said she had noticed it for about fourteen months. The tumor was obviously carcinoma. However, despite our urging, all forms of treatment were refused. I have had the opportunity to observe this growth up to the present time. It has been growing slowly and is now about the size of a baseball, fixed not only to the skin but to the underlying structures, evidencing, however, no axillary, supraclavicular, lung, or skeletal metastases.

The second case is that of a woman, aged forty-two, who, having two sisters with carcinoma of the breast, was naturally apprehensive and made a point of having her breasts examined at periodic intervals. She reported to us for examination in November, 1939, stat-

ing that she had noticed a small lump on the lateral side of the left breast, which to the best of her knowledge, had been present for about two weeks. The tumor was hard, appearing to be about 2 centimeters in diameter and fixed to the skin—clinically, a malignant tumor. After radiographs of the chest and spine had been found negative, radical interference was advised. We operated two days later, and despite the fact that no glands could be palpated in the axilla, numerous metastatic nodules were found in this location at the time of operation.

History of Operative Procedures

It is interesting at this time to review briefly the methods of handling breast cancers, and the steps leading up to our present radical operation. As near as I can determine, it was the Flemish surgeon Vesalius⁷ who, in 1562, reported two cases of carcinoma of the breast, with operation, although he did not publish just what type of procedure he had used. In the diary of Rev. John Ward, Vicar of Stratford-on-Avon, we find a notation that a Dr. Edwards, in the year 1650, operated upon a woman for a cancerous growth in the breast. Naturally, the entry gave no technical description of the operation. Heister,¹¹ in his book on surgery published in 1753, gives some detail as to the method of treating malignant conditions of the breast, and it is interesting to note that Heister lays some stress on the uselessness of the operation when axillary glands are involved and the growth is fixed to the underlying tissues. However, he does qualify the opinion by stating that not all axillary glands which may be palpated in a case of cancer of the breast are malignant. Heister's method of removing the breast for this condition was to use a large pair of pliers, sometimes called the *Tenaculum of Helvetius*, which completely encircled the breast, raising it upwards to make the operative procedure easier and at the same time, to aid in the control of hemorrhage. It is further interesting to note,⁶ that a number of the foremost surgeons following Heister, such as Gross, Agnew and Sands, were very much discouraged in the handling of malignant breast lesions, and were quite frank about never having cured a case. Agnew, especially, stated that in later years he operated upon this condition solely for the moral effect upon the patient.⁶

It was Volkmann's observations⁶ and reports published in 1875, that really marked the beginning of a scientific operative approach to cancer of the breast. His main contribution was the in-

formation that the fascia covering the pectoralis major should always be removed, since it had been clearly demonstrated that carcinomatous cells often permeate this fascia. Kuester, in 1883, and his assistant Heidenhain in particular, advanced the theory, that not only the fascia should be excised, but also some of the fibres from the pectoralis major muscle.⁶ It is also to Kuester's credit that the first thorough dissection of the axilla was made, although Volkman had suggested this procedure some years before. It was in 1882 when Halsted, as a result of following the lead given him by European surgeons and reported observations of various pathologists, removed the entire pectoralis major muscle (the reason again being obvious), that he discovered the new growth permeating or extending into the muscle itself. It is also interesting to note that Halsted early advocated the desirability of dissecting the supraclavicular fossa, but after a short trial period, he apparently arrived at the conclusion that this procedure was not satisfactory.

Willy Meyer,¹³ in 1894, went a step further by advising the removal of the pectoralis minor muscle, and nineteen years later, Handley advocated the inclusion of the upper portion of the sheath of both recti muscles. All of these steps of course have been logical, and of untold advantage to the patient, as is witnessed by Halsted's report⁶ on his first fifty cases wherein the local metastases or recurrences were decreased to 6 per cent. In previous reported series, the recurrences ran from 55 to even 80 per cent, so it would seem to me that any surgeon, who fails to perform a radical operation, that is, the removal of both pectoral muscles, and as complete a dissection of the axilla as is possible, in addition to the removal of the breast (providing the case falls in the group that is considered clinically operable) is not even giving the patient a "sporting chance" for a fair recovery.

Technic

In performing a radical operation for malignant lesions of the breast, practically all experienced surgeons agree that a large amount of skin surrounding the tumor should be excised. All the newer types of incisions which have been described are a distinct aid to the individual operator. Nevertheless, they are all modifications, practically speaking, of the type of incision de-

scribed by Meyer and Halsted in their original articles. I believe with Harrington, that the surgeon should not always use the same type of incision, when doing this operation, but that he should plan and execute his incision according to the location of the lesion. It is my belief that sharp dissection should be resorted to in doing the entire operation, and as described by Halsted⁶ in his original article, the axilla should be thoroughly dissected before the breast and muscles are removed. The reason is obvious, in that by doing the axilla first, the hazard of spreading any loose cells which may be present is lessened. Despite the opinion of some surgeons, that the cutting and removal of the external respiratory nerve of Bell or the long subscapular nerve is inconsequential, it has always been my policy to carefully preserve these nerves in every case. Hemorrhage, of course, must be carefully controlled. Adequate drainage must be provided, when closure is attempted, but the drains should be removed within forty-eight hours. If there is any difficulty encountered in the closure of the wound, we believe that undue stress of the sutures should be carefully avoided, or rather that the wound be left open, and skin grafting later resorted to. Application of Thiersch grafts has been the most ideal procedure in our hands.

Directly after the patient is returned to her bed, it has always been our policy to extend the arm well above the head, and hold it in such a position for at least forty-eight hours, at which time the nurse should be instructed to begin movement of the extremity. The use of this procedure, we believe, has been of great benefit to the patient in the early improvement of function. In the event of local recurrences our method of treatment is to use the actual cautery, and, as in the original procedure, to burn well around the involved area.

X-ray and Radium

In attempting to evaluate radiation therapy for carcinoma of the breast, one finds that the views of various men with a great deal of experience in this field are quite divergent, and no one technic is universally practiced. It is not within my scope to determine what is the correct dosage, whether or not treatment should be administered through an aluminum filter, or what amount of therapy is really adequate. It is after studying the papers written on this subject by

a goodly number of men interested in this particular line of treatment, and the procedures practiced in various institutions that I base my opinion. It seems to be quite the consensus of opinion, that the use of the x-ray is of considerably more value than radium in its various forms, although Levin¹² believes that radium has a very definite place in the treatment of carcinoma of the breast. Adair¹⁵ has used it somewhat as an adjunct, while Keynes¹⁵ of London is the only person who maintains that the treatment of carcinoma of the breast should be limited to radium. The status of x-ray therapy in the management of carcinoma of the breast, that is, whether it should be used preoperatively or postoperatively or both or whether treatment should be limited to x-ray radiation is an important question and, I believe, a debatable one. Men of experience all agree that the so-called inoperable carcinoma of the breast should be placed immediately in the hands of the roentgenologist.

These cases are, of course, quite desperate in character, and naturally the percentage of cures is small. When carcinoma of the breast is operable, few recommend x-ray therapy alone. Pre-operative x-ray therapy may or may not have been given a fair trial, because physicians generally believe that the time which would elapse before operation, in giving such therapy, would be more harmful than the anticipated gain from radiation. Adair advocates a three-month period between the termination of x-ray therapy and operation. Furthermore, section of the new growth will correct the error in diagnosis which is likely to befall any surgeon, and, in addition to saving the patient the ordeal of a radical mastectomy, may also obviate unnecessary x-ray therapy. In most clinics, however, operation is followed by deep x-ray therapy, on the assumption, of course, that all cancer cells may not have been removed. Neither pre-operative nor post-operative x-ray therapy has been given in any operated cases of breast cancer at the Ancker Hospital in Saint Paul. However, at the present time, it is not possible for us to give the percentage of cures in these cases. In my own private series, however, I have never had a case in which I have advised pre-operative x-ray therapy, and only about 60 per cent have been given x-ray treatments postoperatively. Statistics do vary as to the evaluation given to x-ray therapy before

or after operation but it is probably the consensus of opinion that radiation increases five-year cures from 4 to 11 per cent.

It is pertinent, I believe, to say a few words regarding the complications which may arise during and following x-ray treatments. The most immediate effect is nausea and vomiting which occur during the interim between treatments. We have found that the administering of Vitamin B for about a week before the treatments are given and a continuation of this medication during the treatment alleviates to a great extent the nausea and vomiting which occur in a relatively high percentage of individuals. The second distressing complication is the persistent cough which, it has been thought, is due to a pneumonitis developing as a result of the treatment and usually appears sometime after the treatments have been terminated. In our group of cases, various cough preparations have been given, but we have discovered that the administration of a quarter of a grain of codeine sulphate at stated intervals is perhaps the most efficacious manner of controlling this symptom. Fortunately, this cough will usually disappear in from six to eight weeks.

Lastly, when the individual has been given sterilizing doses of rays, a great percentage will naturally present the various symptoms so common to the menopause. Theelin or some of its related extracts have proven excellent in relieving these distressing symptoms.

Beatson,³ a number of years ago, first suggested that the removal of the ovaries as a treatment of inoperable carcinoma was indicated on the basis that the artificial menopause thus induced would excite evolutionary changes, not only in the normal epithelium of the breast but also in the cancer cells themselves. This method was also studied and advocated by Abbe, Lett, and Boyd. However, this procedure was practically discontinued until Torek¹⁶ reported eight cases of inoperable carcinoma, where oöphorectomy was done on the basis of "being unable at that time to do anything better." The influence of the ovary in the development of cancer of the breast has received intensive study, and the fact appears to be well-established that cancer of the breast is considerably more malignant in the young woman, as is witnessed in Davis'¹⁵ report of no cures in cases of carcinoma of the breast in women under thirty. This is verified by de

Lee, who states that in a series of patients under forty years of age, only 27 per cent are alive and well at the end of five years, while in the group of patients over forty years of age, forty-five per cent are alive and well at the end of the same period of years. It further appears to be unanimously agreed that pregnancy is a serious complication in the patient who has cancer of the breast. In Trout's series of cases, in which pregnancy occurred after operation, 87 per cent developed carcinoma in the remaining breast. Numerous authors, with Pfahler¹⁵ in particular, cite startling statistics to prove that either surgical sterilization or sterilization by the use of the x-ray has produced marked benefit in recurrent or metastatic cancer of the breast. Harrington's belief¹⁰ that 75 per cent of the operable cases have remnants of the disease after radical operation, would suggest routine employment of ovarian sterilization to avoid estrogenic influence on the cancer remnants. It has recently been Carroll's opportunity to have seen and studied a case of metastatic carcinoma, arising from the breast and causing a pathologic fracture in the right femur.⁴ X-ray therapy was resorted to, and the patient was given sterilizing doses immediately following the fracture. It was surprising to note the rapid healing that occurred, and the apparent regression of the lesion, so that the patient after two years is able to get around in a very able manner. It would therefore appear that either pre-operative or postoperative ovarian sterilization is justified, on the basis of preventing further pregnancies, and in avoiding the deleterious stimulative influence of ovarian internal secretion, associated with the menstrual function, and that the use of the x-ray seems to be the method of choice after such a procedure has been decided upon.

Arguments have been advanced pro and con, as to the desirability of doing a biopsy, which is a more or less routine procedure in the hands of many men, the anti's taking the position that in the removal of a tumor for micro-examination, there is great danger of dissemination of some of the cancer cells. This group are also strong advocates of the theory that breast tumors should not be repeatedly examined, and that the utmost gentleness must be employed in palpating these lesions for the same reason. While we have no direct proof as to the damage palpation may cause, it has always nevertheless been hard for

me to believe that one may disseminate malignant cells in such a manner; and I am just as firmly convinced, that when a surgeon removes a growth for microscopic examination, he should be prepared to immediately proceed with a radical operation, should the tumor be found malignant. The reason for this is of course that if part of the malignant process be accidentally spread by the biopsy, the removal of the entire breast within a few minutes will remove these cells. Fortunately for the patient, I believe a biopsy is rarely necessary. In other words, the benignity or malignancy of breast tumors may be determined in a high percentage of instances by clinical examination alone.

Conclusion

The most important consideration in the treatment of carcinoma of the breast is the early diagnosis. Radiographs of the chest and spine should always be taken before any surgical procedure is attempted. While operative removal is contra-indicated in certain advanced lesions, this is by far the most valuable means we have for curing carcinoma of the breast. Bearing in mind that cosmetic considerations have no place in the treatment of cancer, wide excision should be practiced in every case. The value of pre-operative x-ray therapy is still more or less indicated, but there is definite evidence that postoperative x-ray therapy has a definite place in the treatment of this disease. Lastly, sterilization of the individual has undoubtedly proven sufficiently beneficial to warrant its performance in certain cases.

PRIMARY CARCINOMA OF THE BRONCHUS*

HERMAN J. MOERSCH, M.D.

Rochester, Minnesota

PRIMARY carcinoma of the bronchus has come to assume a place of increasing importance among pulmonary diseases and it is estimated at present that primary carcinoma of the bronchus constitutes approximately 10 per cent of all carcinomas that occur in the body. Its importance becomes more apparent when it is realized that out of approximately 150,000 people who die yearly in this country as a result of carcinoma, 15,000 die as a result of carcinoma of the bronchus.

Primary carcinoma of the bronchus is no respecter of age, and may occur at any period of life. As a rule, however, it is most likely to appear after middle age. It is more common among men than women; the proportion of men to women is approximately 3:1. One of the greatest obstacles in its early diagnosis is the fact that its onset is often insidious and its symptoms may closely resemble those produced by other forms of pulmonary disease.

The symptoms produced by primary carcinoma of the bronchus depend mainly on the situation of the tumor and the degree of bronchial obstruction it produces. When the tumor first develops in the lumen of the bronchus, it is usually so small that it produces no symptoms of obstruction. It does, however, cause irritation of the bronchial mucous membrane which manifests itself in a dry, nonproductive cough. This is usually the first, and is by far the most common, symptom of the disease. As the tumor increases in size, it interferes with normal drainage of the bronchial tree distal to the point of obstruction, and the normal secretions tend to accumulate in this portion of the lung. With time, the retained secre-

tion becomes infected, and as a consequence the sputum, which was at first mucoid, soon becomes purulent. Depending on the degree of obstruction and the virulence of the infecting organism, bronchitis, bronchiectasis, pulmonary abscess or gangrene of the lung may develop distal to the point of obstruction and may give rise to symptoms and findings that may obscure those of the primary lesion itself. The tumor, as it increases in size, undergoes ulceration and trauma, which give rise to bleeding and the appearance of blood in the sputum. The quantity of blood may vary from a small amount which produces blood-streaked sputum up to and including a massive pulmonary hemorrhage.

Further increase in size of the tumor brings about interference with air entering and leaving the lung distal to the point of obstruction, and as a result atelectasis soon develops. As a consequence of this development, the patient may have dyspnea, wheeze and a sense of discomfort over the thorax which is often out of proportion to the degree of involvement of the lung.

With the development of bronchial obstruction and interference with drainage of bronchial secretions, episodes of chills and fever may appear. Such episodes will occur in approximately 53 per cent of cases of primary carcinoma of the bronchus. During these episodes of chills and fever, there is usually an area of increased dullness over the portion of the involved lung, and the condition frequently is diagnosed erroneously as bronchopneumonia. This impression may be further substantiated by the fact that, after from three to five days the patient may suddenly expel the retained secretion with almost prompt subsidence of chills, fever and, frequently, cough. As a consequence, many patients are permitted to go on for variable lengths of time, and only when

*From the Division of Medicine, The Mayo Clinic, Rochester, Minnesota. Read in the symposium on diagnosis and treatment of chest tumors at the meeting of the Minnesota State Medical Association, Rochester, Minnesota, April 22, 1940.

there is a recurrence of such an episode is the true nature of the underlying pathologic process determined.

Pain usually is not an early manifestation of primary carcinoma of the bronchus. When present, it indicates either that secondary inflammatory reaction has taken place in the pleural cavity, or that the malignant process has extended to the thoracic cage. Pleural effusion, which occurs in approximately 10 per cent of cases of primary carcinoma of the bronchus, is likewise a bad prognostic sign and generally indicates an extension of the malignant process to the pleura. In a high percentage of cases of primary carcinoma of the bronchus loss of weight is noticeable, but this is not necessarily of prognostic value. On the other hand, hoarseness, which is noted less frequently, is invariably an indication of inoperability.

It must be pointed out that absence of symptoms does not exclude the possibility of primary carcinoma of the bronchus. In a study made some years ago, I found that in 3 per cent of cases there were no symptoms referable to the lung, and the condition was discovered on roentgenographic examination of the thorax during routine examination, or as a result of the development of some peculiar neurologic lesion for which the neurologist referred the patient for special examination to rule out the possibility of bronchiogenic carcinoma.

Although the symptoms which have been described are more or less characteristic in most cases of bronchiogenic carcinoma, there is one group in which the lesion, because of its peculiar situation, gives rise to an entirely different train of symptoms. In this group the carcinoma originates in the extreme apex of the lung, and Pancoast, who first described it, gave it the name of "superior sulcus tumor." Because of its location in the apex of the lung, this type of tumor tends to spread rapidly and impinge on the neighboring structures; it thus gives rise to characteristic symptoms. The earliest symptom usually is pain around the tip of the shoulder and about the shoulder girdle. Because of lack of pulmonary symptoms, the condition is often thought to be neuritis, and the majority of patients have their tonsils or teeth removed in the hope of obtaining relief of their so-called neuritic pain. The pain tends to spread down the arm to the fingers, and

definite muscular weakness soon follows. As the tumor increases in size, it also impinges on the sympathetic chain and Horner's syndrome soon develops on the homolateral side.

The physical findings in primary carcinoma of the bronchus are dependent on the stage of development of the tumor and on its location. When the tumor first develops, there are practically no physical indications. As it increases in size and produces bronchial obstruction, if the part involved is near the surface of the lung, increased dullness may be found over this area. By far the most valuable and important finding is that of suppression of breath sounds. Whenever this finding is elicited in the course of physical examination, the possibility of primary carcinoma of the bronchus must always be considered, and the patient should have the benefit of bronchoscopic examination.

A careful search should be made for metastasis in every case, because carcinoma of the bronchus tends to metastasize early in the course of its development and to spread widely throughout the body. Metastatic nodes are found in approximately 20 per cent of all cases.

I shall not attempt to consider the roentgenographic findings in carcinoma of the bronchus, as they will be discussed by Dr. Weber. I do wish to point out, however, that in cases in which the clinical history is suggestive of primary carcinoma of the bronchus, or in the presence of bronchostenosis as elicited on physical examination, the possibility of carcinoma of the bronchus cannot be excluded even if the roentgenogram of the thorax does not present evidence of carcinoma. In such cases bronchoscopic examination should always be carried out.

Bronchoscopy has probably done more than any other procedure to awaken interest in the problem of primary carcinoma of the bronchus and is of the utmost importance in its diagnosis. It is of value not only because it permits the obtaining of tissue for microscopic examination, but also because it enables the examining physician to determine the situation and extent of the lesion and to judge its operability. In cases in which the lesion is associated with marked secondary pulmonary suppuration, as a result of obstruction and interference of drainage, the patient's general condition may be such that surgical interference would be inadvisable. By bronchoscopic

means, aspiration of the retained secretions can be carried out and the patient's general condition improved.

As might be anticipated, it is impossible to obtain satisfactory tissue for examination when the lesion is in the peripheral portions of the lung. Also, it is important to point out that in cases in which biopsy does not reveal carcinoma and in which a definite tumor mass is seen through the bronchoscope the diagnosis made from the biopsy cannot be accepted as final. The tissue may have been removed from the edge of the tumor, or from that portion of it which has undergone necrosis and the cellular structure is no longer discernible. So far as bronchoscopic examination itself is concerned, it can and should be carried out with a minimum of discomfort to the patient, and with practically no risk.

The differential diagnosis of primary carcinoma of the bronchus at times may be exceedingly difficult. The lesions that most closely simulate primary carcinoma of the bronchus are dermoid, neurofibroma, and foreign body in the bronchus, broncholith, lymphosarcoma and tuberculosis. The differential diagnosis when the results of bronchoscopic examination are negative is usually dependent on the roentgenographic findings.

Primary carcinoma of the bronchus originates from the bronchial mucous membrane and tends to develop into either a squamous-cell carcinoma or an adenocarcinoma. The diagnosis as to the character of the tumor is of the greatest importance in determining the type of treatment that is most suitable in a given case. In my experience, cases of squamous-cell carcinoma of the bronchus have been slightly more numerous than cases of adenocarcinoma. The majority of the malignant tumors of the bronchus are of an extremely high degree of malignancy.

There is one variety of bronchial tumor which grossly appears distinct from other bronchial carcinomas. This tumor is generally pedunculated and usually does not metastasize. Many pathologists regard such tumors as benign, and designate them as adenomas. Broders, Robertson and their associates, however, regard such tumors as adenocarcinomas of low degree of malignancy. It is my opinion that such tumors should be regarded as potentially, if not actually, malignant, and treated accordingly, for if no treatment is given, they will lead to the patient's death.

The treatment that is to be employed in any given case is dependent on the location, extent and character of the tumor, the presence or absence of metastasis, and the general condition of the patient. In my experience, if the tumor is of the adeno-carcinomatous type, is localized and polypoid in nature, and can be readily reached through the bronchoscope, it is best handled by destruction of the tumor by means of surgical diathermy and insertion of radon needles into the base of the tumor. This procedure can be employed with very little risk to the patient and with excellent postoperative results. All of the patients with this type of lesion whom I have treated by this method are still living and well.

If the tumor is extensive, or in such a position that it cannot be readily reached by bronchoscopic means, and if there is no evidence of metastasis, surgical extirpation should be considered. In carcinoma of the squamous-cell type without metastasis, if the patient's condition is satisfactory, pneumonectomy is the procedure of choice. If, on the other hand, the tumor has metastasized, or is placed so that it cannot be removed readily at operation, and if the patient's condition warrants it, roentgen therapy may be indicated. Although no cures are to be offered from this form of therapy, there is a prospect in approximately every sixth case of prolonging the life of the patient.

Summary and Conclusions

It may be stated, therefore, that primary carcinoma of the bronchus presents an ever increasing problem in the diagnosis and treatment of pulmonary disease. The possibility of its existence should be considered seriously in any case in which the patient gives a history of chronic cough, especially if the cough is associated with expectoration of blood. If progress is to be made in the successful management of this disease, the condition must be diagnosed in an early stage. Bronchoscopic examination should be employed whenever such a lesion is suspected. Satisfactory biopsies can be obtained in approximately 75 per cent of cases by this means. With earlier diagnosis, and with the improvements that have taken place in the fields of thoracic surgery and bronchoscopy, there is an increasing opportunity of affording relief to the unfortunate sufferers from primary carcinoma of the bronchus.

FRACTURE OF THE ELBOW

M. H. TIBBETTS, M.D.
Duluth, Minnesota

BECAUSE of the complexity of the various phases of elbow fractures I should like to confine my remarks to fractures in and about the elbow occurring in childhood and early adolescence. I would like to point out the difficulties of diagnosis, outline different methods of reduction and immobilization, and finally discuss briefly the common complications that one may expect but must attempt to avoid or correct.

The first stumbling block in diagnosis may be the varying number of epiphyseal lines that are seen in the x-ray film at different age periods. These vary from none during the first year to as many as seven during the early 'teens. There is an excellent chart which has been published by Camp and Cilley that is of considerable aid. Another helpful procedure is to take a roentgenogram of the uninjured elbow. The line that may fool us most frequently is the one in the olecranon, which is visible over a relatively short age period.

After the diagnosis is established the question of treatment comes next. This, of course, varies with the type. Let us consider first the supracondylar. Prompt reduction is needed here pre-eminently. The longer the delay the greater the swelling, the more difficult the replacement and the greater the likelihood of complications.

One can more readily appreciate this when he realizes that the lower fragment tears the periostium from the posterior margin of the shaft, thus opening a wide area of hemorrhage. The lower end of the proximal fragment at the same time slides forward and downward jeopardizing the vessels and nerves in the bend of the elbow.

When one comes to the actual manipulation it is perhaps trite to say that there must be complete anesthesia and relaxation of the injured area. This can be accomplished in the very young with ether. Older children can often be handled with local novocaine.

The first maneuver must be directed toward disimpacting the fragments, using extreme care to prevent any added injury to nerves or vessels

in the cubital space. The fingers are then used to drag the distal fragment downward. When one feels that the ends are clear the thumbs are placed on opposite sides of the anterior surface of the proximal fragment and a rotary pincer action begun. At the same time an assistant acutely flexes the forearm. I feel that this maneuver works better without strong traction on the forearm. The latter tends to clamp the lower fragment against the upper. Now one must make sure that the radial pulsation is palpable and adequate. If it isn't the flexion must be diminished to the point where the pulse can be felt. If the circulation is adequate and the reduction appears complete so that the fragments are apposed and the distal one angles forward about 40°, the arm should be immobilized in this position. This may be done with the Jones sling. I like to add to this as posterior moulded plaster splint to prevent rotation or loss of the carrying angle. Another excellent splint is the one recommended by Eliason.

Dunlop has reported excellent results from traction in bed with counter traction at right angles to the forearm traction. The former is to be applied above the elbow. The points claimed for this procedure are: less additional injury which manipulation may inflict; less danger of ischemic paralysis; and excellent position and function are possible.

If one is called to see a supracondylar type of fracture after repeated manipulations have already been done I feel that open reduction is often the most conservative way to treat it. The tissues should be allowed to rest several days before operating. As a rule internal fixation is not needed.

Fractures of the olecranon are not common in children. When present, open reduction with internal fixation is indicated.

Fractures of the medial epicondyle almost always result in non-union unless internal fixation is carried out. Injuries to the capitellum often result in fractures irreducible by closed methods. Rotation of the fragment is often present. Open reduction should be done and it is often neces-

*From the Duluth Clinic. Read in the Fracture Symposium at the annual meeting of the Minnesota State Medical Association, Rochester, Minnesota, April 23, 1940.

CASE REPORTS

sary to remove the loose fragment as its blood supply may be gone.

Fractures that involve one or both condyles must be very accurately replaced or growth disturbance almost surely will ensue. If closed manipulation does not accomplish this, open reduction is called for. One should not hesitate to use a pin or nail even if it crosses the epiphyseal line.

We come now to the complications, one of which may be more serious than the bone injury. I refer now to ischemic paralysis. This is explained on a pressure basis but this pressure may occur without any splint being used. The fascial coverings of the flexor muscles of the forearm will not stretch as readily as the soft walled veins collapse. Therefore if elevation of the arm does not allow good circulation, these fascial sheaths must be opened to relieve the internal pressure.

The next complication to be mentioned is nerve injury. This may be immediate or appear later.

Usually unless there is actual tearing the nerve lesion will clear up after a few weeks.

Loss of carrying angle may be due to improper reduction or to epiphyseal growth disturbance on one side. The latter, of course, cannot be an immediate complication; when it is due to the former the reduction must be corrected.

In conclusion:

1. One must be able to differentiate a fracture from epiphyseal lines.
2. Early treatment is essential.
3. If gentle manipulation is not adequate, it may be safer to employ gradual traction and counter traction in bed, according to Dunlop, or resort to open reduction.
4. Certain types of elbow fracture call for open reduction.
5. The complications may be serious and call for prompt and radical intervention in the case of ischemia.

CASE REPORTS

HEMOPHILIA WITH INTESTINAL OBSTRUCTION

ERLING S. PLATOU, M.D., and RALPH V. PLATOU, M.D.

Minneapolis, Minnesota

THE clinical picture of acute intestinal obstruction occurring in hemophilia is fortunately rare. Because this condition constitutes such a grave emergency it seems worthwhile to record the findings and the method of therapy employed in such a case.

C. B., an eight-year-old male, was admitted to the hospital because of acute abdominal pain. Although there was no family history to suggest hemophilia in any of his antecedents traced carefully as far back as the early American Colonial period, the child's past history was considered characteristic of this condition. The first hemorrhagic manifestation had occurred at about ten days of age, consisting of prolonged and serious bleeding from the prepuce necessitating transfusion. Since that time there had been innumerable episodes of bleeding into the skin, muscles, and joints, and even occasional transient hematuria after apparently trivial accidents. The child had previously been observed and treated by Dr. Cannon Eley of Boston and Dr. Montgomery Blair of Washington. They concurred in the diagnosis of hemophilia. Practically all methods of therapy suggested in the literature during the past ten years had been employed at different periods, all with uniformly unsuccessful results in controlling the bleeding. Studies of the blood calcium and protein levels had always been normal, as had the total platelet

count. Bleeding time had been repeatedly normal or slightly elevated, while the coagulation time had varied from twenty minutes to several hours, and was rarely under thirty minutes.

One week previous to admission to the hospital the child developed an acute upper respiratory infection which was soon followed by rather severe bleeding into the right knee joint, the left elbow, and muscles of the left arm. Four hours prior to admission he complained of abdominal pain, which became progressively more severe and was soon followed by occasional vomiting. The significant physical findings were the typical chronic hemarthrotic joints, together with abdominal pain referred to the right lower quadrant. Tenderness in the region of McBurney's point was present. The leukocyte count was 11,300 per cu. mm. with 83 percent polymorphonuclear cells, and 17 percent lymphocytes. Temperature was 100.2°, pulse 86, respiration 22, clotting time of blood one hour and thirty-three minutes. The tentative diagnoses on admission were acute appendicitis, intestinal obstruction due to hemorrhage into the bowel wall, or possibly, intussusception.

The child was transfused at once. Four hours after this procedure he seemed more rather than less ill but the pain and tenderness had shifted to the mid-portion of the abdomen and had become more colicky in nature. Vomiting occurred again and visible peristalsis could be observed on the abdominal wall just preceding these

CASE REPORTS

colicky pains. There was a rather indefinite boggy mass just below the umbilicus, and loud borborygmi occurred over the upper abdomen only. No stool or flatus was passed. Radiographs were made of the abdomen (Fig. 1) and were reported as typical of obstruction in the small intestine in the right lower quadrant. There was

Fig. 1.

no increase in the leukocyte count, and because of the undoubted great risk involved in any surgical procedure, especially in the abdomen, it was decided to treat the obstruction symptomatically with nasal suction (Wangenstein¹) and supportive measures. The nasal tube was passed into the duodenum without difficulty, and fluids were administered by vein. Within an hour after the suction had been established, the child had relief of the abdominal pain and passed a quiet night without sedation. During the next day the tube was clamped off at intervals without recurrence of symptoms and after twenty-four hours it was removed. There was no hematemesis or melena and for this reason it was felt that the obstruction might have been due to a

hemorrhage into or near the bowel wall. The indefinite mass which had been palpated just below the umbilicus disappeared rapidly after the suction had been instituted and as the symptoms and signs of the obstruction abated. Four days after the suction had been discontinued there was a moderate hemorrhage from the nostril through which the tube had been passed which was readily controlled by transfusion. Aside from this there was no further bleeding and no further complaint referable to the abdomen.

It is not within the scope of this report to discuss the precautions necessary in hemophilia; suffice it to say that surgery should be avoided whenever this is at all possible, and that transfusion remains the most satisfactory agent to control the hemorrhagic manifestations. The well known fact that remarkable variations of clotting time of the blood occur in these patients when tested at frequent intervals renders even this determination of dubious value in choosing the time for operation. The case reported illustrates well the need for careful consideration of the surgical indications. Some might maintain that this case warranted surgical intervention although a review of the literature reveals that the prognosis in abdominal surgery is especially grave in hemophilia. The subsequent course of events certainly justified the conservative therapy employed and rendered the tentative diagnosis of intestinal obstruction due to a hemorrhage into or near the bowel wall as most tenable of those considered. Intussusception, segmental ileitis, appendicitis, mesenteric adenitis or thrombosis, Meckel's diverticulum and various causes of ileus were ruled out as far as possible. While no attempt is made here to minimize the dangers of delay in intestinal obstruction, the results, in this instance at least, served to emphasize the wisdom of a preliminary period of employment of conservative management when the acute condition is complicated by the presence of hemophilia.

Intestinal obstruction in hemophilia is a very rare condition, no similar instance having been reported in the past twelve years. The obstruction in the case here reported was probably due to the occurrence of hemorrhage into or near the bowel wall and there was a favorable outcome with non-surgical therapy.

AMYOTROPHIC LATERAL SCLEROSIS WITH PSYCHOSIS (PARANOID TYPE)

CHARLOTTE MELLER, M.D.
Minneapolis, Minnesota

THIS case is reported because of its obvious interest. In going through the literature it was found that only a few cases of amyotrophic lateral sclerosis with psychosis have been reported recently. The use of new therapeutic agents, especially alpha-tocopherol, should stimulate study in this chronic disease.

This disease is characterized clinically by a lower

motor neuron paralysis of the upper extremities and an upper motor neuron paralysis of the lower extremities. It usually begins with atrophy, weakness and fibrillary tremors in the muscles of the arms, the atrophy being most pronounced and characteristic in the hands. The palmar fascia becomes rather prominent. This together with paralysis of the fingers in

the position of flexion causes the claw hands. Gradually signs of pyramidal tract involvement appear, giving the typical picture of spastic atrophic extremities with increased reflexes. As the disease progresses, bulbar symptoms appear, speech becomes dysarthric and swallowing difficult. Death is due either to bulbar involvement or to intercurrent infection.

Charcot is credited with having first described this disease in 1865. It then became known as Charcot's disease. Since that time much work has apparently been done but little is known of its etiology or its treatment.

Grinker, in his textbook of neurology, does not consider this a distinct disease entity, but rather classifies it with the muscular atrophies.

The disease usually begins in the third decade, affecting males three times more frequently than females. No mention was found in the American literature of its geographical distribution.

Etiology is unknown. More appears in the older literature concerning etiology. Lead and arteriosclerosis have been said to play a part. There may be a hereditary factor present for Moleen reported cases in three brothers. A congenital predisposition of certain nerve cells to undergo early atrophy has been suggested; in the sense of Gowers, this represents an abiotrophy. In common with modern trends, vitamin deficiency has been suggested.

Pathologically characteristic are the signs of degeneration without signs of inflammation involving the anterior horn cells of the cord and the large Betz cells of the cortex. This degenerative process usually begins in the anterior horn cells of the cord. The Betz cells first involved are those of the paracentral lobule where the leg fibers originate.

The depression which such an incapacitating disease should be expected to cause does not appear in all cases. The most frequently mentioned personality changes are irritability and recent memory loss. I. S. Wechsler and C. Davidson in a report of three cases stated that no pathologic changes were observed in the brain except degeneration of the large Betz cells. Other authors reported the same findings. Some even suggest that the lack of mental change is dependent upon the fact that the small cells of the cortex are not involved in the degenerative process.

In 1925 Von Bogart reviewed the literature and published his account of thirty-one cases. In 1930 Ziegler completely reviewed the literature and published this together with three case reports.

Since that time only a few more cases have been reported in English literature. Apparently no new conclusions have been made concerning the relationship between neuropathology of this disease and the personality changes. No one has found any single personality change which can be considered of any statistical significance.

Results of therapy have been rather discouraging until the recent report of I. S. Wechsler in which he

states that the use of alpha-tocopherol in three cases resulted in startling improvement in two cases.

*Case Report.**—A white man, aged fifty-nine, was admitted to the psychopathic ward from the workhouse where he was serving a sentence for disorderly conduct. He had entered one of the large department stores demanding to see the president of the company. He refused to have anything to do with anyone except the president, because he felt only the president could straighten out his grievance. He had had trouble with that store about three years previously and he had continued to hold a grudge. At that time his conduct had not been considered dangerous. At the present time, however, he threatened bodily harm to the office personnel.

Upon arrival at the hospital he was indignant. He told a long, involved, scrambled, wandering story of the brutal treatment he had received from the hands of the employees of this store. He spoke in a loud vehement manner frequently repeating meaningless details for emphasis. He would frequently wander from the point of the story to bring in some unimportant detail.

He stated that one year ago he had noticed weakness and stiffness in his legs and arms. He noticed in particular that his hands were becoming clumsy, stiff and weak. He very boastfully said that about three months previously, a doctor had told him that he had the same disease as Lou Gehrig.

Physical examination showed claw hands and atrophied muscles, spastic lower extremities, bilaterally positive Babinski and Chaddock signs. Blood serology was negative; spinal fluid, entirely negative.

During his stay in the observation ward, the patient spoke loudly, always demanding to be the center of attention. He was commanding and bossy. His mood was generally euphoric although at times he was easily angered. He would cooperate, only when by so doing he would be getting attention. He was oriented as to time, person and place. His recent memory was fair. He could repeat the cowboy story. He repeated an address after five minutes. He retained his persecutory ideas toward the employees of the store. He never threatened the staff. The patient was diagnosed amyotrophic lateral sclerosis with psychosis.

History of previous personality and family background could not be obtained.

HISTORY OF MEDICINE IN MINNESOTA

HISTORY OF MEDICINE IN DAKOTA COUNTY

MENDOTA, the first permanent white settlement in Minnesota, is a small town located at the junction of the Minnesota and Mississippi Rivers, which derives its name from the Indian words meaning "the meeting of the waters." At first it was called St. Peters and its proximity to Fort Snelling, which was occupied the following year just across the Minnesota river in Hennepin County, was partly responsible for its growth. Mendota, although practically deserted today, is still interesting because of its location and the history connected with the old stone home of General Sibley.

The first force of ninety-eight soldiers and twenty boatmen arrived at St. Peters in the fall of 1819 and at the time of their arrival, almost half of the men were suffering from scurvy. This disease continued through the winter in an extremely malignant form. For a time garrison duty was suspended since there were only enough well men to care for the ill and bury the dead. Stories are told of men who went to bed apparently well and were found dead in the morning. General Sibley told of a soldier who, being relieved from his tour of sentinel duty, stretched himself upon the bench of the guard room and four hours later when he was called upon to resume his duty was found to be lifeless.† Colonel Leavenworth, who was the first commander at Fort Snelling (or Fort St. Anthony as it was then called), set out with a party through Indian country searching for antiscorbutics. Spruce was obtained from the St. Croix and Chippewa Rivers and vinegar at Prairie du Chien. Nevertheless, nearly half of the company died. At this time, Major Edward Purcell was the surgeon stationed at the post.

This illness returned again the following winter. It was finally discovered that dishonest contractors, from whom the settlement's supply of salt pork had been ordered, had drawn the brine from the barrels at St. Louis in order to lighten the load and refilled them again with river water just before delivery at the post. This fraud was not uncovered until after two seasons.

No other settlements were made in Dakota County until 1851, when the Mendota treaty was made with the Indians who agreed to give up their land on the west shore of the Mississippi.

At this time the first actual settlers came to the Kaposia Mission, south of Saint Paul. Previous to that date only traders and Indian farmers had frequented the mission which had been kept by Rev. Thomas S. Williamson since 1846. Rev. Williamson had received the degree of Doctor of Medicine from Yale University in 1824, but had given up his medical practice in 1833 when he began to study theology. He practiced as a physician, however, in Minnesota. When settlers began to come to Kaposia he moved to Yellow Medicine, where he continued his services as a missionary.*

In 1821 a Lieutenant Oliver of the army, while on his way up the river with

†See the article entitled "Edward Purcell, the First Physician in Minnesota" which will appear in a later issue of MINNESOTA MEDICINE.

*See the article entitled "The Missionary as Practitioner," and the articles written by Rev. Williamson, MINNESOTA MEDICINE, October, 1940, pp. 723 and 725.

supplies for the garrison was forced by the ice to spend the winter at the present site of Hastings. From this time until 1851, the place was known as Oliver's Grove or more generally, Olive Grove. Joe Brown, a private soldier of Fort Snelling, was sent from time to time to herd cattle because of the fine grass in the region. In 1850 Alexis Bailey, Sr. established a trading post there and built the first log house. The next year, when it was deemed safe for settlers to come, Dr. Thomas Foster, the first practising physician in the county, built the second log cabin on the shore of Lake Isobel, on a site which he had picked out the year before. About the same time Alexis Bailey sold a one-fourth interest in his property to H. G. Bailey, his son, General H. H. Sibley, and Alexander Faribault. The town plan was laid out in 1853 by John Blakely. In 1854, General W. G. LeDuc bought out Alexander Faribault's interest in the town for \$3,000 and also purchased from H. H. Graham a claim of 160 acres adjoining the falls of the Vermillion, now within the city limits. Each of the original proprietors suggested a name for the town and, by drawing lots, General Sibley's middle name, Hastings, was chosen.

The growth of the settlement, like many others of the period, was extremely rapid. The first ferry across the river was established in 1854 by Wm. Felton. The immigration was such that, at ten cents per person, the day's receipts often amounted to eight or ten dollars.

The next year the first hotel, the New England House, was built. In 1856, General LeDuc took charge of the town site for the company and homes and stores went up rapidly. In January of that year the population was about 700 persons; by the end of the year it numbered 1,918. In 1857 the city of Hastings was incorporated by the territorial legislature and at the election in May, a physician, A. H. Hanchett, M. D., was elected mayor. The same year the county seat was moved from Mendota to Hastings.

Scurvy was prevalent in various settlements. In the reminiscences of the Honorable Thomas C. Hodgson who, when a boy of twelve years, spent the winter of 1854-55 in the company of four men at "Club Creek," now known as North Greenvale. Their purpose was to locate and build homes for each family. About mid-winter one of the men developed the symptoms of hypochondria. By March another began to complain of severe rheumatism and soon after Hodgson developed the same symptoms, but his pride forced him to say nothing about it. In April, two of the men started out for Hastings, and a third followed in a half-demented condition. Hodgson and Kegg, the remaining men, were both very feeble and both thought that they probably had leprosy. Their meat supply was exhausted, their flour supply was very low, and they also started to make their way by slow stages to Hastings. At Lamphrey's, near Waterford post office, they were given lodging, and there they met a small group of settlers going to their little colony. Hodgson returned with them, but was soon in such a state that he could not even walk. Fortunately, however, a stranger who was posing as a government inspector of boundaries stopped at the shanty and found Hodgson almost dead from scurvy. The man admitted that he was a physician, ruined from drink, and that he had been known formerly in Indiana as Dr. Charles Ferry. The disease was diagnosed, and the boy was given a diet of raw potatoes and lightly boiled eggs. He finally recovered although he remained stunted in growth.

1850-1859

Of the physicians who practiced in Dakota County in the fifties, Dr. Thomas Foster had quite a varied career aside from his medical practice. He came to

Minnesota as private secretary to Governor Ramsey and edited newspapers at Hastings, Saint Paul, Minneapolis, and Duluth. He was a member of the constitutional convention and was also state librarian. Of Dr. A. H. Hanchett, the first mayor of Hastings, little is known. He had an office for a while with Dr. William Thorne. He resigned soon after his election and later went east to live. Doctor Thorne was born in Devonshire, England, in 1820. He came to New York state in 1833. He studied medicine with several physicians, took some preliminary lectures at Buffalo College in 1847, practised for a short while and received his degree of Doctor of Medicine from the Buffalo Medical College in 1850. In 1856 he came to Hastings. He was a charter member of the Dakota County Medical Society and also a member of the State Medical Association and the American Medical Association.

In 1856 the *Dakota Weekly Journal* printed the cards of William Gibson, M. D., and D. S. Cummings, M. D., who specialized, according to his card, in the diseases of women and children, and E. D. Ayres, M. D., physician, surgeon, and oculist. The latter also ran a drug store. In 1856 Dr. Horace Phelps came to Lakeville and Dr. T. C. Potts came to Castle Rock township where he practiced for about seven years. There was also a Dr. E. Hammond who came to Waterford that year but there is no record of his having followed his profession in Dakota County.

The next year J. M. Whipple, M. D., published a card advertising that he gave "particular attention to the diseases of the eye and ophthalmic surgery" and also sold drugs and medicines. Jeremiah E. Finch, M. D., one of the well established and well known physicians of Hastings, arrived in 1858. Dr. Finch received his academic and medical training in the east and practiced for a short time in Illinois and Wisconsin. In 1862 he was appointed surgeon of the Seventh Minnesota Infantry and the next year returned to Hastings. He owned a drug store there, served a long term as president of the school board, and was elected mayor in 1866.

The first dentist, H. O. Mowers, and two more druggists came to Hastings in 1858, and in the following year Dr. Otto Stannis, the first homeopath in the county, arrived. He had received his training in Germany and had practiced both in that country and in the United States.

C. P. Adams also came during this period. He was born in Pennsylvania in 1831, and was of Scotch-English and German descent. He studied in Pennsylvania and Ohio and graduated from Ohio Medical College in 1851. He first began practice in Indiana, but his health being injured by malaria and overwork he came to Hastings. At the age of twenty-five, he had the honor of being elected a member of the territorial legislature, and was appointed chairman of the committee on corporations. In his first years in Hastings he supplemented his earnings from medical practice by running a grocery store and editing the *Hastings Democrat*. During the early days of the Civil War, Dr. Adams was instrumental in securing aid for the families of volunteers in the army. His own military record was a meritorious one. He enlisted as a private soldier in the Dakota County Volunteers and was elected captain of his company. He was promoted the next year to the rank of major in the First Minnesota Regiment of Volunteers and in March, 1865, was made a brigadier general. According to the history of Dakota County written by Neill and Williams he was in every battle from the first battle of Bull Run to that of Gettysburg. He suffered severe wounds and was at one time left for dead on the field. He won renown as an officer and continued in

service after the close of the war. In 1866 he commanded a corps of cavalry and artillery sent against the Sioux Indians and was successful in his undertaking in spite of heavy snows and extreme cold. In July of that year he returned to Hastings and resumed the practice of medicine.

In 1869 Dr. Adams took an active part in the reorganization of the Minnesota State Medical Society and on its recommendation helped to organize the first medical society in Dakota County. He held many offices in both the state and county organizations. He was a member of the American Medical Association, an honorary member of the California State Medical Society, a member and ex-president of the Rocky Mountain Medical Society. In local politics his sympathies were with the Democratic party. He served as mayor of Hastings and also as a member of the state senate for a four-year term (1878-1882). Among other organizations to which he belonged was the Dakota County Veterans' Association for former Civil War soldiers which was organized in 1878 and of which he was the first president.

1860-1869

Among the physicians who came to Dakota County in the sixties were Francis B. Etheridge and Levi P. Dodge. The former's professional card first appeared in the *Hastings Independent* in May, 1860, wherein he stated that he had had thirty years' experience in his profession. He was a surgeon with the rank of major in the Fifth Regiment of Minnesota Volunteers during the Civil War. He was taken prisoner at Corinth, Mississippi, and returned to resume his practice in Hastings late in May, 1862, his health somewhat impaired by his war experiences. Levi P. Dodge was born in New Hampshire in 1839. He was left an orphan at the age of six months and from the age of eight years he cared for himself. After studying medicine with Dr. S. M. Whipple, he enlisted in the army in New Hampshire and received an appointment on the medical staff which he held until 1863. He entered the medical school at Dartmouth and received his diploma that same year. After practicing in New Hampshire he came to Farmington in 1865.

Jenks S. Sprague, who will be mentioned later, came about this time. Other physicians of this period who practiced in Dakota County were Dr. J. L. Arming-ton, who was a surgeon with the rank of major during the Civil War; J. G. Bemis of Farmington and E. D. Ault, a graduate of McGill University, Canada. The latter's card announced him to be a "physician, surgeon, and obstetrician, late of the New York Hospital." Dr. Ault was also an agent of the Mutual Life Insurance Company of Boston, supplementing his income by a side line, which was not an unusual procedure for physicians during these years. Dr. D. L. Webster, Dr. C. C. Richter, Dr. Nichols, homeopaths, and Dr. J. Davidson, an eclectic physician, practiced in Hastings. Dr. Weems ran a drug store there for a number of years. There were also a number of physicians scattered over the county of whom very little is known and there were of course the "traveling physicians" whose spectacular "cure-all" advertisements and guarantees often covered half sheets of the local papers. In 1867 the *Hastings Gazette* printed a list of those men who, having complied with the laws passed by the state legislature requiring an examination or an exemption certificate, were qualified to practice medicine in the state. As this list included only four names, C. P. Adams, L. P. Dodge, R. L. Weems, and R. F. Goodwin, it was probably an incomplete one.

HISTORY OF MEDICINE IN MINNESOTA

The following are listed by Mitchell in his history of Dakota County as the practicing physicians of that district in 1868.

L. P. Dodge, Empire
J. G. Bemis, Empire
Dr. Torgerson, Empire
T. N. Berlin, Empire
Wm. Thorne, Hastings
J. E. Finch, Hastings
C. P. Adams, Hastings

J. S. Weems, Hastings
H. D. L. Webster, Hastings
F. B. Etheridge, Hastings
Wm. Willson, Hastings
Dr. Munson, Pine Bend
Dr. Barton, Pine Bend
C. C. Knight, Rosemount

The first expenditure of county funds for persons requiring medical care was made in 1865 when the poor bills covering the year from March, 1864, through March, 1865, were listed as nearly \$300. This included the salary of Dr. J. E. Finch for his services as county physician, medicines for the poor, and extra expenses for post-mortem examinations. There was, apparently, only one office of county physician in the sixties and the expense list as given above was probably about the same for the following years.

According to the *Hastings Independent*, March 28, 1861, there was an epidemic of diphtheria that year and the disease was referred to as being "of considerable interest in the community at present." Typhoid fever was prevalent and severe in Hastings in the winter of 1865-1866. In August, 1866, several persons on the steamboat "Canada" were stricken with an illness described as "cholera morbus." Two persons were buried at La Crosse and six at Reed's Landing, and Hastings officials, who very probably feared that the disease might be dreaded Asiatic cholera which in previous years had been brought up the river, prudently telegraphed the boat not to stop.† There was a considerable amount of bowel disturbance accompanied by fever in the summer of 1868 and the next year whooping cough and measles attacked the children.

The obvious reluctance of the newspapers to mention any illness in the community and the vagueness and indecision with which they did so is explained in the course of an argument between Dr. Adams and a man named Graves. Dr. Adams, at a meeting of the state medical society had read a paper which was later published in the *Northwestern Medical and Surgical Journal*, in which he expressed the opinion that the unhealthy lowlands around Hastings might be largely accountable for the illness in that vicinity. As examples he called attention to the malaria prevalent in 1856 and the unusual amount of typhoid fever in 1858. Those who objected to the opinions held by Dr. Adams and his medical associates argued that there was remarkably little illness in the county, that stagnant water had no connection with disease and, above all, that any mention of unhealthy conditions was unpatriotic to the community since it would scare away prospective settlers. It is also to be noted that neither during these years nor later was it a practice of the newspapers to publish articles on preventive medicine or the improvement of sanitary living conditions.

1870-1879

In 1871 Dr. D. J. Cummings reported a case of leprosy, the first that he had encountered during his practice in Dakota County. It created quite a little excitement in the village of Farmington. The next year there were rumors of smallpox and in February, 1873, a number of cases appeared in the German settlement at Hampton. In 1877 scarlet fever was prevalent in Hastings, Empire and Rosemount, as well as in some of the other towns, and it reappeared the two following

†See the account of the appearance of Asiatic Cholera in Ramsey County, MINNESOTA MEDICINE, issue of April, 1939, p. 252. Account of its appearance in Goodhue County will appear in a later issue.

years. There were a few cases of diphtheria reported in 1878 in Hastings and the next year (August) there were several cases at Castle Rock and also within a four mile area around Farmington. The surrounding sanitary and water conditions were reported as good and isolation and disinfection kept the disease from spreading. The same year an epidemic of diphtheria broke out in July and August in Lakeville where there were twenty-one cases in four families. Six deaths were reported. The total number of deaths from all causes for that year, in Dakota County, numbered 156, and of these eighteen were from diphtheria.

In 1870 the first medical society in the county was organized through the efforts of Drs. L. P. Dodge and D. J. Cummings of Farmington. The first meeting was held in Farmington in December and the physicians present included the two mentioned above, as well as Drs. J. S. Sprague, F. B. Etheridge, J. Dennis Smith, J. C. Fitch, J. E. Finch, R. L. Weems and C. P. Adams of Hastings. These included the majority of the important county practitioners. The name adopted for the organization was the Dakota County Medical Society. A committee of permanent organization composed of Drs. C. P. Adams, D. J. Cummings, and J. E. Finch, nominated the following who became the first officers of the organization:

President—J. S. Sprague
 Vice president—F. B. Etheridge
 Corresponding Secretary—L. P. Dodge
 Treasurer—J. C. Fitch
 Board of Censors—J. E. Finch, D. J. Cummings, and F. B. Etheridge.

The president, Dr. Sprague, had been for many years an active member of the State Medical Society of New York. He was president of that organization at the time the bill legalizing dissection in that state was passed and it was mainly through his efforts that the measure was enacted into law.

Committees were appointed to draw up a constitution and by-laws and to arrange the financial organization of the society. The next meeting was scheduled for the following March. According to the constitution adopted at that time membership was open, by a majority vote of the society, to any physician residing within the county who was a graduate of any medical school or a licentiate of any state or county medical society recognized by the American Medical Association. The admission fee was two dollars and at each annual meeting two honorary members over sixty years of age might be elected. The next year it was decided that meetings should be semi-annual (in January and in June) rather than four times a year. Dr. Sprague remained in the office of president of the society until 1874. Other physicians who served in this capacity during the seventies were Dr. Thorne (1874 and 1877), Dr. Finch (1875 and 1876) and Dr. Dodge (1878). In 1875 two new members, Drs. C. P. Fuller and J. R. Marvin, were elected.

The office of county physician remained the same as in the preceding ten years with much the same duties. In 1873 Dr. C. P. Adams was appointed county physician at the salary of \$200 per annum. 1877 Dr. Thorne received \$250 and in 1879 he received \$270 for the same services.

Visiting "physicians" gave series of lectures in the different towns several times a year. For example, in September, 1873, a Dr. Voltz lectured in German on physiology and anatomy. He was followed the next month by a Dr. Anderson who illustrated his lectures with charts and a manikin. The next summer a Dr. O'Leary of Boston gave a number of talks in the Hastings court house which were well attended. His wife gave two lectures to the ladies. Drs. Humphry and

Stoltz of the Winona Institute came to Hastings occasionally for short periods. Dr. C. A. Miner of Chicago made a regular habit of coming to Hastings every three months and there was a Dr. Wheeler "who for fourteen years traveled with the celebrated Indian doctor." Among the newcomers who remained in Hastings was Dr. R. Freeman who established an electro-thermal bath institute. He advertised widely in the newspapers but there is no indication that he ever attended a medical school. Some years later, after pleading guilty to running a house of ill fame, Dr. Freeman moved to Minneapolis. All degrees of quackery were represented yet such "physicians" must have had a moderate success since they continued their visits.

Drs. F. D. Chapman and G. H. Hawes were both reputable homeopaths who established themselves in Hastings.

Dr. L. M. J. Leonard and Dr. J. D. Brundage were among the regular physicians who settled as newcomers in Hastings. Dr. W. C. Eustis, who was one of the first students at the state university and who studied medicine at the University of Michigan, settled in Farmington. Drs. R. F. Goodwin, Dennis Smith and W. W. Furber each practiced in partnership with Dr. C. P. Adams for a short period. Dr. W. H. Thurmond came to Rosemount in 1879 and remained there several years.

1880-1889

During the first years of the eighties, Dr. P. A. Heitz, a member of the Missouri and the Minnesota State Medical Societies, settled in Hastings as did also Dr. Henry Hahn, formerly of Young America, and Dr. Alfred Adsit who became one of the prominent physicians in the city. Dr. E. W. Hammes located in New Trier where he was very well known for many years. Dr. H. C. Johnson located in Farmington. In 1889 Dr. H. Van Beeck, who served the county as physician and coroner for many years, opened an office in Hastings. Other physicians who practiced for short periods in the county were Drs. A. C. Dockstader, J. M. Tucker, W. F. Kertson, W. O. Tessier, W. R. Endris, James Gravelli, V. J. Hawkins and C. F. Miller.

In 1882 and 1883 there were a few cases of small pox and several deaths from typhoid fever. The only diseases that assumed epidemic forms, however, were scarlet fever and diphtheria. In the summer of 1881 the former was reported as "raging" in Hastings and the surrounding vicinity. Physicians were reported to have their hands full and authorities were taking steps to prevent its spread. It occurred again in the fall of 1882 in Douglas and Hastings and continued to be prevalent and severe until the spring of the next year. In 1889 there were a number of cases.

Diphtheria occurred in a mild epidemic form in Hastings and Vermillion in 1882 and severe cases were recorded in 1885 in Farmington and Vermillion. The citizens of Vermillion were finally stirred to organizing a local board of health under the charge of Dr. C. P. Adams. This board was to make rules and regulations, in conformance with those of the Minnesota State Board of Health, to prevent the spread of contagious disease. This, apparently, was the first local board of health in the county. Three years previous the state medical society had sent a questionnaire to leading physicians in most of the larger towns of Minnesota in order to make a survey of local boards of health.† Dr. L. P. Dodge of Farmington replied that there was no such board in his town, and in answer to

†Transactions of the Minnesota State Medical Society for 1882.

a question as to the chief difficulties which prevented the establishment of such a board, he replied that it was "the pure hellishness of a certain class of people that you will find in all communities but particularly in small towns—a class that cannot conceive of a medical man being interested in the well-being of his neighbors to the detriment of his own pocket." He suggested as the solution stringent laws and the means to enforce them. In Hastings also a board of health was organized aboutt his time. Dr. J. M. Tucker filled the office in 1886, Dr. H. Hahn served in 1887, and Dr. J. C. Fitch was elected for the two following years.

By 1880 the population in the county had increased so much that it was impossible for one man to attend all the indigent sick in the county. Consequently there were several county physicians instead of one. One physician was appointed to attend all sick persons in the county jail for the sum of \$100 per annum, another to attend those at the poor farm at Auburn for the same salary, and a third to attend all the county charges within a six mile radius from Hastings for \$150 per annum. These salaries included medicines. Since other physicians presented small bills to the county commissioners from time to time, it may be assumed that those who did not fall into the above districts were cared for locally.

These appointments were generally made by the commissioners on the basis of the bids received. There was an objection to this, as may be seen from the following statement which was presented to the commissioners in January 1887:

"We, the undersigned physicians and surgeons of Hastings and vicinity, believing it to be as unprofessional as it is uncomplimentary to receive employment as the lowest bidder, hereby refuse to tender our services as bidders to the commissioners of Dakota County for the medical and surgical treatment of the paupers, including inmates of the poor house and prisoners in the jail of said county.

"We believe, further, that said paupers and prisoners have as much right to choose their attendant as they have to gratuitous treatment at the county's expense.

"And we believe also that no physician whose name appears below will make exorbitant charges for services rendered the county, while, at the same time, all should be fairly remunerated for such services when faithfully and honestly performed."

This document, which was signed by all the reputable physicians practicing in the county at the time, included the following names: J. C. Fitch, A. M. Adsit, H. Hahn, J. E. Finch, G. H. Hawes, J. M. Tucker, P. A. Heitz, Wm. Thorne, W. C. Eustis, L. P. Dodge, H. C. Johnson, J. P. Caldwell, E. W. Hammes, C. P. Adams, and P. Barton.

A short time after this agreement considerable stir was occasioned among the physicians when it was learned that Dr. Henry Hahn, who had supported the movement, agreed to treat all paupers within a ten mile radius of Hastings including prisoners at the county jail and to supply all medicines for the sum of \$300 per year. Dr. Hahn met the barrage of criticism in a letter which he wrote to the *Hastings Gazette* and by a statement from the county commissioners in both of which he maintained that he did not bid for the position but that it was offered to him and he was not obligated to refuse. The situation was unpleasant, however, and Dr. Hahn left the city at the end of the year.

(To be continued in January issue)

President's Letter

THE PHYSICIAN'S REWARD

MEDICINE of tomorrow will be Preventive Medicine. It is in this field that the greatest progress can be expected. Prevention of disease is the highest attainment and the ultimate goal in medical achievement. To prevent disease is a much greater boon to humanity than curative measures.

Already progress has been made. Diseases and accidents in industry have declined markedly, and time loss has been greatly shortened. The same is true of diseases of childhood. Typhoid fever, smallpox, diphtheria, yellow fever, and malaria are among the diseases that should not exist in any intelligent country, now that we have learned how to control their occurrence. The next step will be control of tuberculosis. The prevention of tuberculosis in cattle has been so spectacular that our State Medical Committee on Tuberculosis is fully convinced that this disease should and can be prevented in the human family. November 7, 1940, may be looked upon in the future as an important date. On that night in Meeker County a movement was started by organized medicine to eliminate all tuberculosis in that county. If successful, and we believe it should be successful, other counties will follow suit, and we anticipate the day when tuberculosis in our state will be as completely controlled as is typhoid or diphtheria.

Many diseases are still beyond the reach of medical science. This is particularly true of those diseases most common in middle and advanced age. The degenerative diseases, such as cancer, hypertension, renal, and cardiac diseases, are increasing in incidence with a steadily growing mortality rate. The treatment of these diseases, unless detected very early, is palliative only. If allowed to become firmly entrenched, eradication is usually impossible.

This brings to the fore a duty as well as an opportunity, which the great body of physicians does not yet fully appreciate; that is, thorough periodic physical examinations. In the University of Minnesota Student Health Service every new student is given a comprehensive medical examination. Those in charge claim that one of its most important functions is in educating the student to have periodic physical examinations. Many larger clinics and many individual physicians stress this matter. But to large numbers of physicians, it is a subject to which too little attention is given, partly perhaps because the physician does not feel qualified to carry out the details required, and partly because he does not realize its importance. A periodic examination, to be of any value, must be thorough and complete. A physician must be observant and painstaking. A mere casual examination is not of much value. To be worthwhile to the individual the examination should be repeated annually and more frequently in case of suspicious findings. Not only should the examination include a full general physical examination, including heart, lungs, blood pressure, blood and Wassermann, but particular attention should be given to the cardio-vascular-renal system, the entire gastro-intestinal tract, and the genito-urinary tract. Many cancers can be discovered by this means sufficiently early to obtain surgical cure. Many individuals with beginning cardiac, renal, or hypertensive troubles, if caught sufficiently early, can be advised how to live so that progress of the disease may be kept minimal and a useful life maintained. Too many catastrophes are occurring every day which might have been avoided had foci of disease been discovered in time and proper measures instituted.

A complete, thorough, physical examination requires much time and intensive effort on the part of the examining physician, and in many cases a meager fee can be expected. But if we are to measure up to our responsibility as physicians, we must realize that this is one of our most important duties to humanity. To a true physician the welfare of his patient is of first importance—his chief reward is the satisfaction of having given the best advice and service possible.

Volume 23 DECEMBER, 1940 Number 12

THE PROFESSION AND THE DRAFT

IN KEEPING with the resolution passed by the House of Delegates of the American Medical Association last June in New York, and in keeping with professional principles, the medical profession is donating its services in connection with the draft as its part in the national defense program. Physicians over the draft age and not members of the military service or reserve have volunteered to serve without pay—one in each district—to examine those drafted. Advisory boards consisting of specialists give their services when requested by the district examiner. Then the state has five appeal boards, each consisting of seven lay members and one physician, to which the registrant can appeal. These medical services are rendered gratis and

no provision has been made for fees except for certain laboratory examinations.

Induction into the service takes place at just one place in the state—Fort Snelling. Here the so far accepted soldier undergoes another physical examination at the hands of an induction board made up of a group of civilian specialists, who may be called upon to spend several days a month. The members of this board are compensated at the rate of a major's pay. The intent is to have this examination so thorough that experiences following World War I will not be repeated.

It is the purpose of the defense program to mobilize a sufficient body of men without disrupting civilian life more than necessary. That considerable disruption will occur, however, is unavoidable. In the medical profession, for instance, there are some 608 Reserve Officers in the state, subject to call on only ten days' notice. This is obviously too short a time for a physician to arrange for the medical care of his patients and for disposition of his family and business affairs.

Then there are the several hundred medical students, interns and young doctors in the draft age group. The drafting of medical students and interns is deferred to enable them to complete their training. It is the purpose of the military authority to place inducted men according to their trade or professional fitness. As the enlisted personnel increases and the need for physicians in the service increases, there is no doubt but what inducted physicians will be given commissions as first lieutenants whose salaries are \$2,695 for single men and \$3,152 for married men.

The chairman of the committee for Minnesota of the Committee on Medical Preparedness of the A.M.A. and chairman of the Committee on Military Affairs of the State Association, Dr. F. L. Smith of Rochester, reports that 93.4 per cent of the questionnaires sent to the profession of the state by the A.M.A. have been filled out and returned. Those members who have not so far returned these questionnaires are requested to do so. Duplicate forms may be obtained from

Mr. R. R. Rosell at the office of the Minnesota State Medical Association, 493 Lowry Medical Arts Building, Saint Paul. The Seventh Corps Area, under the leadership of Dr. R. M. Fouts of Omaha, is the only district that shows a better coöperation by a better percentage return of questionnaires.

Reserve officers are inquiring as to the likelihood of their being called into service. Dr. Smith states that medical officers of company grade are likely to be called first, before those of field grade. A questionnaire was sent out by the First Military Area shortly after the A.M.A. questionnaire was mailed, in which the question was asked, "How much time is needed for closing up local affairs before going into active duty?" Presumably the desires of reserve officers as expressed in this questionnaire will receive consideration.

The preparedness campaign is a stupendous undertaking and is vital, although we are not at war. The unanimity of public opinion as to the need for defense is gratifying. The medical profession is doing its part in connection with the draft.

THE BLOOD BANK

MOST hospitals have either a "blood bank" or its near equivalent; that is, a list of readily available donors of known groupings and negative flocculation tests. A hundred years ago Blundell pointed out that hemorrhage is the most important indication for a blood transfusion.¹ This, we feel, is still the primary need for whole blood, but it must be granted there are many other indications in which whole citrated blood is invaluable. However, the intravenous administration of blood plasma is recognized as a rational procedure in the treatment of secondary shock resulting from the loss of blood plasma with consequent hemoconcentration. In our mechanized life where war, automobile and industrial accidents occur, and also where burns, operations and states of hypoproteinemia are met with daily, the use of blood plasma is proving of real value.

The blood plasma may be obtained from the citrated bloods in the "blood bank" by siphoning off the supernatant fluid from the cells which have been deposited at the bottom of the container after several days' storage. If fresh blood

plasma is preferred, blood is withdrawn from a donor, the cells are separated from the plasma by centrifuging, and in turn the supernatant plasma is siphoned off. The blood plasma from various donors can be pooled irrespective of the donors' groupings. In turn the individual or the pooled plasmas can be administered subcutaneously or intravenously, irrespective of the recipient's blood grouping. In an extreme emergency this eliminates the necessity of knowing a prospective recipient's blood grouping if a plasma transfusion is needed in a great hurry. Liquid blood plasma can be stored at room temperatures for indefinite periods, the addition of 1:10,000 aqueous solution of merthiolate (sodium ethylmercurithiosalicylate) acting as a bacteriostatic agent. For increased convenience of storage or transportation the citrated blood plasma may be dried to a powder and kept in a sterile container.² For use the powdered plasma is dissolved in sterile distilled water. Investigations now in progress will eventually lead to the development of a mixture of materials already known which may provide us with a synthetic dried plasma or its equivalent. As experimental and clinical data continue to be presented to the profession, we shall become convinced of its value in specifically indicated cases. It would be a considerable contribution to medical science if quantities of blood were given voluntarily to provide material to carry on this work.

A CLINICAL COMMENT ON THE USE OF BARBITURATES

SOME clinicians are fully aware of the over-enthusiastic use of metals in syphilis. The syphilis "is cured" but the patient may have a nice hard liver or a full blown arteriosclerosis. Nothing very definite has been established on the end-results with the use of the barbiturates. The commonest associated clinical lesion in an epileptic colony was biliary tract disease.⁴ This was blamed on the prolonged use of phenobarbital. Acute poisoning has occurred with clinical dosage in cases of idiosyncrasy. Untoward action has

been noted in patients with cardiorenal involvement.⁵ The psychiatrists are growing wary of the barbiturates.⁶ State laws have been passed to inhibit indiscriminate use of the barbiturates, mainly to avoid homicidal intent.^{1,2,3}

Aside from these dramatic possibilities, there still is a phase of barbiturate usage which deserves comment. The barbiturates have their place as a hypnotic or sedative or analgesic in emergencies in fairly healthy patients. Never have there been drugs which make sleep so easy. But their continued use for this purpose is a questionable procedure. Such use has often fogged the issue in bedside consultations. Increased nervous irritability has been observed. A sort of delayed reversible action is sometimes established. All of which prolongs hospital stay and demands reeducation of sleeping habits. In the average situation why not go back to our old friends, hydrotherapy and psychotherapy to bring about sleep? But that is work. Work for the doctor; work for the nurse. There is the rub. Sleep made easy for all concerned seems like an ideal arrangement. These drugs have made the clinician "soft"; the nurses lazy. When it comes to the problem of sleep for a patient, the old gag about the WPA worker has "nothing on us."

FOR COUNTRY

FEAR, though unwarranted, that a change in the attitude of our government towards warring Europe would follow a change of administration at Washington, doubtless accounted in part for the outcome of the recent election. The acceptance of the will of the people as expressed in the post-election radio address of the defeated Republican candidate was a fine example of good sportsmanship. The sentiments expressed could well be adopted by the medical profession.

The medical profession should and will join the government to present a united front to foreign nations. As to domestic affairs, however, we shall continue to fight for what seems right for our country and our profession, as we see the right. We shall fight for the preservation of the American system of medical practice as expressed in the Platform of the American Medical Association. We may well add to our objective the support of the American system of private enterprise in all lines of activity.

It is with some satisfaction that we note that the government's suit against the American Medical Association is postponed indefinitely. We should think the government had more important things to do. It may be, too, that the enormous sums being appropriated for national defense will indefinitely postpone the consideration of governmental expenditures of Wagnerian proportions for medical activities.

There is no reason, however, to expect that there will be a total let down in the activities of those Utopia-minded citizens for whom state medicine is the final and only answer. The recent attempt on the part of the U. S. Public Health Service to utilize the draft for a public health measure is an indication of how the national emergency may be used in the future for a smoke screen in advocating pet measures. It behooves the profession as individuals and in groups to be on the alert to bring into the open and oppose extreme socialistic trends in government. This is not inconsistent with wholehearted support of the government in international affairs.

MORE OR LESS OF A QUACK

EACH month reports from the State Board of Medical Examiners concerning investigations, arrests and convictions of persons who have attempted to practice medicine without a license are published in MINNESOTA MEDICINE.

The number of convictions among these cases is extremely high. That means that the State Board and its attorney are doing their work with great care and efficiency. It also means that they have coöperation of a high order from law-enforcement agencies and courts of Minnesota.

It is rare, however, for a judge of the district court to issue the kind of rebuke administered

by Judge Gustavus Loevinger of Saint Paul in the case against a Saint Paul chiropractor, Edward Ferdinand Jacobson, who pleaded guilty to the charge of practicing medicine without a license in Judge Loevinger's court last month.

The complete text of Judge Loevinger's remarks and of the entire Jacobson case appear on page 877 of this issue. They should be read by every physician. It is unfortunate that they could not have been heard in person also by every holder of a license to practice healing who is tempted from time to time to overstep his own qualifications and the field in which his license permits him to practice.

The effects of the rebuke by the Court upon the man who was sentenced in this case was undoubtedly considerable and it probably extended to his friends and even to associates who were not in court to hear Judge Loevinger pass sentence.

Physicians who read it in full will be especially grateful to Judge Loevinger for his understanding of medical ethics and requirements and for the humanitarian feeling displayed in his remarks.

"It is unfortunate," the Judge said to the chiropractor in this case, "that when some people are in physical trouble, when they are ill or have any other physical difficulty, instead of going to some person who is qualified to treat them, they are likely to go to some person who is more or less of a quack in that particular line. I am not reflecting on your ability as a chiropractor, but on any other line you are just a quack. You have no authority to practice medicine and anyone who pays you money, therefore, pays it to you under false pretenses."

This is a forceful statement of the case against the practice of medicine by unlicensed and unqualified practitioners of any kind. Coming from a jurist of Judge Loevinger's standing it is likely to have a very wholesome effect on the shady fringe and also upon all who do not draw the line carefully, dividing their field from the legitimate practice of medicine.

It is to be hoped that it will also open the eyes of a few patients to the limitations of some fields and some practitioners who are licensed under the law to practice healing in Minnesota.

CHRISTMAS SEALS

A CALL for the enlistment of all of our people in the crusade against tuberculosis is made by Dr. Nathan B. Van Etten, president of the American Medical Association, in a statement issued in connection with the thirty-fourth annual sale of Christmas Seals.

Dr. Van Etten's statement follows:

"We have come to a time when every health agency must be mobilized for national defense. Defense against disease is quite as important as defense against a military enemy. Education has played a most important part in the defense of our people against the invasion of tuberculosis. We must not only consolidate our gains, but we must push forward with objective planning. The enlistment of all of our people in the crusade against tuberculosis through subscription to the Christmas Seal Sale is more important than ever before—and all of us should do our best to promote a continuous campaign."

COST OF TUBERCULOSIS

Tuberculosis, during and after the World War, has cost approximately \$960,000,000 to date in compensation, vocational training, insurance and hospitalization. The moist rôle, which was the criterion of fitness for the World War, is shown by experience, much of which has accumulated since that time, to be much less reliable than radiography in situations analogous to the examination of recruits. A huge amount of compensation has been paid out to men manifestly tuberculous at the time they were sent to camp who should have been rejected by the local draft boards, but were not.

A normal chest roentgenogram should be the criterion of acceptance in a future mobilization, including the draft for training, and it should be made and reported before the recruit has spent a night away from his own roof to obviate a repetition of the claims for aggravation of pre-existing tuberculosis which occurred during and after the World War.—RAMSAY SPILLMAN, M.D., Jour. A.M.A., Oct. 19, 1940.

REPRINTS REQUESTED

Notice has been received from the Surgeon General that the Army Medical Library will gratefully receive reprints for filing under the author's name. Thus the bibliography of any writer will be readily available and the reprints will provide an additional source of material for loaning. MINNESOTA MEDICINE will automatically send reprints of articles ordered to the Army Medical Library at Washington.

MEDICAL ECONOMICS

Edited by the Committee on Medical Economics
of the

Minnesota State Medical Association

W. F. Braasch, M.D., Chairman

IS THERE A DICTATORSHIP IN THE AMERICAN MEDICAL ASSOCIATION?

An article recently published in *The Public Opinion Quarterly* entitled "Organized Medicine Enforces its 'Party Line,'" by Oliver Garceau is typical of many recent articles which contain biased and misinformed criticism of the American Medical Association by the layman advocate of reform in medical practice. This article is largely devoted to a critical discussion of the attitude of medical organizations toward reform in medical practice and the methods employed by the officers of the American Medical Association to influence the opinions of its membership.

Lack of Culture Charged

The author introduces his diatribe by accusing the physician of a lack of culture and intellectual background, and states that he has no interests other than medical. To those of us who know of the many members of our profession who have shown an active interest in various arts and sciences the accusation seems ridiculous. The physician's love of music is attested by the existence of several excellent orchestras which are composed entirely of physicians, as well as many other orchestras in which they form a large portion of the personnel. Several exhibits of paintings which have appeared in recent years have been contributed entirely by members of the medical profession. Some of these paintings have received national recognition.

All Arts Among Hobbies

Anyone who has visited the various hobby shows conducted by county and state medical societies would realize the wide variety of interests with which the medical mind has occupied itself. The field of literature has been overwhelmed in recent years with contributions from

the ranks of physicians. It is true that some of these publications are of questionable merit, nevertheless there are a number which have received unusual recognition and several are included in the list of "Best Sellers." In fact, it would seem that the only fields which the physician has not invaded in large numbers are the narrow lanes of economics and sociology, from which the author makes his academic criticism. Although it is true that there are not many physicians who are instructors in these fields, nevertheless there are a number who have given these subjects careful study and are not entirely unfamiliar with the problems involved.

It's a Common Fallacy

The author of this article is guilty of a fallacy common to many reformers who are critical of the policies adopted by the American Medical Association in assuming that the Association is so organized that it can dominate the opinions of its members. He fails to realize that the policies adopted by the American Medical Association are guided by the convictions of the majority of its members. The intelligent-minded liberty loving physician would resent the dictation of any medical oligarchy. In fact, the officers of the American Medical Association have been criticized sometimes for their conservatism in carrying out new policies advocated by branch societies. The answer always has been that they wanted to be sure that it would have a favorable reaction among the rank and file of physicians and among constituent societies before adopting a national policy. If there ever was a truly democratic and representative body it is the House of Delegates of the American Medical Association. The members of this well-informed, intelligent body would vigorously represent the charge that their opinions were being forced into line by the officers of the American Medical Association.

They Needed No Urging

It hardly seems possible that anyone, unless his vision were obstructed by cloistered academic walls, would criticize the American Medical Association for its efforts in perfecting the medical defense of the nation. The members of the A.M.A. wish no credit for doing their patriotic duty. Their only desire is to be of every possible aid to national defense, and that their efforts may not be hampered by literary sniping and ill-advised threats from the Department of Justice. The members of the American Medical Association needed no command or urging from their officers to volunteer in defense of the nation. The medical officers of the Army and Navy were the first to receive the coöperation of the members of the A.M.A. when the emergency arose. It might be said that if other fields of national defense were as well equipped and ready for action as that of the medical profession, there would be but little danger of invasion of the western hemisphere.

A large part of this article is devoted to a discussion of the methods employed by organized medicine in enforcing its policies, and the influence exerted by the *Journal* of the American Medical Association. He admits the excellence of the *Journal* and the strength of its editorial policies, but grossly exaggerates the influence it has on the readers. Although the virile editorials usually reflect the thought of the majority of the members of the Association, differences of opinion have arisen from time to time, which have been freely aired in the House of Delegates.

Editors Would Resent

The author apparently believes that the opinions of physicians concerning the economic phases of medicine can be held in line by the editorial columns of the *Journal* as easily as the recent barrage of articles on reform seems to have influenced a section of the laity. The statement that the various state medical journals merely echo the sentiments expressed in the editorial columns of the *Journal* of the A.M.A. would be vigorously resented by their editors. In singling out the militant editor of the Illinois Medical *Journal* as an example the author makes a grievous error, since the worthy gentleman usually is several laps ahead of the rest of us. It is insinuated that officers of the American Medical Association go around pussyfooting

among the various state societies to discover any evidence of insurrection against the policies of the A.M.A. The author evidently is not aware that no representative of the A.M.A. attends a meeting of a constituent society unless he is invited. There is no field officer of the Association and many of the state societies would resent the suggestions of such an officer if appointed.

Object is Public Welfare

Attention is called in the article to extreme methods which have been employed occasionally by some of the medical societies in dealing with their members who violate the principles of medical ethics. There may be some justice in this criticism. It is open to question whether medical organizations should adopt methods of enforcement commonly employed by trade unions. Average laymen, however, do not realize that the main objective of the principles of ethics adopted by the medical profession is to further the best interests of medical care and the public health. If they also confer any economic advantage, as the author intimates, it is a secondary consideration.

Ignorance concerning the details of organization of the American Medical Association and failure to appreciate the various factors involved in carrying on its activities and in determining its policies is common to most social reformers. If they would take the trouble to make a careful and unbiased investigation of the facts involving the A.M.A. and its activities, as well as a careful study of all of the factors involved in the present methods of medical practice, there are not many who would write the articles they do.

W. F. B.

WHAT ABOUT THE YOUNG DOCTOR?

Draft board examinations are now under way and the machinery virtually complete for final induction of draftees—from a medical standpoint—to the centers for military training.

Preparedness questionnaires have also been filled and mailed to Chicago by the vast majority of Minnesota physicians.

With these essentials to the National Defense plan out of the way, the problems of individual physicians who are expecting to go into service, for a limited period, themselves, demand attention by both army authorities and medical organizations.

In time of actual war, the punch card information on every doctor, now in possession of the American Medical Association and the War Department, will undoubtedly be put to use. On a wartime emergency basis, physicians who are not eligible for active duty will undoubtedly be sent by the government to fill the gaps.

Peacetime Problem

But we are not functioning now on a war emergency basis. Will the War Department and the American Medical Association arrange for substitutes for the young physician who, for example, is a member of the Reserve Corps and will perhaps be called to service soon and upon short notice? Will they protect his lease, his investment in the tools of his trade? Take the case of the young physician who practices alone in a small community. He has built up a promising practice; he has long term obligations for office equipment and, probably, a long term lease for office space. What is to become of this young physician's practice during a period of his peacetime service with the military forces?

Many plans have been proposed to take care of this young physician. Several state and county medical societies have drawn up schemes. A New York plan calls for a substitute who will turn over all fees collected to the county medical society for the physician's account. Other plans call for a substitute who will retain half the net income of the practice, depositing the other half for the absent physician with the county medical society.

Penalty Unfair

Obviously, no matter how careful and ethical the substitute may be, no practice can be turned back intact to a physician.

Some patients will object to the substitute; others will prefer him and, if he refuses to accept them after their own physician returns, they may go elsewhere. In any case, a costly equity in equipment and office space may be lost.

These problems must be discussed fully and some solution discovered—if an unfair penalty is not to be imposed upon many patriotic young physicians who have more than a job to lose when they give their services to Uncle Sam.

PHYSICIANS MUST WATCH

In company with commentators and columnists of all shades of opinion, doctors are wondering what direction the third term will take.

According to most, the direction will be far different from that of the second term, just as the second term was different from the first.

The special interest of physicians lies, of course, in possibilities for expanding the Social Security Act and particularly for early passage of a new national health program.

Current Washington comment is unanimous in a belief that this time the administration is prepared to enter upon a world stage. In the years just ahead the power and influence of the United States is to be directed toward a hemisphere New Deal and domestic reform, according to this opinion, plays very little part in any planning now under way.

"More inside attention is being given to a nod of approval by the Emperor of Japan," says the *United States News*, "or to a statement by America's Ambassador, Joseph Grew, than is being given to broadening Social Security legislation, or for creating health insurance or for injecting more reform taxation into taxation policies at home."

The danger to American forms of medical practice obviously lie not so much by way of pending legislation but in the sweeping regulations that may be made, ostensibly, to speed and strengthen national defense.

Physicians who are doing their utmost to aid the National Defense program must also watch closely to see that an exclusively military program does not almost insensibly become a domestic reform program carrying with it the worst aspects of government medicine for the civilian population.

"WHAT IS YOUR ANSWER?"

[Monthly Editorial Prepared by the Medical Advisory Committee]

The type of medicine and surgery practiced in Minnesota today is as efficient as any carried on any place in our country and yet the men of our society are still menaced by entirely too many malpractice suits. How can this be? Each reader may have his answer to the question.

Can it be that in our endeavor to obtain the perfect result, we are overdoing our treatment, especially in the fracture case, and defeating the endeavor of nature to help us to effect a cure?

Is it that we are depending too much on the results of so-called scientific research and the newer medical drugs and too little on common sense in the treatment of diseased conditions?

Are we jumping at conclusions from laboratory studies before taking into consideration the findings of a careful and pains taking history?

Do we, because of the medical education which we have, hold ourselves aloof from the commonplace and forget that tact and courtesy are of great use in the dealing with any type of psychopathic personality?

These, and many other questions and thoughts have run through the minds of the members of your Medical Advisory Committee as, for the past five years, they have scanned the questionnaires sent in by members of our Society who find themselves in trouble.

We believe that 1941 will be successful in molding the members closer and closer together in harmonious pursuit of the ideal—a lessened number of suits—by a close adherence to common sense, keener judgment and a use of tact and courtesy towards patients and other members of our profession.

Let the study of medical ethics and their promulgation be made a New Year's Resolution. A keener sense of responsibility will be the result.

B. J. B.

NEW WRINKLE

Group insurance is now being written, according to the current issue of *Business Week*, for the trucking company members of a large Chicago motor freight association. The policy covers hospital expense, surgical fees, sickness, and accidents.

This represents a new wrinkle in commercial group insurance. The insurance company agrees to write the insurance at group rates below individual rates for comparable coverage. The employee makes his own decision about buying but if he decides in favor of insurance he gets his own policy and tells his employer to take the premium out of his pay.

Other loosely knit groups of individuals such as drug store chains, the retail hardware association, and the American Institute of Decorators are also arranging for similar group

policies for employes of members, even when the individual member-employer operates only a small business with a limited group of employes.

The development of commercial insurance plans to cover hospital expense and surgical fees has obviously only begun but may reach proportions that will completely eclipse non-profit community experiments in sickness insurance of this type.

MINNESOTA STATE BOARD OF MEDICAL EXAMINERS

Julian F. DuBois, M.D., Secretary

California "Health Lecturer" Pleads Guilty to Fraudulent Advertising in Minneapolis.

Re. State of Minnesota vs. Stanford Kingsley Claunch.

Stanford Kingsley Claunch, fifty-five years of age, who stated he lived "in California," entered a plea of guilty in the Municipal Court of Minneapolis on October 25, 1940, to a complaint charging him with fraudulent advertising. Claunch was sentenced by the Hon. P. W. Guilford to a straight term of ninety days in the Minneapolis Workhouse, which sentence was suspended on the condition that Claunch refrain from any more activities in the State of Minnesota, and upon the further condition that Claunch leave the State within 4 days.

Claunch was arrested on October 23, 1940, at the Andrews Hotel in Minneapolis, following a joint investigation of his activities by the Minnesota State Board of Medical Examiners, the Hennepin County Attorney's office and the Minneapolis City Attorney's office. Claunch had advertised in the Minneapolis papers that he would give four health lectures at the Brunswick Room of the Andrews Hotel on October 14, 15, 16 and 17. During these health lectures he announced that he was formerly "a practicing naturopathic physician," and "first vice president and director of the American Health Foundation, chartered in Washington, D. C., by the United States Congress." Claunch also announced that he was going to conduct two master courses in Minneapolis, the first one entitled "The Physical Life," and the second one called "The Mental Life." The fee for the first course was \$15.00 and \$10.00 for the second course, or the two courses combined for \$20.00. Claunch professed to his audience that he would have no trouble in treating epilepsy, tuberculosis, diabetes and many other ailments. One of the mistakes made by Claunch was to distribute a circular reading as follows

"THE CLAUNCH SYSTEM OF SCIENTIFIC EATING
Based on the Electrical Energy (Life Force), as Well as the Chemicals, in Food
Is the Only Plan—

That will actually feed illness right out of your body and positive, dynamic health into it. That will eliminate deposits of mucus, pus, acids, drugs and other poisons and at the same time keep up your strength. That will thoroughly nourish your brain and nerves. That will make your skin as soft as velvet and free it from blemishes. That will return your body to normal weight from either extreme. That will completely reshape your body and restore it to its original beautiful form."

Based on the foregoing statement, a complaint was issued by Mr. Joseph A. Hadley, Assistant City Attorney of Minneapolis, charging Claunch with fraudulent advertising. Claunch was immediately arrested and

his bail fixed in the sum of \$200.00, which was not immediately furnished. The following morning Clauch was arraigned in Municipal Court, and despite the fact that he had repeatedly told his audience about his own excellent health, he became very faint in the Court Room and had to lie down. Clauch entered a plea of not guilty and the case was set for trial for October 26. Arrangements were made to have several prominent physicians testify as expert witnesses on behalf of the State in proving the falsity of Clauch's representations. However, Clauch changed his mind about having a trial and entered a plea of guilty.

The Minnesota State Board of Medical Examiners wishes to acknowledge the very splendid coöperation that it received in this case from Mr. Joseph A. Hadley, Assistant City Attorney of Minneapolis, and Captain of Detectives, Clarence E. McClaskey of the Minneapolis Police Department. It should be perfectly obvious that a person who circulates the statements that were made by the defendant in this case, cannot be serving the best interests of the public, and it is encouraging to know that there are public officials who will promptly and effectively act to put a stop to such an imposition upon the public.

Saint Paul Chiropractor Pleads Guilty to Practicing Medicine Without a License

Re. State of Minnesota vs. Edward Ferdinand Jacobson

On November 1, 1940, Edward Ferdinand Jacobson, sixty years of age, entered a plea of guilty in the District Court of Ramsey County, Minnesota, to an information charging him with the crime of practicing medicine without a license. The Honorable Gustavus Loevinger, Judge of the District Court, sentenced Jacobson to pay a fine of \$200.00 or to serve sixty days in the Saint Paul Work-

house. Jacobson paid the fine.

Jacobson was arrested on July 27, 1940, by the Saint Paul Police Department following Jacobson's complaint to the police that a young couple had come to his home and demanded \$300.00 to pay the hospital expense of a 19-year-old Saint Paul divorcee. In the subsequent investigation it was learned that this young lady had gone to Jacobson on July 18, 1940, for what Jacobson described as "delayed menstruation." Jacobson stated that he proceeded to treat her with an electrical device which he inserted in the vagina. The girl subsequently became ill and was taken to a Minneapolis hospital. Upon recovering her health it was reported that the girl again attempted to secure some money from the defendant, ostensibly for the purpose of leaving the city. The defendant stated at the time of his arrest that he had been employed by the Railway Mail Service since 1907, and was receiving \$2,450.00 per year. He stated that he practiced chiropractic in his spare time at 244 Hamm Bldg., Saint Paul, Minnesota. Following his arrest, Jacobson retired from the Railway Mail Service on a pension, and due to the reluctance of the State's chief witness to testify, it was decided to permit the defendant to plead guilty to a charge of practicing medicine without a license. Jacobson was soundly rebuked by the Court for his conduct, the Court stating:

"You have been licensed by the state to practice a particular form of healing. You have not been licensed to practice any other form of healing. When you undertake to perform any other form of healing beyond that which you have been licensed, you are perpetrating a fraud upon your patients as well as violating the law. It is unfortunate that when some people are in physical trouble, when they are ill or have any other physical

difficulty, that instead of going to a person who is qualified to treat them they are likely to go to some person who is more or less of a quack in that particular line. I am not reflecting on your ability as a chiropractor, but on any other line you are just a quack. You have no authority to practice medicine and anyone who pays you any money therefore, pays it to you under false pretense. It is the purpose of the law to discourage that sort of thing so that people with pain and suffering shall not be preyed upon by people who are not qualified to render competent services. Should you attempt to practice any other form of medicine than chiropractic and appear in court again I suspect the court will be considerably less considerate than I think it has been this time."

Saint Paul Woman Sentenced to Two and One-half Year Term for Abortion

Re: State of Minnesota vs. Bertina Stoyke

Following her conviction by a jury in the court of the Honorable James C. Michael, Judge of the District Court of Ramsey County, Mrs. Bertina Stoyke, sixty years of age, was sentenced by the Court to a term of not to exceed two and one-half years in the Women's Reformatory at Shakopee, for the crime of abortion. The defendant was arrested on August 3, 1940, in her home at 723 Fauquier St., Saint Paul, by

police following the removal to a Saint Paul hospital of a twenty-year-old girl who was critically ill following a criminal abortion.

Mrs. Stoyke was arraigned in the Municipal Court of Saint Paul on August 10, at which time she waived a preliminary hearing and was held to the District Court for trial. The defendant's trial commenced on October 14 with the jury returning a verdict of guilty on October 16, following which she was immediately sentenced.

Notwithstanding the fact that the defendant had no medical training or license of any kind, the evidence indicated that she had performed other abortions. Her charge in the present case was \$30. The girl finally recovered and testified for the state. According to the girl, a catheter was used to induce the miscarriage.

The case was personally tried for the State of Minnesota by Mr. James F. Lynch, County Attorney of Ramsey County. Splendid coöperation was received in this case, not only from Mr. Lynch and his staff, but from the Saint Paul Police Department under Chief Clinton A. Hackert.

United States Supreme Court Refuses to Review Five-Year Suspension of Lake City Physician's License

Re. In the Matter of the Revocation of the License of Gottfried Schmidt, M.D.

Re. Gottfried Schmidt vs. Minnesota State Board of Medical Examiners. (Supreme Court of the United States.)

On November 12, 1940, the Supreme Court of the United States announced its refusal to review the case in which the Minnesota State Board of Medical Examiners had suspended for five years, the license of Dr. Gottfried Schmidt of Lake City, Minnesota. Dr. Schmidt's license was suspended on December 16, 1938, following a hearing before the Minnesota State Board of Medical Examiners, during which hearing it was charged that Dr. Schmidt was guilty of immoral, dis-

honorable and unprofessional conduct as defined by law. The testimony at the hearing before the Medical Board disclosed that Dr. Schmidt had attempted to diagnose various ailments, including cancer, tumors, ulcers, and many other serious conditions, by the use of a piece of wood pulp paper moistened with the patient's saliva. The moistened paper was placed on the abdomen of either the patient or a woman subject employed by Dr. Schmidt in his office at Lake City. Dr. Schmidt also represented that he had a machine in his office with which he was able to broadcast to absent patients.

Following the suspension of his license, Dr. Schmidt appealed to the District Court of Ramsey County. After a hearing before Judge Carlton F. McNally, the Court affirmed the action of the Medical Board, holding that the Board's action "was neither arbitrary, oppressive nor unreasonable." Dr. Schmidt then appealed to the Supreme Court of Minnesota, which Court, on May 17, 1940, handed down an unanimous opinion written by Justice Royal A. Stone, affirming the District Court of Ramsey County. Thereafter Dr. Schmidt served notice of appeal to the Supreme Court of the United States.

Dr. Schmidt was born in Minnesota in 1871, and is a graduate in Medicine from the University of Minnesota in the Class of 1903. Dr. Schmidt was represented by Ray E. Lane of Chicago, and John C. Zehnder of Saint Paul. The Minnesota State Board of Medical Examiners was represented by Hon. J. A. A. Burnquist, Attorney General; John A. Weeks, Assistant Attorney General, and F. Manley Brist, all of Saint Paul.

A. M. A. REFUTES PICTURE MAGAZINE STORY

In twenty-four states osteopaths legally can not under any circumstances use drugs.

In eight states by far the greatest number of osteopaths can not use drugs but it is possible for candidates possessing certain qualifications to obtain that right.

In twelve states osteopaths may utilize stated drugs to a limited extent.

Only in five states, probably, may osteopaths use drugs without restriction. Obviously, then, from the standpoint of the right to use drugs, which an osteopath must possess if he is "to practice on equal or almost equal footing with doctors of medicine," the article in *Life* (August 19) is, to put it charitably, indulging in gross exaggeration when it states "In 33 States qualified doctors of osteopathy are permitted to practice on equal or almost equal footing with doctors of medicine."—*From Pittsburgh Medical Bulletin, Sept 7, 1940.*

THEY PREFER TO RIDE

The United States Department of Labor is authority for the interesting observation that Americans in the low and middle income brackets spend far more on care of their automobiles than they do on their health.

Here is what the figures show in a study just completed of consumer purchases by families in the Rocky Mountain and West Central states:

"The upkeep of the family car exceeded the amount of annual medical bills at every income level covered, from \$750 a year to \$5,000 and over. The average family of all the groups surveyed spent about two or three times its sickness costs on motoring. West Central families with annual incomes of from \$1,250 to \$1,499 spent \$151 on automobiles and \$51 on medical care."

In Memoriam

Samuel Scott Blacklock

Dr. Samuel Scott Blacklock was born December 22, 1874, at Vergennes, Jackson County, Illinois.

His preliminary education was obtained at Dixon College, Dixon, Illinois. Later he went to Valpariso College in Indiana, where he received the degrees of B.S. and Ph.G. in 1898. From there he went directly to Rush Medical College in Chicago where he received his M.D. in 1901. In 1902 he came to Hibbing, Minnesota, and joined the Rood Hospital staff, where he became Senior Surgeon, and remained there until his untimely death. In 1908 he went to Vienna for further surgical study.

Dr. Blacklock was a member of the American Medical Association, Fellow of the American College of Surgeons, Minnesota Medical Association and local societies. He was of the Presbyterian faith. He was a Mason and a Shriner, a member of the Kiwanis Club, Mesaba Country Club, Algonquin and the Kitchi Gammi Club. He was married November 14, 1931, to Mrs. Walter Wischgar, who survives him.

Dr. Blacklock was widely known for his surgical and medical ability which was always coupled with sound judgment. He was a loyal friend and a generous giver to any good cause. He will be missed by his many friends, patients, and the entire staff of the hospital where he has labored for thirty-eight years.

Thus has passed in memoria Dr. Samuel Scott Blacklock of the Rood Hospital Staff.

D. C. ROOD AND STAFF.

Henry H. Clark

Dr. Henry H. Clark, who practiced medicine in Edgerton, Minnesota, for twenty years, died October 31, 1940, in Eitel Hospital, Minneapolis. He was seventy-six years old, and had retired from the practice of medicine five years ago.

Dr. Clark was born in Pleasant Grove, New Jersey, June 30, 1864.

He was a member of Elks Lodge No. 443 of Decorah, Iowa, and of the Pipestone County Medical Association.

Survivors include four brothers, two sisters and a nephew.

Maximilian Joseph Kern

Dr. M. J. Kern, for thirty-five years a practitioner in Saint Cloud, Minnesota, died at the age of fifty-nine, August 10, 1940, following a stroke suffered the night before.

Dr. Kern was born in Wadena, Minnesota, March 17, 1881. He took his preliminary studies at Saint John's University, Collegeville, and received his medi-

IN MEMORIAM

cal degree from Creighton University, Omaha, in 1904.

Dr. Kern practiced two years at Freeport and for a short time at Albany before locating in Saint Cloud in 1906. He took some postgraduate work in internal medicine in Vienna soon after locating in Saint Cloud, and upon his return in 1908 became associated with Dr. J. B. Dunn and Dr. C. B. Lewis. He maintained his association with Dr. Lewis until 1927 when he founded the Saint Cloud Clinic. He served as chief roentgenologist at the Saint Cloud Hospital the past seven years.

Dr. Kern was married in 1905 to Anna L. Welle of Freeport. Besides his wife he is survived by the following children: Mrs. John P. Broderick, New York City; Mrs. Paul Borlin, Detroit Lakes; Dr. Max Kern, Freeport; Mrs. Donald Daubanton, Henrietta Eugene, Margaret, and Virginia Mae of Saint Cloud.

Dr. Kern had been a staunch Catholic all his life. Having been educated in Catholic schools he educated all his children in church schools and colleges. He was one of the most generous supporters of his parish church and was known for his interest in the welfare of Saint Cloud and its people. He served one four-year term as a member of the Saint Cloud City Council and was coroner for several years before his death. He was a member of the American Roentgenological Society, the Stearns-Benton Medical Society, and the Minnesota State and American Medical Associations.

Walter List

Dr. Walter List, former superintendent of the Minneapolis General Hospital, passed away recently in Cincinnati, where he had been superintendent of the Jewish Hospital for the past ten years.

He was fifty-four years old.

Joseph Nicholson

Dr. Joseph Nicholson, former Brainerd physician who built the Northwestern hospital there, passed away, November 5, at his home in Los Angeles. Dr. Nicholson was a practicing physician in Brainerd for many years before moving to California more than ten years ago.

His wife and three children survive.

Theodore L. Streukens

Dr. Theodore L. Streukens, 26, a graduate student in the University of Minnesota Medical School, died October 31.

His mother, a sister and four brothers, all of Minneapolis, survive.

Dr. Streukens was born in Staples, Minnesota, November 14, 1913.

Clinton C. Tyrrell

Dr. Clinton C. Tyrrell, a resident of Minneapolis forty years, passed away, October 22, at the family home, 2422 Johnson Street N. E.

Sixty-three years old, Dr. Tyrrell was born in Norfolk, Nebraska, November 3, 1876. He was a graduate of Hamline University and also the University of Minnesota Medical School. During the World War, he was a member of the Medical Reserve Corps, and served as lieutenant commander of the U. S. hospital ship, Sally. He retired from his practice of medicine and surgery in 1928.

Dr. Tyrrell was a member emeritus of the Hennepin County Medical Society.

Survivors include his wife; a daughter, Thyrsa; a brother, Dr. A. H. Tyrrell of California; and a sister, Mrs. L. H. Burch of Everett, Washington.

PRESENT STATUS OF INJECTION TREATMENT OF HERNIA

In September, 1936, the Council on Pharmacy and Chemistry published a report on the injection treatment of hernia based on the replies to a questionnaire which had been addressed to a selected list of hospitals throughout the country. After consideration of the replies the Council concluded that, although there are cases in which this treatment is applicable and effective, nevertheless it should be borne in mind that the attempted cure of hernia by the application of the method of adhesive inflammation is not new; that it had failed to establish itself as a routine method for such treatment and was still in an early experimental stage; further, that physicians who practice this method should realize the dangers from an ethical, a legal and a financial point of view. To keep the Council's information up-to-date on this subject, the same questionnaire was again addressed to those hospitals which formerly replied. After due consideration of the second hospital survey and the reports in the recent literature, the Council voted to adopt this report to reaffirm its previous opinion that the injection method of treating hernia may not be recognized for general use and should be employed only by those with special experience and with full cognizance of the dangers involved in the use of such solutions. The Council now concurs in the opinion that the method involves less danger of serious complications than surgery when employed only in selected cases of hernia by those skilled in the injection of suitable standardized solutions of known composition and action. The Council is not, however, willing to recognize any such solutions for New and Nonofficial Remedies until sufficient follow-up experience in their application has been gained to establish the success of the injection method of treatment. Present evidence indicates that better types of solution are to be desired. (J.A.M.A., Aug. 17, 1940, p. 533.)

OF GENERAL INTEREST

Twin daughters were born to Dr. and Mrs. Douglas P. Head, October 28.

* * *

Dr. and Mrs. Jerome A. Hilger of Saint Paul are the parents of a son, Michael, born October 13.

* * *

Dr. and Mrs. Wesley W. Spink of Minneapolis announce the birth of a daughter, Helen Gayden, November 12.

* * *

Dr. Reuben F. Erickson of Minneapolis was elected to the House of Representatives from the Thirty-sixth district, South Half, at the recent election.

* * *

Notice—The University of Minnesota library desires back issues of MINNESOTA MEDICINE, separate or bound. Volume 2, No. 7, is especially desired.

* * *

Dr. Arnold E. Naegeli, Saint Paul, married October 31, 1940, Miss Audrey Elinor Miller at Toronto, Canada.

* * *

Dr. Karl Lind, who has held a National Cancer fellowship at the University of Minnesota, has gone to Washington, D. C., to take a governmental position as pathologist in the National Institute of Health.

* * *

Dr. Rigler also presented a paper at the meeting of the American Roentgen Ray Society, which met in Boston in October. Title of the paper was "Roentgen Kymography in Constrictive Pericarditis."

* * *

Dr. R. E. Fricke of Rochester is the newly elected president of the Rochester Kiwanis Club. Dr. H. E. Essex has been named to the board of directors for a two-year term.

* * *

Dr. W. D. Beadie, superintendent of the Mineral Springs Sanatorium at Cannon Falls for the past twenty years, has resigned his position because of ill health. His resignation will be effective January 1.

* * *

Dr. W. F. Braasch of Rochester was recently made a corresponding member of the Sociedad Venezolana de Urologia, in Venezuela, and of the Sociedad Cubana de Urologia, in Cuba.

* * *

Dr. John D. B. Galloway has opened an office at 1251 Medical Arts Building in Minneapolis. He will limit his practice to orthopedics. Dr. Galloway was a Fellow in the Mayo Foundation from 1936-39.

* * *

Dr. H. J. Kurtin of Blooming Prairie and Miss Isabella Shimota of Lonsdale were married November 16. Dr. Kurtin, who opened his office in Blooming Prairie last summer, practiced two years in Lonsdale before going to Blooming Prairie.

Dr. George S. Bergh announces the opening of offices for the practice of general surgery at 1635 Medical Arts Building, Minneapolis. Dr. Bergh is a clinical instructor at the University of Minnesota Medical School.

* * *

Dr. Robert R. Tracht announces the opening of offices at 404 Lowry Medical Arts Building, Saint Paul. He is specializing in the care of the eye. Dr. Tracht is a clinical instructor in refraction at the University of Minnesota Medical School.

* * *

Dr. John T. Kometani announces the opening of his office for the general practice of medicine at 2124 South King street in Honolulu, Hawaii. Dr. Kometani was an intern in the University of Minnesota Hospitals last year.

* * *

Governor Harold E. Stassen has announced the re-appointment of two physicians to the Minnesota State Board of Medical Examiners. They are Dr. F. H. Magney of Duluth, who will serve until 1946, and Dr. Albert Fritsche of New Ulm, until 1947.

* * *

A recent visitor at the University of Minnesota Hospitals was Dr. O. P. Pedroso of Sao Paulo, Brazil. Dr. Pedroso, who is visiting hospitals and clinics in this country, studying hospital administration, will become superintendent of the Sao Paulo Hospital in Sao Paulo on his return to Brazil.

* * *

Dr. W. W. Yaeger of Marshall has purchased the facilities of the Cowin Hospital, it is announced, and has renamed it the Anna Maria Memorial Hospital in memory of his mother. The hospital has ten beds and four bassinets. Dr. Yaeger will continue to maintain his office above the Sward-Kemp drug store.

* * *

Dr. A. C. Kelly, who has been an assistant to Dr. E. K. Rowles at the Rood Hospital in Coleraine for several months, has gone to Duluth to take over the practice of Dr. Roy Mayne. Dr. Mayne, a reserve officer in the United States Navy, has been called to active duty.

* * *

Dr. William C. Bernstein of Minneapolis, who is doing graduate work in proctology at the University of Minnesota Medical School, will go to California about the twentieth of January to spend six weeks as a clinic guest of Dr. Dudley Smith of San Francisco.

* * *

Dr. Jennings C. Litzberg presided at the October meeting of the Central Society of Obstetrics and Gynecology held in Indianapolis. Dr. Litzberg's presidential address was "Continuation Study in Medical Education" based on methods of graduate education at the University.

OF GENERAL INTEREST

Dr. Hymer Friedell, who received his Ph.D. degree in radiology at the University of Minnesota in June, has been studying with Dr. Max Cutler and his associates at the Tumor Clinic in Chicago. He plans to spend the next six months at the Memorial Hospital in New York and then go to San Francisco to be with the radiologist, Robert Spencer Stone.

* * *

Dr. Elmer L. Sevringhaus of Madison, Wisconsin, professor of medicine at the University of Wisconsin Medical School, was convocation speaker at the University of Minnesota, November 28. The subject of his illustrated talk was "Meet Your Endocrine Glands."

* * *

Dr. Leo G. Rigler, professor of radiology at the University of Minnesota Medical School, read a paper at the meeting of the Radiological Society of North America, which met in Cleveland, Ohio, December 2-6. The paper, prepared by himself and Dr. Curtis Nessa of the University of Minnesota was entitled, "Roentgen Findings in Pulmonary Edema."

* * *

Dr. Walter Boothby and Dr. W. Randolph Lovelace, II, of the Mayo Clinic, and Captain Harry Armstrong of the United States Army Medical Corps were awarded the Collier trophy this year for their research work in connection with low atmospheric pressure affects on airplane pilots. The trophy has been presented annually since 1911.

* * *

Dr. Edward M. Baldigo of Red Wing and Miss Marcia Draves of Milwaukee were married, October 19, and are now at home in Red Wing, where Dr. Baldigo recently became associated with Dr. Donald R. Claydon and Dr. L. E. Claydon. Dr. Baldigo is a graduate of the University of Minnesota Medical School.

* * *

Dr. Wallace H. Cole of Saint Paul, director of the Division of Orthopedic Surgery at the University of Minnesota Medical School, will leave for England the latter part of December to replace Dr. Philip Wilson as director of the American Hospital in Britain.

Dr. W. T. Wenner of Saint Cloud announces the association of Dr. J. J. Prendergast, formerly of Saint Paul.

* * *

Dr. Philip S. Hench of Rochester was awarded an honorary doctor of science degree by Washington and Jefferson College in Washington, Pennsylvania, October 26. He participated in the dedication program of the Lazear Memorial Building there.

Last month, Dr. Hench addressed several medical meetings in the East. He spoke before the Delaware Academy of Medicine in Wilmington, November 8; and attended a meeting of the executive committee of the American Rheumatism Association in New York, November 9.

Before returning, he spoke in Champaign, Illinois, at a meeting of the County medical society there.

Dr. Robert Rosenthal of Saint Paul had an interesting pediatrics exhibit at a tea given at the Children's Hospital in Saint Paul for nurses attending the recent state meeting. The exhibit included pictures showing the history of vaccination; pictures portraying the development of lying-in rooms, as well as a miniature lying-in room; a collection showing the development of nursing bottles and other feeding devices.

* * *

The offices of Jolin, Jolin and McKenna in Bovey have been modernized and enlarged. New equipment includes a shock-proof x-ray machine, quartz lamp, basal metabolism equipment and electrocardiograph.

Physicians in the firm include Dr. F. M. Jolin of Coleraine; Dr. M. J. McKenna and Dr. R. V. Jolin of Grand Rapids. It is planned to add another physician to the staff.

* * *

Dr. Cecil J. Watson, professor of medicine and director of the Division of Internal Medicine at the University of Minnesota Medical School, spoke before the Central Society of Clinical Research in Chicago, November 2, on "Variations in Clinical and Chemical Findings in Three Cases of Acute Zinc Porphyrin."

He will speak before the National Gastro-enterological Society in New York City, April 21.

* * *

Dr. W. A. O'Brien of the University of Minnesota Medical School spoke at a special postgraduate course on recent advancements in medicine, sponsored by the Medical Society of Milwaukee County, in Milwaukee, October 29. His subject was "Pathology of the Infant." An unusual feature of this society's meetings is "Fifteen Minutes of Preventive Medicine" which is a part of every program.

* * *

Dr. Joseph B. Gaida, eye, ear, nose and throat specialist, announces the opening of new offices at 207 St. Mary's Building, St. Cloud. Dr. Gaida has been practicing in St. Cloud for more than eight years, being associated with the late Dr. John Gelz and Dr. W. T. Wenner for five years. Since Dr. Gelz' death more than three years ago, he has been associated with Dr. Wenner.

* * *

Dr. Conrad A. Elvehjem, director of the department of biochemistry at the University of Wisconsin, presented the first Minnesota Medical Foundation Lecture at the University of Minnesota Medical School, November 12. Dr. Elvehjem's topic was "The Biochemistry of the Vitamin B Complex." He also spoke on "Vitamins and Nutrition" at a meeting of the Hennepin County Medical Society, November 13.

* * *

As the result of competitive examinations held in July, three Reserve Officers in Minnesota have been appointed as first lieutenants in the Medical Corps of the Regular Army:

Dr. William H. Cleveland of Rochester, Minnesota, a graduate of the Northwestern University Medical School; Dr. John N. Furst of Hallock, Minnesota, and Dr. R. A. Lawn of Minneapolis, graduates of the University of Minnesota Medical School.

OF GENERAL INTEREST

Dr. Wesley W. Spink, assistant professor of medicine at the University of Minnesota Medical School, has received a grant-in-aid from the Committee on Scientific Research of the American Medical Association to support an investigation of antistaphylococcal immunity and the nutritional requirements of staphylococci.

Dr. Spink has also received a grant from Merck and Company in support of a study of ascorbic acid and its relation to the immune mechanism.

* * *

Dr. Henry W. Woltman of Rochester, a member of the committee on research for the prevention and treatment of after-effects for the National Foundation for Infantile Paralysis, attended the first medical meeting to be devoted entirely to the disease in New York, November 7 and 8. Dr. M. S. Henderson of Rochester is also a member of the Foundation's research committee.

* * *

Presiding at the twenty-first annual meeting of the American Student Health Association when it convenes in Ann Arbor, Michigan, December 27 and 28, will be Dr. Ruth E. Boynton of Minneapolis, association president, and director of the University of Minnesota Student Health Service.

Dr. Boynton will give the president's address at the convention, which will have a "Coming of Age" theme. A highlight of the program will be the dedication of the new University of Michigan student health service.

* * *

Words of praise on the University of Minnesota Medical School's Fiftieth Anniversary Volume, "Chemistry and Medicine," appeared in the October 12 issue of *The Lancet* published in London.

The article, in part, follows:

"There could be no more eloquent testimony to the value of chemistry than the volume of papers presented at the fiftieth anniversary of the founding of the Medical School of the University of Minnesota. Under the editorship of Professor Maurice B. Visscher reviews are published in physical chemistry in medicine, investigations in metabolism, aspects of immunity and chemotherapy, and the nervous control of the organism. The writers are men who have earned recognition as researchers, and they present their own work in proper perspective against a background of selected literature."

* * *

Three medical continuation courses were conducted at the University of Minnesota Center for Continuation Study last month.

Twenty-two physicians registered for the course in *General Surgery*, November 4-9, at which Dr. Edward William Alton Ochsner, Professor of surgery at the Tulane University of Louisiana School of Medicine, was the visiting member of the faculty. The registrants were:

Drs. R. J. Wilkowske, Owatonna; Leslie A. Moren, Saint Paul; Arnold Larson, Detroit Lakes; F. Paul Kortsch, Prior Lake, and Harold W. Havel of Jordan, all Minnesotans; John I. Appleby, Bellevue, Ohio; John F. Sparks, Kingston, Ontario Canada; Maurice L. Whalen, Bruce, Wisconsin; H. T. Skovholt, Williston, North Dakota; Paul Reed, Rolla, North Dakota; T. P. Ranney, Aberdeen, South Dakota; Arthur J. Offerman, Omaha, Nebraska; Charles I. Meredith, Valley City, North Dakota; D. S. MacKenzie Jr., Havre, Montana; Everett H. Lindstrom, Helena, Montana; Harvey L. Jorgenson, Marinette, Wisconsin; Elmer N. Hunter, Detroit, Michigan; W. Max Gentry, Gering, Nebraska; Clarence E. Crook, Lincoln, Nebraska; Julius Bloom, Woodville, Wisconsin; M. A. Blackstone, Sioux City, Iowa; and Ellis E. Baker, Scottsbluff, Nebraska.

The Committee on Public Education of the American Psychiatric Association, of which Dr. C. Charles Burlingame is chairman, has organized the country into twelve regional districts, each to have a regional chairman who will have charge of disseminating sound psychiatric information especially suited to each district. An important phase of the committee's work will be to make known the Association's advocacy of better hospital standards for psychopathic patients.

Dr. Ralph C. Hamill, Chicago, is chairman of the district which includes Illinois, Michigan, Wisconsin, Iowa, Nebraska and Minnesota. Dr. Hamill has specialized in psychiatry since 1909, and since 1921 has been with the Public Health Department of the United States and with the Veteran's Bureau.

* * *

Hundreds of his friends from Randall, Minnesota, and the surrounding area honored Dr. Samuel G. Knight and his family at a community gathering, November 9, in celebration of Dr. Knight's thirty years of service to the Randall community.

A large gold key to the village, in whose affairs Dr. Knight has been active, was presented by little Jean Marie Hegg. Dr. Knight has been mayor of Randall, a member of the school board and of the Boy Scout board.

As an expression of the community's appreciation, a purse was also presented to the honored guests. Mrs. Knight was given a bouquet of flowers by the Civic League.

Among the congratulatory telegrams read was one from Dr. Allen Dafoe, a classmate of Dr. Knight.

Attending the event, which was a double celebration inasmuch as Dr. and Mrs. Knight noted their twenty-seventh wedding anniversary November 5, were their three children: Dr. Edwin Knight of Minneapolis, an intern at General Hospital in Minneapolis; Robert, University of Minnesota student; and Mrs. Virgil Miller of Randall.

* * *

Scheduled to speak at meetings of the Medical Guild of St. Luke of the Newman Foundation at the University of Minnesota this year are several prominent physicians.

Lt. Col. Quigley will address the December meeting on the subject, "Medicine and the United States Army"; Dr. Charles E. Rea, January, "Interesting Figures in the History of Surgery"; Dr. Raymond Bieter, February, "Catholic Scientists in America"; Dr. Thomas Kinsella, March, "Chest Surgery"; Dr. William E. Peyton, April, "Brain Tumors and Brain Surgery."

Drs. L. F. Richdorf and John F. Fohl spoke at the October meeting on "Poliomyelitis"; and Dr. William A. O'Brien, November, "Medical Ethics."

The guild is made up of approximately 60 medical students, 20 medical technologists, 25 pre-medical students and 40 alumni medical practitioners. Dr. Bieter is faculty advisor.

Gerald Taylor, senior in the Medical School, heads the organization. Members of the board include Austin McCarthy of Watkins, Robert Delmore of Roseau, Laurence Thouin of Hibbing, Thomas Glynn and John Hays of Saint Paul.

OF GENERAL INTEREST

Among medical reserve officers ordered to active duty in the United States Army by commanding general, Seventh Corps Area, up to November 8, are the following Minnesotans:

Major Frederic Stuart Richardson, Minneapolis, The Executive, First Military Area, Minneapolis.

Captain Henry Irvin Yaffe, Minneapolis, Commanding General, Fort Snelling.

Captain Walter David Coddon, Saint Paul, Commanding General, Fort Snelling.

Also the following First Lieutenants: Dr. Philip Rains Beckjord, Willmar; Dr. Lester Sanford Frogner, Grand Marais; Dr. George Waltermann, Holt, Wabasha; Dr. Ronald Walter Steube, Saint Paul; Dr. Gunnar Linner, Minneapolis; Dr. Frederick Gunnar Gunlaugson, Mankato, all assigned Commanding General, Fort Snelling.

Dr. Burton Piper Grimes of Saint Peter, first lieutenant, has been assigned Commanding General at Fort Benning, Georgia. Dr. Grimes, the son of Dr. and Mrs. H. B. Grimes of Madelia, has been a member of the staff at the State Hospital in Saint Peter for the past two and a half years.

Naval medical reserve officers assigned to active duty include:

Dr. Lawrence M. Larson, lieutenant, Minneapolis, to N.R. A.B., Minneapolis.

Dr. John A. C. Leland, lieutenant, Minneapolis, to N.H. Mare Island, California.

Dr. N. H. Lufkin, lieutenant, Minneapolis, to 18th Bn., Saint Paul.

Dr. Roy Malone Mayne, lieutenant commander, Duluth, assigned to the U.S.S. Paducah.

Dr. Donald McCarthy, lieutenant commander, Minneapolis, assigned to N.R.S. Minneapolis.

Dr. Frank F. Wildebush, lieutenant, Minneapolis, to Naval Mobile Hospital No. 1.

* * *

Of the 114 members of the freshmen class admitted to the University of Minnesota Medical School this fall, twenty-one are sons or daughters of physicians.

They include:

Donald E. Bergan, son of Dr. Otto Bergan (U. of M. '12), Clinton, Minnesota; Catherine Burns, Albert Lea, daughter of the late Dr. H. D. Burns; Kenneth W. Covey, Bagley, Minnesota, son of Dr. W. C. Covey; Ralph L. Estrem, son of Dr. C. O. Estrem, Fergus Falls (U. of M. '07); Jack D. Ewing, son of Dr. B. F. Ewing, Omaha, Nebraska.

Also John George Freeman, St. Peter, son of Dr. George H. Freeman (U. of M. '05); Alice H. Gamble, daughter of Dr. Joseph W. Gamble (U. of M. '18), Albert Lea, Minnesota; Neill F. Goltz, son of Dr. E. V. Goltz, Saint Paul; Edward D. Henderson, son of Dr. Melvin S. Henderson, Rochester; Douglas Raymond Kusske, son of Dr. Arthur L. Kusske, New Ulm; Robert Elkon Litman, son of Dr. M. H. Litman, Minneapolis.

Also, Martin A. Nordland, son of Dr. Martin Nordland, Minneapolis (U. of M. '13); Robert J. Petters, son of Dr. F. H. Petters with the United States Army at Cristobal, Canal Zone; Norris S. Rothnem, son of Dr. T. P. Rothnem (U. of M. '12), Fargo, North Dakota; David John Sanderson, son of Dr. A. G. Sanderson, Granite Falls; Marvin J. Shapiro, son of Dr. M. J. Shapiro (U. of M. '17); Helene M. Templeton, daughter of Dr. E. W. Templeton, Seattle, Washington; Robert H. Vadheim, son of Dr. A. L. Vadheim (U. of M. '09), Tyler, Minnesota; Robert M. Watson, son of Dr. A. M. Watson, Royalton, Minnesota.

Also John E. Withrow, son of Dr. Morrill E. Withrow, International Falls; Thomas D. Wright, Minneapolis, son of the late Dr. C. B. Wright.

The class is made up of 102 residents of Minnesota, and twelve residents of other states.

Nine of the class are women, four of them daughters of physicians. Seventeen are doctors' sons.

Forty-three had an average of "B" or better in their premedical work, and the whole class had an average of 1.88 honor points per credit hour ("B minus") in college, a fact which should augur well for their success in medical school.

Dr. Harold S. Diehl, dean of the Medical School of the University of Minnesota, has been appointed a member of the sub-committee on Medical Education of the Health and Medical Committee of the National Defense Council.

The general Health and Medical Committee was appointed by President Roosevelt on September 19 to survey and coördinate the medical resources of the country in the interests of national defense. This committee is composed of Dr. Irvin Abell of Louisville, Kentucky; General James C. Magee, Surgeon General of the Army; Rear Admiral Ross T. McIntyre, Surgeon General of the Navy; Dr. Thomas Parran, Surgeon General of the United States Public Health Service; and Dr. Lewis H. Weed, chairman of the Division of Medical Sciences of the National Research Council.

* * *

Dr. Edith L. Potter, instructor and pathologist at the Chicago Lying-In Hospital, University of Chicago, was a visiting member of the faculty for the course in *Obstetrics*, November 11-16.

Registrants for this course were:

From North Dakota: Drs. L. Almklov, Cooperstown; John P. Bartle, Langdon; W. E. Blatherwick, Van Hook; William Campbell, Valley City; William H. Cuthbert, Hillsboro; C. R. DuKart, Richardton; Arnold J. Gumper, Dickinson; Simon W. Hill, Regent; B. J. Hughes, Rolla; G. Wilson Hunter, Fargo; John B. James, Page; P. O. C. Johnson, Watford City; H. A. LeFleur, Lakota; V. H. Moats, McClusky; A. F. Panek, Milton; Albert H. Reiswig, Wahpeton; E. H. Richter, Hunter; Carl I. Rollefson, Crosby; Norman J. Rose, Finley; Samuel I. Rothman, Belcourt; E. J. Schwinghamer, New Rockford; John Simon, Napoleon; Felix F. Vonnegut, Hague; A. J. Welker, Max; Floyd E. Wolfe, Oakes; and C. E. Reynolds, Strasburg.

From Minnesota: Drs. Melvin L. Hovland, Minneapolis; H. C. Otto, Frazee; Benjamin J. Singer, Saint Paul.

From South Dakota: Drs. Julius Mueller, Flandreau; Hugo C. Andre, Vermilion; John Edward Curtis, Lemon; Magin Davidson, Brookings; John H. Davis, Belle Fourche; Louis C. Dick, Spencer; F. Daniels Gillis, Mitchell; David A. Gregory, Milbank; Ernest J. Hofer, Freeman; N. K. Hopkins, Arlington; R. E. Jerntrom, Rapid City; M. W. Larsen, Watertown; C. L. Olson, McIntosh; A. W. Pearson, Sisseton; R. J. Quinn, Burke; K. E. Sherman, Sturgis; H. P. Volin, Lennox; John W. Bushnell, Elk Point; Hazel Lamb, Sioux Falls.

From Wisconsin: Drs. Walter C. Andrews, Frederic; John J. Boersma, Sheboygan; Raymond T. Shima, Turtle Lake.

Other registrants were: Drs. Marjorie R. Bennett, Winnipeg, Manitoba, Canada; M. A. Currie, Regina, Saskatchewan, Canada; Elma M. Howard, Miles City, Montana; Frederick F. Kumm, St. Petersburg, Florida; Draper Long, Mason City, Iowa; Charlotte P. Seiver, Fremont, Nebraska.

Visiting member of the faculty for the course in *Proctology*, November 11 to 16, was Dr. Frank Clark Yeomans, professor of proctology, New York Polyclinic Medical School and Hospital, New York City.

Physicians who attended this course were:

Drs. A. D. Hoidale, Tracy; W. G. Johanson, St. Paul; Mellvin E. Lenander, St. Peter; Harvey T. Petrahorg, Aitkin, and Charles B. Will, Bertha, Minnesota.

From Iowa: Drs. M. G. Bourne, Algona; Olin A. Elliott, Des Moines; Jay E. Houlahan, Mason City; Clarence E. Lynn, Dubuque; Carroll C. Nelson, Red Oak, and Glen E. Snyder, Grimes.

From Wisconsin: Drs. Philip J. Eisenberg and Leonard J. Schwade, Milwaukee; A. L. Schemmer, Colby, and Woodruff Smith, Ladysmith.

Others were: Drs. F. H. Lowe and John Paul Ritchey, Missoula, Montana; and Erwin E. Stephens, Eureka, South Dakota.

REPORTS and ANNOUNCEMENTS

MEDICAL BROADCAST FOR DECEMBER

The Minnesota State Medical Association broadcasts weekly at 11:00 o'clock every Saturday morning over Station WCCO, Minneapolis, Station WLB, University of Minnesota, and KDAL, Duluth.

Speaker: William A. O'Brien, M.D., Professor of Preventive Medicine and Public Health, Medical School, University of Minnesota.

The program for the month will be as follows:

December 7—Otitis Media

December 14—Cause of Hearing Loss

December 21—When Deafness Comes

December 28—Modern Scientific Achievements

AMERICAN ACADEMY OF DERMATOLOGY AND SYPHILOLOGY

The Academy meets at the Palmer House, Chicago, December 8, 9, 10 and 11, 1940. Some sixty lectures are scheduled and, in addition, numerous round-table discussions and clinics at the University of Illinois Medical School.

Dr. Harry R. Forester, Milwaukee, is president and Dr. Earl D. Osborne, Buffalo, secretary of the Academy.

CONGRESS OF INDUSTRIAL HEALTH

The third annual Congress of Industrial Health, sponsored by the Council on Industrial Health of the American Medical Association, to be held at the Palmer House in Chicago, January 13 and 14, merits the special attention of industrial surgeons throughout the country at this time, particularly with the speeding in industry and with added importance to the saving of man-hours.

The two-day program will be devoted to subjects such as hand and eye injury, acute respiratory disease and preventive medicine as applied to industry.

The probable need for the use of the physically handicapped to replace those more able-bodied, who will be inducted into the service, will receive consideration.

Sickness and accident prevention and rapid rehabilitation of those injured are subjects of growing importance in the national economy.

JOHN W. BELL LECTURE

"Manifestations of Tuberculosis in the Silicotic Subject" was the subject of the John W. Bell Tuberculosis Lecture before the Hennepin County Medical Society in the society's rooms, Medical Arts Building, December 2.

The lecture was delivered by Dr. Leroy U. Gardner of Saranac Lake, New York, director of the Trudeau Foundation of the Trudeau Sanatorium and the Saranac Laboratory for the Study of Tuberculosis. For the past twenty years, Dr. Gardner has supervised the

work of the Saranac Laboratory in its study of industrial diseases of the lungs. He is a member of the Council on Industrial Health of the American Medical Association.

The John W. Bell Tuberculosis Lectureship in the Hennepin County Medical Society was established and is maintained by the Hennepin County Tuberculosis Association.

CONTINUATION COURSES

The University of Minnesota announces the winter schedule of continuation hospital and medical courses, as follows:

January 2-4—Problems of Executive Housekeepers (for representatives of hotels, hospitals, and institutions)

January 20-25—Ophthalmology (for ophthalmologists and otolaryngologists)

January 27-February 1—Hospital Administration

February 3-5—Uterine Bleeding (for gynecologists and radiologists)

February 13-15—Medical Social Service

February 20-22—Dietetics (for dietitians)

March 3-5—Internal Medicine

March 6-8—Obstetric and Pediatric Nursing

The sessions will be conducted at the Center for Continuation Study which also provides living accommodations for those who attend the courses at an average rate of \$1.25 a day for room and \$1.50 a day for meals. Tuition varies from \$5 to \$10 for hospital courses and \$15 to \$25 for medical courses. For further information, address Director, Center for Continuation Study, University of Minnesota, Minneapolis, Minnesota.

OPHTHALMOLOGY-OTOLARYNGOLOGY COURSE

A special course for ophthalmologists and otolaryngologists will be conducted at the Center for Continuation Study at the University of Minnesota, January 20-25, 1941.

Guest lecturers will include Dr. Ramon Castroviejo of the Ophthalmic Institute of New York City; Dr. Albert D. Ruedemann of the Cleveland Clinic, Cleveland, Ohio; Dr. Derrick T. Vail, professor of ophthalmology at the University of Cincinnati College of Medicine, Cincinnati, Ohio; Dr. Thomas D. Allen and Dr. Robert Von der Heydt, associate clinical professors of ophthalmology, Rush Medical College, University of Chicago.

Other members of the faculty will be members of the ophthalmology and otolaryngology department of the University of Minnesota Medical School and the Mayo Foundation, and also the anatomy, radiology departments, the division of neuropsychiatry, and of the anesthesiology department.

MINNESOTA PATHOLOGICAL SOCIETY

The Minnesota Pathological Society will be addressed by Dr. H. P. Smith of the Department of Pathology, University of Iowa, Iowa City, December 17. Title of Dr. Smith's talk will be "The Coagulation of Blood

with Special Reference to Vitamin K Therapy," according to Dr. E. T. Bell of the University of Minnesota, secretary of the society.

MINNESOTA SOCIETY OF INTERNAL MEDICINE

Dr. Max H. Hoffman of Saint Paul was elected president of the Minnesota Society of Internal Medicine at a meeting in Rochester, November 11. He succeeds Dr. Russell M. Wilder of Rochester.

Named vice president was Dr. Cecil J. Watson of Minneapolis. Dr. Reuben A. Johnson of Minneapolis was re-elected secretary-treasurer.

New members elected were: Dr. J. Allen Wilson of Saint Paul, Dr. Philip Hallock of Minneapolis, and Dr. T. J. Dry of Rochester.

Program chairman for the meeting was Dr. B. T. Horton of Rochester.

Papers were presented by Dr. Thomas Ziskin of Minneapolis; Dr. A. R. MacLean and Dr. E. V. Allen of Rochester; Dr. H. E. Essex of Rochester; Dr. Max H. Hoffman of Saint Paul; Dr. E. L. Tuohy of Duluth. Other papers were by the following Rochester men: Dr. Robert Woods and Dr. A. B. Barnes; Dr. L. E. Prickman and Dr. H. J. Moersch; Dr. E. C. Kendall; Dr. H. F. Helmholtz; Drs. C. R. Maino, B. E. Hall and H. Z. Giffin.

Principal speaker at the banquet was Dr. Irvine McQuarrie of the University of Minnesota, who held a visiting professorship in pediatrics in Peiping, China, early this year. He spoke on his experience in China, and discussed political, military and health problems of occupied North China.

On account of the blizzard, most out-of-town members attending were unable to return to their homes until the 13th.

The next meeting of the society will be held in Minneapolis in the spring.

MEEKER COUNTY TUBERCULOSIS CONTROL DEMONSTRATION

Plans for the Meeker County Tuberculosis Control Demonstration were discussed at a meeting held in Litchfield, November 7, by members of the committee on tuberculosis of the Minnesota State Medical Association and the physicians of Meeker county and adjoining counties. As previously announced, the committee has selected Meeker county for a three to five year demonstration of modern control methods. This was the second meeting held in Litchfield and a third is scheduled for December 5.

Members of the state committee attending were: Drs. B. S. Adams of Hibbing, president of the Minnesota State Medical Association; B. J. Branton of Willmar, president-elect of the Association; J. A. Myers, Minneapolis, professor of medicine, University of Minnesota, chairman of the Tuberculosis Committee of the Minnesota State Medical Association; E. A. Meyerding, Saint Paul, executive secretary of the Minnesota Public Health Association; C. A. Stewart of Minneapolis, one of the councillors of the Medical

Association; S. A. Slater, medical superintendent of Southwestern Sanatorium, Worthington; K. H. Pfuete, assistant medical director of Mineral Springs Sanatorium, Cannon Falls; C. A. Scofield, Benson, former president of the Minnesota Department of Health; H. A. Burns, superintendent of the Minnesota State Sanatorium, Ah-Gwah-Ching; and Arthur J. G. Henderson of Kiester.

MINNESOTA SOCIETY OF OBSTETRICS AND GYNECOLOGY

The Minnesota Society of Obstetrics and Gynecology will meet Saturday, December 14, at the Kitchi Gammi Club in Duluth. The program for the one-day session will include the following papers:

- "Actinomycosis of the Ovary"—W. A. Coventry, M.D., Duluth.
- "Stilbestrol"—L. M. Randall, M.D., Rochester.
- "Evaluation of Serologic Tests in Pregnancy and During Menstruation"—F. T. Becker, M.D., Duluth.
- "Alar Scapulæ"—M. H. Tibbets, M.D., Duluth.
- "A Case of Severe Dysmenorrhea and Sterility Effectively Treated With Pranone"—C. J. Ehrenberg, M.D., Minneapolis.
- "Certain Pulmonary Complications in Parturition and Pregnancy"—F. J. Hirschboeck, M.D., Duluth.
- Vitamin "C" Deficiency in Pregnancy"—A. L. Dippel, M.D., Minneapolis.
- "Intravenous Use of Ergotrate in the Third State of Labor"—J. R. Manley, M.D., Duluth.

Dr. J. C. Masson of Rochester is president of the society, and Dr. E. C. Hartley of Saint Paul, secretary.

BLUE EARTH VALLEY MEDICAL SOCIETY

Dr. P. W. Demo of Wells is the newly elected president of the Blue Earth Valley Medical Society. He succeeds Dr. V. M. Vaughan of Truman. Other officers are Dr. J. J. Heimark of Fairmont, vice president; Dr. J. L. Mills of Winnebago, secretary-treasurer. Dr. A. W. Sommer of Elmore was elected a trustee.

Dr. W. C. Chambers of Blue Earth was named a delegate to the state medical convention; and Dr. R. C. Hunt of Fairmont, alternate.

New members accepted into the society are Dr. D. G. McMillen of Triumph, Dr. Robert Hunt of Fairmont, and Dr. Ralph Parsons of Monterey.

OLMSTED-HOUSTON-FILLMORE-DODGE COUNTY MEDICAL SOCIETY

Dr. B. E. Hempstead of Rochester was elected president of the Olmsted-Houston-Fillmore-Dodge County Medical Society at the organization's annual meeting in Rochester, November 6. Dr. C. B. McKaig of Pine Island was named vice president, and Dr. M. J. Anderson of Rochester was re-elected secretary and treasurer.

Eleven delegates and alternates were chosen for the annual state convention.

Delegates are Drs. H. R. Baker of Hayfield, H. Paul Johnson of Harmony, J. W. Helland of Spring Grove, C. B. McKaig of Pine Island, and J. E. Crewe, M. C. Piper, N. W. Barker, A. H. Sanford, M. J. Anderson, Waltman W. Walters and L. A. Buie of Rochester.

Alternates are Drs. J. P. Nehring of Preston, G. E. Olson of West Concord, E. A. Olson of Pine Island,

N. E. Anderson of Harmony, W. W. Canfield of Houston, Claude W. Woodruff of Chatfield, and J. D. Camp, J. A. Paulson, J. M. Berkman, G. L. Joyce and H. C. Haben of Rochester.

Besides the business meeting, there was a symposium on first aid at accidents for the casually present physician. Dr. J. S. Lundy discussed "Poisoning; Shock by Electricity; Artificial Respiration." Snake bite treatment was discussed by Dr. J. W. Pender. Other speakers were Dr. E. B. Tuohy, "Control of Bleeding;" Dr. A. W. Adson, "Head Injuries;" Dr. R. D. Mussey, "Accidents to Pregnant Women;" Dr. G. B. New, "Injuries to the Face" and A. J. Lobb, "Legal Advice: Responsibilities that a Physician Would Incur When He Steps in to Give First Aid at Scene of Accident."

SOUTHWESTERN MINNESOTA MEDICAL SOCIETY

The Southwestern Minnesota Medical Society, meeting in Worthington, elected Dr. W. G. Benjamin of Pipestone, president; Dr. P. W. Harrison of Worthington, president-elect; Dr. H. Basinger of Windom, vice president; and Dr. B. O. Mork of Worthington, secretary-treasurer.

Dr. S. A. Slater of Worthington and Dr. Benjamin were named delegates to the Minnesota State Medical Association meeting.

CHRISTMAS SEALS

Help to Protect Your Home from Tuberculosis

WOMAN'S AUXILIARY

MRS. M. A. NICHOLSON, Duluth, Minnesota, *President*
MRS. E. V. GOLTZ, 2259 Summit Avenue,
Saint Paul, *Publicity Chairman*

We have received an urgent plea from our National President Mrs. V. E. Holcombe as follows:

"Subscribe to the Bulletin, the official publication of the Woman's Auxiliary to the American Medical Association; issued quarterly, \$1 a year. Send subscriptions to Mrs. H. E. Christenberry, Highland Drive, Knoxville, Tennessee."

And from Mrs. George H. Ewell, Editor of the Bulletin, the following message:

"The Woman's Auxiliary of the American Medical Association is making a special effort at this time to awaken wide-spread interest in its activities, by increasing the number of readers of the *Bulletin*.

"This little booklet is a successor to the *News Letter* which for many years has kept the officers and board members acquainted with the progress of the Auxiliaries of all the States. It is published quarterly and contains reports of conventions, places of work, inspirational messages from leaders, and news of the hour in the medical world. It is a great help in promoting interest in local auxiliaries, especially where the program is new.

"The fall issue contains the inaugural address of Mrs. V. E. Holcombe, the National Auxiliary president. Also a message to women from Dr. Van Etten, president of the American Medical Association. Many other interesting items are to be found within its forty pages. It is hoped to have 6,000 women, one-fourth of the membership, reading the *Bulletin* before the year is over. In this way the members may keep abreast of the trends in the medical world and be better able to function as members and leaders of the Auxiliaries—local, state, and national.

"The coöperation of the Advisory Councils and the goodwill of all members of the Medical Association is earnestly requested."

Our state president, Mrs. M. A. Nicholson, wishes all members of the Woman's Auxiliary of the Minnesota State Medical Society a "very merry Christmas and a happy and prosperous New Year."

Hennepin County

On Nov. 14, 15 and 16 members of the Hennepin County Auxiliary sponsored the sale of handicraft of the patients at Glen Lake sanatorium, which was held at Dayton's in Minneapolis, the proceeds from this sale going to the patients who made the articles. This worthy project has been carried on for a number of years by the Hennepin Auxiliary. The chairman this year was Mrs. J. C. Davis.

Scott-Carver Counties

Word has been received from the Scott-Carver Auxiliary that six new members have been added to their group. At the fall meeting a Public Relations and a Hygeia chairman were appointed. The meeting was held Nov. 7th in Belle Plaine and the members met with the doctors for dinner and later at the home of Dr. H. M. Jourgens.

St. Louis County

Mrs. M. H. Tibbetts, member of the St. Louis County Auxiliary, is chairman of the Committee of Management of the International Institute and was the general chairman for the International Harvest Festival held Nov. 12, at the Y.W.C.A., Duluth. Mrs. A. T. Laird also served on this committee.

* * *

Mrs. D. W. Wheeler of Duluth was a speaker at a recent meeting of the Duluth Woman's Club. Her subject was "Puppetry as a Hobby."

* * *

The Matinee Musicale of Duluth held its first meeting October 29, with Mrs. Inez Molander Hilding, a member of the St. Louis Auxiliary, as violin soloist and Mrs. Peers Buckley, also a member, appearing in a double piano number.

* * *

Mrs. W. N. Graves of Duluth has been elected first vice president of the Children's Home Society of Duluth, and Mrs. L. R. Gowan was recently elected president of the Woman's organization of the "Our Lady of the Rosary" church.

* * *

A group of auxiliary members in Duluth are interested workers in the Needlework Guild including Mrs. P. G. Boman, Mrs. W. A. Coventry, and Mrs. Robert Graham.

* * *

St. Louis County Auxiliary held their annual rummage sale recently. The general chairman was Mrs. W. A. Coventry, assisted by the following: Mrs. M. A. Nicholson, Mrs. W. E. Hatch, Mrs. R. S. Forbes, Mrs. M. G. Gillespie, Mrs. P. S. Rudie, Mrs. M. McFischer, Mrs. William Strobel and Mrs. T. O. Young.

* * *

Nine St. Louis County schools submitted entries in the 10th annual high school essay contest on tuberculosis. Our state president, Mrs. M. A. Nicholson, was instrumental in promoting this contest in the St. Louis county Schools and the St. Louis Auxiliary carried on with the project and will present \$10 to the St. Louis county winner.

Practically all tuberculous individuals are Vitamin A deficient, whether as a cause of tuberculosis or an effect is not known. Marked Vitamin A deficiency might indicate that a thorough chest examination is in order if no other cause be found for this deficiency. Vitamin A deficiency is believed to be widespread.—R. HARRIS and J. HARTER, *Southern Med. Jour.*, Oct., 1940.

BOOK REVIEWS

Books listed here become the property of the Ramsey, Hennepin and St. Louis County Medical libraries when reviewed. Members, however, are urged to write reviews of any or every recent book which may be of interest to physicians.

THE MARCH OF MEDICINE. Number IV of the New York Academy of Medicine Lectures to the Laity. 168 pages. Cloth, \$2.00. New York (Morningside Heights): Columbia University Press, 1940.

In this handy volume are included six essays dealing with the history of various phases of medicine. "From Folkways to Modern Medicine" is presented by Walter C. Alvarez; "Health in Elizabethan England" by Sanford V. Larkey; "Not So Long Ago" by Cecil K. Drinker; "The Romance of Modern Surgery" written by Charles Garden Heyel; "The Story of Insanity" by R. G. Haskins and "The Cinderella of Medicine" by Karl A. Menninger.

The authors present their material in an easily readable style. The essays seem to be written with the purpose of exposing the reader to historical scenes so that in comparing them with the present he may have a perspective which will clearly show the advances which have been made in medical thought. Methods of medical practice with their social and economic implications are not dealt with in this book. Although this subject is highly controversial the layman is profoundly interested in it and elucidation of progress in this phase of medicine might be a valuable subject for a forthcoming essay.

WM. D. COVENTRY, M.D.

VIRUSES AND VIRUS DISEASES. Lane Medical Lecture Series. Thomas M. Rivers, M.D., Sc.D. 133 pages. Illus. Price \$2.50. Stanford University, California: Stanford University Press, 1939.

This is a most delightful, concise, and authoritative review on the present status of facts and theories concerning viruses. It consists of five lectures originally presented in the series of Lane Medical Lectures at Stanford University.

The first chapter on lymphocytic choriomeningitis cleverly reveals the multiplicity of methods used in the field of virus research while at the same time simply narrating the now accepted facts concerning this disease entity. One is convinced the laboratory methods used are not so complicated but that the better hospital laboratories may soon furnish the physician with specific means of diagnosis of this and other important virus diseases of man.

The hyperplastic and necrotizing lesions of virus diseases individually and as a group are discussed in the second chapter with a discussion of the frequently observed Bollinger and Borrel inclusion bodies.

Among many other facts, one learns that the viruses act very much like the wide variety of disease producing bacteria in relationship to their immunological and serological phenomena. One very important and possible exception is apparent in that the intracellular environment of the virus in certain cases is a protection against high titered antibodies in the blood of the in-

fected individual. This has a fundamental bearing on the use of immune sera in certain diseases which is discussed in the last chapter on therapeutics in virus diseases. One of the most discouraging observations in this chapter concerns the probability of a completed spread of the virus of poliomyelitis before clinical manifestations of the disease, thus putting the virus in the protection of the cytoplasm of the nerve cell.

This book is exactly what the busy practitioner wants to read to keep astride with developments in the field of internal medicine.

ARTHUR H. WELLS, M.D.

AS THE TWIG IS BENT. Leslie B. Holman, M.D. Associate in Psychiatry, Johns Hopkins Medical School; Assistant Visiting Psychiatrist to the Johns Hopkins Hospital. 291 Pages. Price, \$2.25. New York: The Macmillan Company, 1940.

Foreword by Adolf Meyer: "There are many books concerning the education of children and advice to parents. Very few are built on the experience of one who is not only an investigator or consultant but also a genuine practitioner intent on seeing good advice actually carried out."

This reprinted book bespeaks the author's success.

LILLIAN L. NYE, M.D.

CANCER OF THE BREAST AND CANCER OF THE UTERUS. Marion Ellsworth Anderson, A.B., M.D. 106 pages. Illus. Cloth, \$3.50; paper, \$1.00. Clinton, Iowa: The Franklin Press, 1939.

The author presents in this miniature volume the observations of his own experience and a résumé of the important literature on cancer of the breast and cancer of the uterus. The text, of about one hundred pages, discusses the theories of cancer as well as showing the various types of malignant growths in both of these organs. There are many photographs and photomicrographs of the malignant lesions found in the breast and the uterus.

A considerable space is devoted to early diagnosis such as transillumination of the breasts, Schiller's test, and biopsies, each of which is fairly well evaluated. The treatment of malignant lesions in these two organs is discussed and included in this discussion is the technique of radium application and illustration of the various procedures used.

This is a concise and brief discussion of malignancies in the breasts and uterus and should be very valuable to the general practitioner who does not have available, or does not desire, the more detailed discussion of lesions in these organs.

RUSSELL J. MOE, M.D.

CHILD CARE AND TRAINING. Fifth Edition. Marion L. Faegre, Assistant Professor of Parent Education; and John E. Anderson, Director of Institute of Child Welfare, University of Minnesota. 320 pages. Illus. Price, \$2.50, cloth. Minneapolis: University of Minnesota Press, 1940.

This is a sensible type of book every physician should be familiar with, so that he may recommend it to those parents who want detailed advice, con-

stantly available, for the many problems arising during the development of their child. Many books of this general type have been published in response to the demand arising from an increased interest in child guidance, but few of them cover the material as well and as interestingly. The questions at the end of each chapter are especially valuable as they lead to an immediate application of the material and a better grasp of the principles involved.

Teachers, nurses, and physicians, as well as parents, will gain a good deal from this book. Much of the material may be familiar to some and others may question it in part, but everyone who reads it will benefit either in the acquisition of new ideas, or in a better crystallization of ideas already held. The book is well illustrated and includes valuable suggestions for toys, reading material, and music, in fact, for everything that will contribute to the fullest development of the child.

ROBERT PEERS BUCKLEY, M.D.

SYNOPSIS OF PRINCIPLES OF SURGERY.

Jacob K. Berman, A.B., M.D., F.A.C.S., Assistant Professor of Surgery, Indiana University, School of Medicine. 615 pages. Illus. Price, \$5.00. St. Louis: C. B. Mosby Company, 1940.

This book takes its place with others of its type as an aid to teaching.

The first portion is devoted to chapters on the history of surgery, bacterial invasion, and the like. Thereafter, the discussion proceeds through the alimentary, nervous, glandular, and other "systems."

Perhaps less space might have been devoted to syphilis. The subject of fractures should be developed more fully.

A welcome feature of this book, which might well be included in more extensive texts, is the chapters on fluid balance, acid-base balance, hemorrhage, and shock.

A bibliography follows each chapter and there are many excellent charts and illustrations.

KENNETH E. FRITZELL.

PRINCIPALS OF SURGICAL CARE. Alfred Blalock, M.D., Professor of Surgery, Vanderbilt University School of Medicine, Nashville, Tennessee. Illustrated. St. Louis: C. V. Mosby Company, 1940.

Now and then some book comes out which "hits the nail on the head" so to speak, in one of the avenues of medicine. In the opinion of the reviewer this is such a book. It is only about two centimeters in thickness, but it contains much valuable information gleaned from experimental data which have contributed to make modern surgery what it is today. It should be a desk book for all surgeons. To the surgeon who received his training twenty or thirty years ago, it should be a great help in the revision of certain routine measures.

The relation of disruption of wounds to low protein content of the blood is discussed. Prothrombin deficiency, its relation to bleeding and its dependency

on certain vitamin ingestion is discussed and the conduct of surgical cases in diabetics is clearly described.

Some of the pitfalls in the surgical after care in hypertensives and nephritics are outlined.

The rationale for the proper use of fluids pre-operatively and postoperatively and the indications for fluids of the right sort are clearly discussed. Routes of error in this respect are pointed out.

Hypertension and nephritis in surgical patients are handled in a sane and matter-of-fact way and post-operative pulmonary complications which constitute probably the greatest hazard in abdominal surgery are given merited space and discussion.

This little book can be made one of the most useful aids to the surgeon of today if he will utilize the material it contains.

ARTHUR N. COLLINS, M.D.

THE FIRST FIVE YEARS OF LIFE; A GUIDE TO THE STUDY OF THE PRE-SCHOOL CHILD. Arnold Gesell, M.D., et al., The Yale Clinic of Child Development. With 21 plates. 393 pages. Price, \$3.15. New York, London: Harper & Brothers Publishers, 1940.

This is a welcome book; the embodiment of fifteen additional years of experience and investigation in the author's entirely rewritten and extended text, "The Mental Growth of the Pre-school Child," published by the Macmillan Company in 1925. It depicts the psychological and medical aspects in a technical manner, with

a very human touch. The gradation from birth to maturity is presented in a complete growth picture.

A Pictorial Survey of Pre-school Behavior is presented in the twenty-one plates. There is a list of 142 Selected References.

Every one interested in a child will await succeeding volumes of this masterful touch from The Yale Clinic of Child Development. This volume is unreservedly recommended.

LILLIAN L. NYE, M.D.

DOCTORS IN SHIRT SLEEVES. Edited by Sir Henry Bashford. 294 pages. Cloth, \$2.50. New York: Veritas Press, 1940.

This group comprises a group of essays, written by a number of English physicians, which first appeared in the British Medical Journal, *Lancet*, under the heading "Grains and Scruples." The subject content, which runs the gauntlet from musings on patients and hobbies to personal reflections, reminiscences, and philosophies, was so well received that it was felt advisable to incorporate the most interesting of them in book form.

A brief review of the titles of some of the essays, "Crabbed Age and Youth," "From the Back Streets," "The Life of a Surgeon," "On Hobbies," "An Old Diary," "Some Forgotten Medical Journals," "Medicine and Philosophy," "Retirement and a Garden," and many others will at once make apparent the vast

SILVER PICRATE

BOOK REVIEWS

store of delightful personal experiences encompassed within the covers of this little volume.

The book can be well recommended for its interesting content, for its ability to capture the interest and hold the attention of its reader; and for its purpose in seeking to afford a few hours of enjoyment and enlightenment to those into whose possession it comes.

A. J. SPANG, M.D.

PROCTOSCOPIC EXAMINATION AND DIAGNOSIS AND TREATMENT OF DIARRHEAS.
M. H. Streicher. 149 pages. Illustrated. \$3.00. Springfield: C. C. Thomas, 1940.

"The object of the book is to present a brief, clear method of proctoscopic examination and to outline the diagnosis and treatment of the most common forms of diarrhea."

The above quotation from Dr. Spreicher's preface to his small volume aptly describes the scale of his work. This short textbook of about 150 pages is well illustrated and is divided into two parts.

Part I consists of three chapters and describes the main points in technic and the equipment necessary for a complete proctoscopic examination. In addition there is an excellent summary of the findings in over

2,400 proctoscopic examinations with a clinical summary of some of the illustrative cases observed.

In Part II there are four chapters concerned with the diagnosis and treatment of diarrheas which includes a practical etiological classification of the types of diarrheas. A short bibliography and index complete the volume which recommends itself to the use of all who would avail themselves of a practical dissertation on a well-established but too often neglected form of diagnostic procedure.

M. L. STRAUS, M.D.

I SAW FRANCE FALL. René de Chambrun. Price \$2.50. New York: Morrow, 1940.

To one who is interested in the causes of the fall of France, the reading of this small book by a citizen of both France and the United States is recommended. When things come to such a pass that a considerable number of the national legislators must refer to a foreign ruler before voting and when the president of a country fears to arrest leaders of a party outwardly advocating overthrow of the government by force, the foundations of the country can be expected to crumble when a storm of foreign invasion arises. There is much of value in the book as an example to our own country.

CLASSIFIED ADVERTISING

PHYSICIAN WANTED—Not subject to draft, to assist in general medicine and surgery in Minneapolis. Chance to take postgraduate work at University. Good opportunity for advancement. State school, hospital and year of graduation. Address C-50, care MINNESOTA MEDICINE.

FOR RENT—Doctor's office in connection with dentist. Located over drug store at 61 West Winifred, Saint Paul. Telephone: RIVerview 1094 or address Mrs. E. C. Jerabek, 677 South Smith, Saint Paul, Minnesota.

WANTED—Physician and surgeon to share office with dentist in Saint Paul, Minnesota. Space used as physician's office thirty years. Fine opportunity. Address C-49, care MINNESOTA MEDICINE.

FOR SALE—Established practice. Central Minnesota. Population 3,000. Complete surgical instruments, x-ray, laboratory equipment; excellent filing and bookkeeping system. \$2,000. Reason—specializing. Address C-51, care MINNESOTA MEDICINE.

WANTED—Locum tenens for Minnesota practice, January 15 to March 1. Address C-38, care MINNESOTA MEDICINE.

CLINICAL PHOTOGRAPHY, Lantern Slides and Photomicrography. Photographs and X-rays reduced or enlarged for manuscripts. SCIENTIFIC PHOTOGRAPHIC LABORATORY, 348 Hamm Bldg., Saint Paul, Minnesota. Telephone CEdar 7125.

INDEX TO VOLUME 23

A

- Abdomen, Surgical drainage of the, 323
 Abdominal emergencies, acute, Management of, 331
 Abdominal pain and ileus due to ureteral constriction, 673
 Abscess, Subdiaphragmatic (case report), 249
 Adair, Fred L.: Prevention and treatment of genital prolapse, 609
 Adams, Bertram S.: Modern trends, 459
 Adams, B. S.: Some observations on Boehler's treatment of fractures, 73
 Adams, John M., and Cochran, Ray F.: Erythroblastosis (icterus gravis) in the newborn, 569
 Adenocarcinoma, Primary, of the appendix and carcinoid tumors, 791
 Adenoma, Benign, of the bronchus, 375
 Adenomyomata, 231
 Air-borne pollen in the Twin Cities area with reference to hay fever, 619
 Alberts, Max W.: Treatment of carcinoma of the breast, 848
 Alexander, H. A., Peppard, T. A., and Hagen, Wayne S.: Toxic effects of carbon tetrachloride, 715
 Allergens, inhalant, Significance of, in the treatment of bronchial asthma of the child, 413
 Allergy in general practice, 173
 Alumni, Greetings from the, 236
 Alvarez, Walter C.: What's wrong with the patient who is always tired? 787
 Amyotrophic lateral sclerosis with psychosis (paranoid type) (case report), 858
 An American health program, 681
 Anderson, Ernest R.: Fracture of the spine of the tibia (intercondyloid eminence), 674
 Anemia, Congenital hemolytic, with splenectomy, 378
 Anemia, pernicious, Gastroscopic observations in, 311
 Anemias, Indications for use of iron in treatment, 712
 Anesthesia, general, Convulsions in children while under, 101
 Ankle, Treatment of trimalleolar fractures of the (summary), 751
 Apical lung tumors or so-called superior pulmonary sulcus tumors, 221
 Appendicitis, acute perforative, Clinical and surgical aspects of spreading peritonitis complicating, 755
 Appendix, Primary adenocarcinoma of the, and carcinoid tumors, 791
 Artery, renal, Total embolism of the, 136
 Arthritis and rheumatism, Present trends in, 533
 Asthma, bronchial, of the child, Significance of inhalant allergens in the treatment of, 413
 Automobile injuries involving the face, The care of, 1

B

- Bacterial endocarditis, Some clinical vagaries associated with, 25
 Baker, A. B.: Intracranial tumors, 696
 Baker, Norman H.: The care of patients preceding gastric operations, 839
 Bagen, J. Arnold, and Schlicke, Carl P.: Fulminating ulcerative colitis, 348
 Barron, Moses: Some uses of sulfamidopyridin preparations in the treatment of infectious diseases (discussion only), 499
 Barry, L. W.: Cesarean section, 149
 Beard, Archie H.: Pre-operative preparation of the diabetic patient, 841
 Becker, F. T.: Tumors of the neuromyo-arterial glomus, 78
 Bell, E. T.: Diagnosis of tumors of the breast, 847
 Benign adenoma of the bronchus, 375
 Benjamin, Walter G.: Adenomyomata, 231
 Bibliography, medical, Fundamental concepts of, 34
 Biliary tract, Pre-operative care in surgery of the, 844

- Blumenthal, J. S.: Histaminase in the treatment of urticaria of pregnancy (case report), 797
 Blumenthal, J. S.: Sulfapyridine in the treatment of staphylococcus septicemia (case report), 122
 Boehler's treatment of fractures, 73
 Borg, Joseph F.: Observations on the occurrence and prevention of sudden death, 783
 Bowel, stomach and, Lympho-sarcoma of the, 144
 Bower, John O.: Clinical and surgical aspects of spreading peritonitis complicating acute perforative appendicitis, 755
 Bowling, Harry H.: Carcinoma of the cervix uteri: factors influencing prognosis, 85
 Brachial plexus neuritis, The scalenus syndrome, 377
 Breast, Diagnosis of tumors of the, 847
 Breast, Treatment of carcinoma of the, 848
 Bronchial asthma of the child, Significance of inhalant allergens in the treatment of, 413
 Bronchus, Benign adenoma of the, 375
 Bronchus, Primary carcinoma of the, 853
 Brown, Alex E.: The sulfamido compounds: their practical applications in clinical medicine, 572
 Buzzelle, L. K., and Tudor, R. B.: Recurrent myxosarcoma of the right inguinal region, 230

Book Reviews

- Aaron, Harold: Good health and bad medicine, 456
 Alvarez, Walter C.: An introduction to gastro-enterology, 606
 American Medical Association: Reports of the Council on Pharmacy and Chemistry, 72
 American Medical Association—Council on Pharmacy and Chemistry: New and non-official remedies, 822
 American Medical Association—Council on Foods: Accepted foods, and their nutritional significance, 70
 Anderson, Marion Ellsworth: Cancer of the breast and cancer of the uterus, 888
 Barnes, Arlie F.: Electrocardiographic patterns—their diagnostic and clinical significance, 382
 Bashford, Sir Henry (editor): Doctors in shirt sleeves, 889
 Berman, Jacob K.: Synopsis of principles of surgery, 888
 Bing, Robert: Textbook of nervous diseases, 72
 Blalock, Alfred: Principles of surgical care, 888
 Campbell, Willis C.: Operative orthopedics, 605
 Cecil, Russell L. (editor): A textbook of medicine by American authors, 821
 Cushing, Harry: The medical careers, 605
 Dargeon, Harold W.: Cancer in childhood, 456
 de Brun, Harry C. W. S.: Manual of fractures, dislocations and epiphyseal separations, 456
 de Chambrun, René: I saw France fall, 890
 Dickson, Frank D., and Diveley, Rex L.: Functional disorders of the foot; their diagnosis and treatment, 381
 Elmer and Rose: Physical diagnosis. Revised by Harry Walker, 458
 Faegre, Marion L., and Anderson, John E.: Child care and training, 888
 Gesell, Arnold: The first five years of life; a guide to the study of the pre-school child, 889
 Gumpert, Martin: Heil hunger; health under Hitler, 458
 Hamblen, E. C.: Endocrine gynecology, 71
 Hohman, Leslie B.: As the twig is bent, 888
 Horsley, J. Shelton, and Bigger, Isaac A.: Operative surgery, 822
 Imperatori, Charles J., and Burman, Herman J.: Diseases of the nose and throat, 282
 Iowa State Medical Society, Cancer Committee: Standards for the diagnosis and treatment of cancer, 605
 Jelliffe, Smith Ely: Sketches in psychosomatic medicine, 380

- Kaplan, Ira I., and Rubenfeld, Sidney: A topographic atlas for x-ray therapy, 72
- Kugelmass, I. Newton: Newer nutrition in pediatric practice, 754
- Levin, S. I.: The Kosher code, 380
- Levine, Samuel A.: Clinical heart disease, 821
- Levy, Robert L.: Diseases of the coronary arteries and cardiac pain, 148
- Lewis, George M., and Hopper, Mary E.: An introduction to medical mycology, 70
- Matheson Commission, Willard C. Rappleye, M.D., chairman: Epidemic encephalitis, 752
- Muncie, Wendell: Psychobiology and psychiatry, 282
- National Tuberculosis Association: Diagnostic standards and classification of tuberculosis, 457, 502
- New York Academy of Medicine Lectures to the Laity: The march of medicine, 887
- Ochsner, Alton M., and Mahorner, Howard: Varicose veins, 71
- Pack, George T.: Tumors of the hands and feet, 148
- Parkinson, Roy H.: Eye, ear, nose and throat manual for nurses, 148
- Pottenger, F. M.: Symptoms of visceral disease, 821
- Rankin, Fred W., and Graham, A. Stephen: Cancer of the colon and rectum, its diagnosis and treatment, 604
- Rivers, Thomas M.: Viruses and virus diseases, 887
- Scudder, John: Shock blood studies as a guide to therapy, 382
- Siegel, Morris: Population, race and eugenics, 283
- Stanford University School of Medicine: Cancer handbook of the Tumor Clinic (Eric Liljencrantz, editor), 605
- Streicher, M. H.: Proctoscopic examination and diagnosis and treatment of diarrheas, 890
- Sulzberger, Marion B.: Dermatologic therapy in general practice, 754
- Sutton, Don C.: Introduction to medicine, 753
- Vaughan, Warren T.: Primer of allergy, 148
- Visscher, Maurice B. (editor): Chemistry and medicine, 502
- Watson, Leigh F.: Hernia; anatomy, etiology, symptoms, diagnosis, differential diagnosis, prognosis, and the operative injection treatment, 457
- Youmans, John B.: Essentials of the diagnostic examination, 605
- C**
- Calculi, common and hepatic duct, Surgery of, 344
- Calvin, Arthur M.: Extension of group hospital service, 391
- Camp, John D.: The roentgenologic diagnosis of intraspinal protrusion of intervertebral disks, 688
- Campbell, Orwood J.: Surgery of carcinoma of the colon, 215
- Cancer, gastric, masquerading as benign disease, The surgical treatment of, 709
- Carbon tetrachloride, Toxic effects of, 715
- Carcinoma, Early gastro-intestinal, 226
- Carcinoma of the breast, Treatment of, 848
- Carcinoma of the bronchus, Primary, 853
- Carcinoma of the cervix uteri: factors influencing prognosis, 85
- Carcinoma of the colon, Surgery of, 215
- Carcinoma of the stomach, The surgical management of, 210
- Carcinoma, Primary, of the ureter, 136
- Carcinomatous gastric lesions, small, simulating chronic benign ulcer: present status of differential diagnosis and treatment, 703
- Care of automobile injuries involving the face, The, 1
- Care of patients preceding gastric operations, The, 839
- Carey, J. B.: Gastroscopic observations in pernicious anemia, 311
- Cecil, Russell L.: Present trends in the study of arthritis and rheumatism, 533
- Cecum, Volvulus of the, a postoperative complication (case report), 250
- Cervix uteri, Carcinoma of the: factors influencing prognosis, 85
- Cesarean section, 149
- Children, Convulsions in, while under general anesthesia, 101
- Chronic duodenal stasis, 68
- Cleveland, William H., and Walters, Waltman: The surgical treatment of gastric cancer masquerading as benign disease, 709
- Clinical and surgical aspects of spreading peritonitis complicating acute perforative appendicitis, 755
- Clinical aspects of Vitamin B deficiencies, 542
- Cochrane, Ray F., and Adams, John M.: Erythroblastosis (icterus gravis) in the newborn, 569
- Colitis, Fulminating ulcerative, 348
- Colon, carcinoma of the, Surgery of, 215
- Communicated insanity, 641
- Congenital cysts and fistulae of the neck (discussion only), 603
- Congenital hemolytic anemia with splenectomy, 378
- Convulsions in children while under general anesthesia, 101
- Coronary arteries, Diagnosis of disease of the, 767
- Coronary disease—its treatment, 770
- Coronary disease, The electro-cardiogram in, 775
- Creighton, Ralph H., and Jones, Wm. R.: Enteric intussusception in an adult, 677
- Criminal cases, The defense of insanity in, 387
- Critchfield, L. R., Simons, L. T., Emmens, T. H., and Newell, F. W.: Pneumococcus (Type III) meningitis with recovery (case report), 247
- Cyst, Infected dermoid, of the thorax simulating chronic empyema, 781
- Cystography in the study of difficulties following prostatic surgery, 40
- Cysts, Congenital, and fistulae of the neck (discussion only), 603
- Communications**
- Merriman, L. L., M.D., 814
- D**
- Daggy, Richard H., Muegge, Oswald J., and Riley, William A.: A preliminary survey of the anopheline mosquito fauna of southeastern Minnesota and adjacent Wisconsin areas, 556
- Dahl, O. A., Rosendahl, C. O., and Ellis, R. V.: Airborne pollen in the Twin Cities area with reference to hay fever, 619
- Defense of insanity in criminal cases, The, 387
- Dermatitis, atopic, The treatment of, 16
- Dermatitis, Rat mite, in Minnesota, 423
- Diabetic patient, Pre-operative preparation of the, 841
- Diagnosis of disease of the coronary arteries, 767
- Diagnosis of tumors of the breast, 847
- Diet, protein, a proper and adequate, for elderly people, 313
- Disks, intervertebral, The roentgenologic diagnosis of intraspinal protrusion of, 688
- Disks, protruded intervertebral, Treatment of, 692
- Dislocation of the head of the fibula (case report), 649
- Diverticulum, Meckel's, Perforation of, by fish bone (case report), 44
- Dixon, Claude F., and Gregg, Robert O.: Management of postoperative intestinal obstruction complicated by hemorrhage on the basis of prothrombin deficiency, 169
- Dixon, Claude F., and Miller, Joseph M.: Volvulus of the cecum, a postoperative complication (case report), 250
- Drake, Carl B.: Some applications of hydromomics to the circulation, 198
- Dunn, George R.: Peripheral nerve surgery, 748
- Duodenal stasis, Chronic, 68
- Dysphagia, 13

E

- Earl, George: Early gastro-intestinal carcinoma, 226
 Early diagnosis campaign—the rural Hennepin County plan, 471
 Early gastro-intestinal carcinoma, 226
 Eckman, Philip F.: Indications for use of iron in treatment of the anemias, 712
 Eitel, George D.: Injuries to the shoulder joint, 747
 Elbow, Fracture of the, 856
 Elderly people, A proper and adequate protein diet for, 313
 Electrocardiogram in coronary disease, The, 775
 Ellis, R. V., Dahl, O. A., and Rosendahl, C. O.: Airborne pollen in the Twin Cities area with reference to hay fever, 619
 Embolism, Total, of the renal artery, 136
 Emmens, T. H., Newell, F. W., Critchfield, L. R., and Simons, L. T.: Pneumococcus (Type III) meningitis with recovery (case report), 247
 Empyema, chronic, Infected dermoid cyst of the thorax simulating, 781
 Encephalitis, epidemic, Periodic hypersomnia, hyperpyrexia, and hunger, secondary to, 82
 Endocarditis, bacterial, Some clinical vagaries associated with, 25
 Endocrine disturbances in relation to skin diseases, 829
 Engberg, E. J.: The treatment of mental defectives in Minnesota, 335
 Enteric intussusception in an adult, 677
 Eosinophilic leukemia or myelogenous leukemia with eosinophilic hyperleukocytosis, 596
 Episiotomy, 97
 Erich, John B., and New, Gordon B.: The care of automobile injuries involving the face, 1
 Erythroblastosis (icterus gravis) in the newborn, 569
 Eusterman, George B.: Small carcinomatous gastric lesions simulating chronic benign ulcer; present status of differential diagnosis and treatment, 703
 Ewing's tumor (hemangio-endothelioma; endothelial myeloma; solitary diffuse endothelioma): a problem in differential diagnosis, 416
 Excretory urography, The indications for, 825
 Extension of group hospital service, 391
 Eye defects causing loss of vision, 400
 Eye-glasses, steamed, Relief from, 194
 Eye injuries due to mechanical causes, 8

Editorial

- 1939-1940, 56
 A. M. A. session, The 1940, 486
 Annual state meeting, 259
 Apropos of "The Magic Bullet", 433

- Garrity, James A.: The defense of insanity in criminal cases, 387
 Gastric cancer masquerading as benign disease, The surgical treatment of, 709
 Gastric lesions, Small carcinomatous, simulating chronic benign ulcer; present status of differential diagnosis and treatment, 703
 Gastric operations, The care of patients preceding, 839
 Gastro-intestinal carcinoma, Early, 226
 Gastrojejunal ulcer following gastro-enterostomy performed twenty-four years before for pyloric stenosis of infancy, 602
 Gastroscopic observations in pernicious anemia, 311
 Genital prolapse, Prevention and treatment of, 609
 Genital tuberculosis, 318
 Glabe, Robert A.: Surgical drainage of the abdomen, 323
 Glomus, neuromyo-arterial, Tumors of the, 78
 Gray, Howard K., and Woodruff, Robert: Infected dermoid cyst of the thorax simulating chronic empyema, 781
 Gray, Royal C.: Schizophrenia in childhood, 565
 Green, Robert G.: Modification of viruses for use as vaccines (abstract), 500
 Greetings from the alumni, 236

Gregg, Robert O., and Dixon, Claude F.: Management of postoperative intestinal obstruction complicated by hemorrhage on the basis of prothrombin deficiency, 169

H

Hagen, O. J.: Greetings from the alumni, 236
Hagen, Wayne S., Alexander, H. A., and Peppard, T. A.: Toxic effects of carbon tetrachloride, 715
Hammes, E. M.: Periodic hypersomnia, hyperpyrexia, and hunger, secondary to epidemic encephalitis, 82
Hammes, E. M.: The scalenus syndrome; bronchial plexus neuritis, 377
Hanson, William A., and Fowler, L. Haynes: Gastrojejunal ulcer following gastro-enterostomy performed twenty-four years before for pyloric stenosis of infancy, 602
Hartmann, C. M., Peterson, H. O., and Macklin, W. E.: Dislocation of the head of the fibula (case report), 649
Hay fever, Air-borne pollen in the Twin Cities area with reference to, 619
Headache, The symptom of, and some conditions suggested by it, 19
Health activities and problems among former University students, A survey of, 397
Health program, An American, 681
Heersema, Philip H.: Management of tetanus with report of use of hyperthermia in one case, 636
Heiberg, E. A.: Inhibition ileus, 94
Hemophilia with intestinal obstruction (case report), 857
Henderson, Melvin S.: Present-day treatment of united fractures of the neck of the femur, 339
Hepatic disease, Recent advances in the treatment of, 551
Hinshaw, H. Corwin, Wilson, Ira H., and Moersch, Herman J.: Apical lung tumors or so-called superior pulmonary sulcus tumors, 221
Hirschboeck, F. J.: Coronary disease—its treatment, 770
Histaminase in the treatment of urticaria of pregnancy (case report), 797
History of Medicine in Minnesota, 45, 116, 177, 252, 353, 425, 479, 578, 651, 719, 798, 860
Hoff, Alfred: Some clinical vagaries associated with bacterial endocarditis, 25
Hospital service, group, Extension of, 391
Hour-glass-shaped meningioma involving medulla, foramen magnum and cervical region, 600
Hunger, Periodic hypersomnia, and hyperpyrexia, secondary to epidemic encephalitis, 82
Hydronomics, Some applications of, to the circulation, 198
Hyperpyrexia, Periodic hypersomnia, and hunger, secondary to epidemic encephalitis, 82
Hypersomnia, Periodic, hyperpyrexia, and hunger, secondary to epidemic encephalitis, 82
Hypotension, like anemia, demands an etiologic research for appropriate therapy, 139

I

Ileum, Leiomyosarcoma of the, 603
Ileus, Inhibition, 94
Indications for excretory urography, The, 825
Indications for use of iron in treatment of the anemias, 712
Industrial health, Organized medicine and, 383
Infected dermoid cyst of the thorax simulating chronic empyema, 781
Inflammatory disease of the thyroid gland, 105
Inhibition ileus, 94
Injuries, automobile, involving the face, The care of, 1
Injuries, Eye, due to mechanical causes, 8
Injuries of the posterior urethra, 751
Injuries to the shoulder joint, 747
Insanity, communicated, 641

Insanity, The defense of, in criminal cases, 387
Intervertebral disks, protruded, Treatment of, 692
Intervertebral disks, The roentgenologic diagnosis of intraspinal protrusion of, 688
Intestinal obstruction, Hemophilia with (case report), 857
Intestinal obstruction, postoperative, complicated by hemorrhage on the basis of prothrombin deficiency, Management of, 169
Intracranial tumors, 696
Intraspinal protrusion of intervertebral disks, The roentgenologic diagnosis of, 688
Intussusception, Enteric, in an adult, 677
Iron, Indications for use of, in treatment of the anemias, 712

University of Minnesota

ROUND TABLE

October 12, 1939

THE fiftieth anniversary of the founding of the medical school of the University was the occasion of a scientific program held October 12, 13 and 14, 1939, at the University. The theme of the three-day meeting was: Some Trends in Medical Progress with Particular Reference to Chemistry in Medicine.

The main address delivered during the three-day session will be published in the near future by the University of Minnesota press. The Round Table discussions, held October 12 and 13, were considered of sufficient interest to warrant publication and are here presented in the form of a supplement to the January, 1940, issue of MINNESOTA MEDICINE.

With the discussions appear brief bibliographic sketches of the leaders in the various Round Table groups.

Supplement to MINNESOTA MEDICINE

No. 1

THE CLINICAL SIGNIFICANCE OF WATER AND ELECTROLYTE BALANCES

Chairman: DR. ANCEL KEYS

Professor of Physiology
University of Minnesota

Leader: DR. JOHN P. PETERS

Professor of Medicine
Yale University

DR. A. KEYS: The subject matter of this Round Table has its general interest distributed over a wide range of subjects from physics to the application in the clinic, and I think this is reflected in the large number of people in attendance today. That makes a limitation, of course, on the freedom of discussion and the intimacy of the conversations which we associate with the idea of the Round Table.

I think all of you were interested this morning to hear Dr. Peters bringing his emphasis to bear on the question as to the freedom of movement, of electrolytes and of water, within the body and within the different organs of the body. Sixteen years ago the classic paper of Van Slyke, Wu and McLean initiated what we thought was a final solution to the problem of distribution of the electrolytes in terms of Donnan equilibrium. Many of these ideas originated from the work of Dr. Peters and his collaborators. The Donnan approach supplied the first approximation, and now that we see that the system is more complicated we need a second approximation.

The interest and research in this general question of mineral and water metabolism began with the osmotic studies of the middle of the last century. We have seen the field grow, the emphasis being placed for a time on the specific physiological properties of the different mineral electrolytes and the concept of antagonism. We saw then the minerals drawn into the field of the acid base balance, particularly in the interrelations with the buffer systems in the blood. A great many researches of a bril-

liant character were carried out along those lines. In recent years there has been a growing interest in the relation between the electrolytes and the hormones, notably the adrenal cortex and secondarily the hormones of the pancreas, the adrenal medulla and the other endocrine organs. A new field has developed which is concerned with the interrelation between the electrolytes and the metabolism of organic substances, particularly the carbohydrates. We see now that when we discuss the mineral ions we must take into account not merely the physical properties of membranes but also the questions of electrolyte-organic combinations and the influence of the endocrine glands and their secretions on these combinations.

DR. JOHN P. PETERS, John Slade Ely Professor of Medicine at Yale University, has for many years combined with the practice and teaching of the healing art at the bedside, a thorough laboratory study of chemistry as applied to the diagnosis and treatment of disease. With Dr. Donald D. Van Slyke of the Hospital of the Rockefeller Institute in New York City, he is the author of authoritative and widely read books on this aspect of science in medicine. Dr. Peters' investigations have dealt for the most part with the chemistry underlying the movement of fluids and dissolved substances within the body, a problem which medical men consider of consequence in many diseases but which have their most obvious application in diseases of the heart and kidneys. A scholarly consideration of these and related subjects has been presented by Dr. Peters in numerous publications and in a book which he has entitled simply "Body Water."

Dr. Peters is a native of Philadelphia and received his earlier training at Yale and Columbia Universities.

Dr. Peters will initiate the discussion now with some informal remarks on the general subject.

DR. JOHN PETERS: The title of this conference, "The Clinical Significance of Water and Electrolyte Balances," seems to me to embody a most invidious concept. It carries the implication that clinical medicine is not part of the physiological sciences but that it merely impinges upon it.

I should like to enlarge somewhat on the subject on which I opened this morning, the necessity of forsaking the categorical method in the consideration of physiological problems. Specialization in technical procedures is essential to expert work, but when specialization is allowed to carry over into the philosophical domain, it becomes a vicious bar to progress. Water and electrolyte balances are not independent functions. They do not exist for and of themselves; hence they are merely expressions of metabolic processes. Their measurement must, therefore, be ultimately purposeless unless this fundamental relationship is kept continuously in mind, and I believe it has not been. In the work of the last ten years certain general hypotheses have been established. The Starling hypothesis concerns the movement of fluids and diffusible solutes to and from the blood vessels; it states that such movements are governed by the interplay of the opposing forces of capillary blood pressure, and colloid osmotic pressure.

The Starling concept is a recognized part of clinical physiology that has worked a beneficent revolution in clinical practice. There are few left to deny that the kidneys perform their function by withdrawing solutes and water and adding certain solutes to a glomerular ultrafiltrate, the formation of which is governed by the Starling principle. However, in this connection physiologists and clinicians have been slow in escaping from their old habit patterns of regarding the kidneys as purely excretory organs resembling somewhat complicated sieves.

The universal equality of osmotic pressure throughout cells and fluids of the body is quite generally accepted, as is the fact that all cells are bathed in an undifferentiated fluid, which has the characteristics of an ultrafiltrate of serum. Likewise it has been reasonably well established that sodium and chloride are, with few exceptions, excluded from the cells of the body and are confined to this interstitial fluid. It follows from these two facts that, other

things being equal, the water content of the cells of the body is determined by the concentration of sodium in the interstitial fluid.

The obvious clinical inference is that conditions which lead to sodium depletion must cause the cells of the body to imbibe water, thus diluting their contents and consequently disorganizing the chemical processes within them. The growing recognition of the necessity of maintaining the concentration of sodium and chloride in the body at optimum levels has greatly improved the treatment of post-operative states, vomiting, diabetes, advanced nephritis, and a variety of other conditions in which dehydration and salt depletion develop for one reason or another. Because the distribution of water and the hydration of cells varies with the sodium concentration of the serum it has been inferred that the osmotic effect of this sodium must be balanced within the cells by an osmotically equal load of potassium. This is not, however, an inevitable corollary; interstitial fluid is a relatively simple medium in which inorganic ions are almost unrestrained.

The contents of the cells are highly complex and all that we have learned of them would lead us to suppose that the activities of even their inorganic constituents are highly conditioned. This difference is evidenced by the extraordinary tolerance of the organism to extreme changes in concentration and quantities of sodium and chloride. All the disturbance produced by such alterations can be attributed apparently to their effects on osmotic or acid-base equilibrium. In other respects, sodium and chloride appear to be physiologically almost inert. They have little or no influence upon metabolic processes from which they are excluded by the cellular membrane. Potassium and magnesium, on the other hand, play important and essential roles. Their injection is followed by toxic symptoms quite unrelated to and out of proportion to their possible effects on osmotic pressure and acid-base equilibrium. These symptoms are presumably evidences of disturbances of the metabolic processes in which these elements participate within the cells.

Exogenous potassium salts are excreted almost like foreign bodies with more economy of water than is exercised in the excretion of exogenous sodium salts. There is something logical then in the conventional association of wa-

ter with sodium and chloride. But if knowledge is to be secured concerning the utilization of other ions, especially potassium and phosphate, other points of reference more closely connected with cellular metabolic processes must be found. Moreover it must be recognized that ultimately the factors that determine the excretion of even sodium and chloride may be indirectly but nevertheless indissolubly related to these same cellular processes. In both Addison's disease and advanced renal insufficiency the concentrations of sodium and chloride in the serum fall; presumably the renal tubules no longer reabsorb salt in the usual manner. In both conditions administration of extra salt has a beneficial effect, but beyond this the analogy fails. The symptomatology of the two conditions is entirely dissimilar. In Addison's disease, moreover, symptoms and signs may be alleviated at once by the administration of adequate amounts of potent cortical extract without addition of salt. In nephritis, as far as we've been able to determine, cortical extract is without influence upon salt wastage or symptoms.

I say this rather emphatically at this moment because so many people are saying, "Cortical extract controls salt excretion by the kidneys and so we should give it in all states of salt depletion."

In some cases with advanced tuberculosis and in pneumonia, the kidneys often allow salt to escape in an inexplicable manner. From the standpoint of salt balance these patients seem to be indistinguishable from those with Addison's disease. I know no test so far provided to distinguish Addison's disease by the electrolyte pattern without some other clinical criteria.

The symptomatology of these cases is quite different. Administration of salt appears to have little influence upon their condition, or less influence than it has in other cases of salt depletion. We have been able to detect neither clinical improvement nor change of salt balances in these conditions after administration of cortical extract. We are forced to recognize therefore that there must be differences in the significance of salt wastage in these conditions. It has been discovered that during the crisis of Addison's disease, or after the removal of the adrenals from animals, the excretion of potassium diminishes as that of sodium increases.

It would be easy to infer, and it was inferred, that the kidney re-absorbs more than the usual amount of potassium, and that the crisis is merely a manifestation of potassium poisoning. However, these crises may come on before the serum potassium has risen appreciably, and bear little or no resemblance to the symptoms of potassium poisoning. The cells seem to be holding excessive amounts of potassium. It was natural to wonder whether the retention in the cells of so much potassium increased their internal osmotic pressure, thus exaggerating the swelling of the cells that resulted from depletion of the extra-cellular sodium.

When this point was examined, Harrison and Darrow found that the cells apparently didn't take up water in response to this excessive load of potassium. This potassium was obviously osmotically inactive. Does it demand a far stretch of the imagination to surmise that the potassium retention is an expression of a derangement of those metabolic processes in the tissue cells in which potassium is involved? Would it seem absurd to consider the failure of the kidney to re-absorb sodium salts as an expression of the derangement of the metabolism of some of the renal tubule cells?

In Addison's disease administration of extra potassium has the most unfortunate effect. But in familial periodic paralysis it was found that administration of potassium salts relieved symptoms. It was thought that the attacks of paralysis were precipitated by the wastage of potassium in the urine, especially when serum potassium proved to be low during attacks of the disease. When the condition was investigated in detail, however, it was discovered that the excretion of potassium during and just before an attack did not increase, rather it diminished, and that the potassium given for the therapeutic purposes was retained without any rise of serum potassium. Apparently something in the muscle cell in familial periodic paralysis creates a demand for unusual amounts of potassium to permit the orderly continuation of the metabolic process.

The study of salt and water balance doesn't need any justification in the clinic at this date but it does need integration with the study of other metabolic processes. And I should like to add again in defense of the clinic that just as the clinic has often led or pointed the way

to physiology in the elucidation of problems of salt and water equilibrium so it need not stand upon the order of its going in this new direction, because experiments are provided every day by disease.

DR. KEYS: I should like, first, to thank Dr. Peters for his discussion and, second, to remind you that Dr. Peters will attempt to answer questions or to discuss specific points which you may raise.

I suspect Dr. Owen Wangenstein may wish to make some remarks on the relation of these questions of water and mineral metabolism to the practice of surgery.

DR. OWEN H. WANGENSTEEN: There are a host of problems which arise every day in the clinic, which are centered in water and electrolyte balance. A number of these are explicable from our present knowledge; many remain a mystery. A number of years ago when I first became interested in the problem of obstruction I happened one day to give some dogs water under the skin and that unfortunately went on for a few days. I learned to my dismay that dogs given water under the skin die. We know that a person can drink water by mouth over a long period of time without taking any food and survive. I've often puzzled over that problem; I wondered how it could come about, whether there is a basal collapse, or what it is.

Problems which concern the surgeons more immediately, of course, are problems which relate to administration of fluids after operation. One thing most surgeons wish for and hope some day to see is a fluid other than sodium chloride which can be given subcutaneously or intravenously. We can use glucose dissolved in water, and it can be given under the skin, but it is a rather painful agent.

DR. KEYS: Dr. Peters, could you attempt to throw some light on those quite difficult questions?

DR. PETERS: I don't know what to say about the dogs getting water under the skin and dying. But I don't think that one can for a moment analyze such a problem in terms of quality. One would at least have to consider terms of quantity. Now the same thing is true also in this surgical procedure; I have been for a long time extremely interested in handling gastric cases.

I have found it peculiarly difficult to penetrate surgery or to do anything with gastro-intestinal cases because there were certain hindrances or conventions. The first one of them was that as soon as the patient arrives some fluid is administered, regardless of other considerations. Therefore, I never had any base line to begin with. So I started off with a condition that no surgeon would ever want to touch, mercury poison, a condition in which the whole gastro-intestinal mucosa is absolutely torn to pieces. I tried to see how much fluid was needed. I also tried to find out what the gastro-intestinal tract could do under those circumstances if you just gave it a chance to do something by itself. I found that if you didn't give such patients any fluid at all by mouth, tube or otherwise, the vomiting and the diarrhea ceased. In fact we had one man who went without vomiting, diarrhea or urination for five days. He seemed to be in pretty good shape and was sitting up reading the paper at the end of that time.

I don't see why people should object to giving sodium chloride. I think the objections to giving sodium chloride lie largely in failing to meet a quantitative equation. Of course, I don't see any reason for attempting to give sodium chloride intravenously to keep up with the surgeon who puts a stomach tube down and washes out the stomach with water. He washes out the chloride faster than I can ever put it in by the skin or veins and we have been able to recover 72 grams of sodium chloride in the washings from the gastro-intestinal tract of a patient in the course of one day while the poor interne was hard put to it to supply chloride in the other direction. Dr. Wangenstein doesn't make this kind of error but it is very commonly done.

In diabetic acidosis, where bicarbonate is low, it may be thought that bicarbonate should be used. However, it won't do the least bit of good to make a completely perfect pattern of the patient's serum if he is still so depleted of chloride and fluid that the total amounts of chloride, bicarbonate, and everything else are far below the normal level. On the other hand, if the patient is given enough sodium chloride and give his kidneys half a chance to work, he can perfectly well adjust this pattern unless he has severe renal disease. The very small

amounts of potassium and calcium required in the serum are being supplied to the patient in more quantities than he needs from all the tissue cells that are being broken down. Apart from these, sodium and chloride make up the whole of the way. Why should I want to give him anything else? Chloride makes up a great part of the anions. Bicarbonate, which is the rest of it, is always available because the patient is continually producing CO_2 in ample amount to make up his bicarbonate. The only trouble is that if you are going to give sodium chloride alone you must make sure you are giving it in proper quantities so that the kidneys will react. Hartman's old experiments prove that. Sodium chloride is the ideal solution because it comes nearer providing everything you need. And if you do not get the proper patterns in the serum of electrolytes as a result don't blame sodium chloride, but blame yourself for having given improper amounts of sodium chloride.

Glucose is given sometimes with sodium chloride and sometimes without. Glucose supplies carbohydrate to prevent the breakdown of carbohydrate metabolism and the acidosis that might result. It is a nutritive material. Water is administered with it also and if the solutions are properly balanced there is available the little extra water needed to provide for his insensible perspiration.

The main thing I should like to bring out is that the patient's urine volume must be followed. It is not necessary to supply enough sodium chloride to make 4 liters of urine a day; you don't have to try to produce edema in a patient who is usually malnourished from lack of proteins. You must see that his kidneys are getting rid of a liter or a liter and a half of urine a day in order that they may adjust the patterns which you can't quite adjust by Hartman's solution or any other expedient. If you want to add a saline plus glucose there is no harm and it provides something to burn. I don't see any reason to give lactate to be burned when CO_2 will form the bicarbonate that you need.

DR. KEYS: The question of water and salt binding by the proteins must remain a key point to be settled before it is possible to discuss water and salt exchanges in the body in a truly quantitative manner. If any appreciable fraction of the water is restrained from its or-

dinary solvent action by the proteins, then osmotic activity calculations based on total amounts of water and salt must be erroneous. Dr. R. A. Gortner has for some years insisted that some of these matters of the inter-relations of electrolytes and proteins are not as simple as they seemed at one time.

DR. R. A. GORTNER: I was very much interested this morning in Dr. Peters' statement that the Donnan equilibrium did not tell the whole story, and that some of the anions and cations were immobilized. I notice that Dr. Peters didn't use any terms which are common in the colloid literature, but, after all, I think possibly the phenomenon of adsorption may explain certain of these ion inactivations. At least I'm rather convinced that way myself. And as long as we are dealing with surfaces, it's perfectly evident that the state of the colloidal material within the cell, if it is varied at all, will vary the surface exposure and will shift—in my terminology or in the colloid chemist's terminology—the adsorption equilibria which are so characteristic in many cases of potassium as contrasted to sodium. Perhaps the colloid chemist's terminology doesn't tell the whole story but it gives us a certain picture and the change from health to disease can be looked upon to some extent at least, it seems to me, as a change in the physical state of those colloidal constituents which go to make up the protoplasm.

I will admit that our technics of measurement are not adequate for solving many of those problems. But I think that with that viewpoint kept in mind and with the intensive studies of acid-base changes, electrolyte changes and water-equilibrium changes which are being made in so many physiological laboratories, some day we shall get to a point of synthesis where the physiologist and the colloid chemist and the physical chemist all will talk in essentially the same terms about the same phenomena. I am sure that the colloid chemist and the physical chemist and the physiologist are not so much interested in defining the terms in which a physiological process is operating as they are in actually getting down to the facts of the case, and in finding out what is actually going on under one metabolic condition or under a pathologic condition which is imposed upon the normal physiology of the cell.

DR. KEYS: I think that Dr. Peters is star game, and as many times as we can get him on his feet is all to our benefit, in spite of the fact that I am sure that he must look forward with dread to this rather concentrated program that we have for these two days.

DR. PETERS: I want to correct what possibly may have been an error in understanding what I said this morning. If I said that the Donnan equilibrium couldn't explain some of these phenomena and things have been squeezed into it, it was no aspersion on the Donnan equilibrium. I believe that has been established on thermodynamic principles by Gibbs and by Donnan which none of us would dare to question. The only point is that it is only applicable to certain provinces and we've tried to squeeze all kinds of things into it. I think perhaps the best illustration I can have of that is the time when Dr. Van Slyke—and remember I should never cast any aspersions on Dr. Van Slyke—explained the distribution of ions between the red cells and the serum on the basis of Donnan equilibrium. Prof. Donnan was there as the first discussor. He got up and said, "I should never have had the temerity to try to apply my equilibrium to such a complicated system. I am lost with amazement that it can have been so applied—and I am still doubtful."

DR. GERALD EVANS: I am interested in these questions with regard to problems of muscle physiology and of the adrenal cortex. I think it is exceedingly significant that Kendall has separated out several distinct compounds from the adrenal cortex, any one of which when injected into the patient with Addison's disease almost miraculously corrects the disturbance of salt and water metabolism.

Moreover, one of those same compounds has been shown recently by Long and his associates at Yale to be apparently equally potent in another direction, namely, effecting the conversion of protein into carbohydrates. I found that in the absence of the adrenal cortex, protein is not converted into carbohydrate very readily. I took a lot of trouble to find out whether or not the defect preceded the defect of salt metabolism. I found that the protein-carbohydrate conversion was damaged before any of the recognized signs of adrenal failure had appeared, namely, the depletion of sodium eleva-

tion, and the potassium and urea increase in the blood.

We might like to think that the protein carbohydrate metabolism determines the electrolyte metabolism. But I can't be sure that that is so. I'm a little bit afraid that the story might equally be the other way around. Of course, that's exactly the point, we are lacking a lot of facts in general physiology.

There is one other point. Although one recognizes that potassium is held within cells and sodium outside of it, we look upon it as a great mystery. We recognize too that phosphates, soluble or inorganic or esters of low molecular weight, are in the fluid. I'd be very interested to have Dr. Gortner's comment on whether phosphate can be in any sense osmotically active and still be held by adsorption to enzyme systems.

DR. GORTNER: Well, yes, a phosphate could still have osmotic activity though held by enzyme systems since in the phosphoric acid the oxygen molecules will attract to themselves water shells, and thus the osmotic activity would be what is heresy to a good many people, that is, a binding or release of colloiddally held water. If that in fact can be done, it will also depend, altogether, on what the phosphate is associated with as to whether you have this variable water relation. There may be osmotically active water and osmotically inactive water if you want to put it in those terms. Some water may be more or less fixed to polar groups of the proteins of phospholipins and of all sorts of systems.

Depending on whether those polar groups are exposed toward a free water surface, or whether those polar groups are buried in a colloidal matrix where the free water surface is not so generally available, there will be a shift, it seems to me, in the osmotic properties of the system, even if you have the same number of osmotically available ions. I realize that this hypothesis doesn't have general acceptance by everyone. But I think the evidence is piling up more and more that we must recognize that a considerable fraction of the water molecules are not freely mobile in the presence of the hydrophilic colloids. They maintain a more or less fixed position. More and more types of evidence have been introduced in recent years pointing in that direction and I don't see any

particular qualitative difference between the immobilization of a water molecule on a colloid surface and the immobilization of five molecules of water in the case of copper sulphate. We know perfectly well from a good many physical chemical measurements that ions are hydrated in solution. The massive protein molecules containing the peptide groupings, amino groupings, carboxyl groupings, and so on and so forth, all tend to attract water molecules which lose a certain amount of kinetic energy when they come within their sphere of action. The more recent studies indicate that after all water is a pretty complex system to begin with; that we have actually, at room temperature, fragments of what you might call ice, floating around in ordinary water. If one shifted the equilibrium between polyhydro and monohydro water molecules theoretically there should be a shift to some extent of the osmotic behavior of ions suspended in that particular system.

DR. KEYS: Many of us will remember the ease with which A. V. Hill some years ago disposed of the phosphates in setting up a balance between the red cells and the plasma to account for the osmotic equilibrium as it seemed to be at that time. I think that we are now well aware, of course, of the extraordinary complexity of the system which Hill lumped together as phosphorus expressed as H_3PO_4 with 70% osmotic activity. Today few would venture to make a final balance sheet for the osmotic relation between red cells and plasma. The uncertainty as to the osmotic activity of the phosphates inside the cells is one major obstacle. This is even more true of the muscle cells where the hexose phosphates confuse the picture still further.

In addition to the complexities already mentioned, we must not forget that we seldom have, in the body, the conditions of a true equilibrium. Membranes which are ultimately permeable to a given ion or molecule may offer considerable restraint and thereby slow down the passage of that ion through them. What is the effective osmotic activity of the solution containing that ion or molecule during that time? When large movements of fluid across a membrane are taking place rapidly, even chloride may have osmotic effects where, given time, it would have zero activity. There seems to be good reason to believe that an osmotic buffering action may

arise in all systems where membranes are differentially permeable to solutes so that they pass through at different rates.

DR. ARILD HANSEN: I should like to ask what criteria are used for determining the amount of sodium chloride to administer, whether it is a measure of the vascular bed, whether it is excretion, whether it is amount of the gastric fluid which has been removed, or whether it is the clinical picture. We are interested in our department, particularly Drs. John Anderson, Thompson and McQuarrie, in the question of the relationship of sodium chloride to the carbohydrate metabolism as it affects the diabetic. A diabetic child in coma given large quantities of sodium chloride by mouth had a very rapid recovery, but with this rapid recovery was a great increase in blood pressure which went to pathological bounds. Diabetics were placed on a regular type of diabetic diet with vegetables, etc., and were given quantities of sodium chloride varying from probably 5 to 30 grams in a twelve hour period. These individuals exhibited a great decrease in the output of sugar as well as a decrease in the insulin requirement. However, when blood pressure was measured these young subjects were found to have become hypertensive with systolic pressures of 160, 170 and 180. When the potassium salt was used in the same type of study the opposite response occurred.

DR. PETERS: I can't help wondering whether Dr. Hansen is speaking of diabetes in general or certain diabetics. In certain attempts to test the effects of sodium on our diabetics we have not been successful in duplicating these effects.

I can't help for a moment just stopping at one point, and asking Dr. Hansen what he means by potassium to sodium ratio. I don't see any reason for the use of the term ratio or applying it to an entirely independent variable. The term "albumin-globulin ratio" is another case in point. Why not take account of the amount of albumin that is in serum and the amount of globulin? As far as we know in origin, and function and every other respect these proteins are entirely different and their effects on osmotic pressure are different. It makes all the difference in the world whether you've got a high globulin or a low globulin and a high albumin and a low albumin but I

don't see that it makes any difference in the world whether you've got a high albumin-globulin ratio or a low albumin-globulin ratio. We have heard of sodium and potassium ratios, calcium and potassium ratios, magnesium and sodium ratios, and everything else; but as far as we know, the further we go the more we appreciate that these ions all have their individual functions and their particular abilities to perform certain reactions or to participate in them.

Now, to go back to the other subject. Potassium is a dehydrating salt. It is excreted with a great economy of water. We never have been able to get any other salts that have such relatively low concentration in the plasma and such enormously high concentrations in the urine. It is excreted as a foreign body and takes with it a certain amount of water, enough to be dehydrating within limits.

Dr. Hansen asked how we found out that people were hydrated or dehydrated. Well, we can't at the present time. We are peculiarly unable to. I don't believe that we have a method that really accurately measures blood volume in the first place. I think that all plasma volume or blood volume methods measure something in addition. There is very good evidence of that in Smith's old experiments which are so much neglected at the present time when we use spectrosopes, spectrophotometers and all kinds of elaborate instruments. We are becoming more accurate in analysis without considering the fundamental defects in the blood volume system which affect the distribution of the dyes in the blood stream.

Now we have tried at Yale to measure the interstitial fluid, and we are at present trying another method. We are also trying to measure the *total* fluid of the body. I believe all such methods will probably be a little complicated to introduce into the home or a general

service. But by the use of such methods we hope to be able to check on the clinical criteria that we now have to use to determine the hydration of the patient. At present you must rely on elasticity of the skin, the general state of the circulation, whether their blood pressure has fallen too far, the serum proteins, etc., but most of all you must look at the patient. No amount of chemistry will eliminate accurate clinical observations. But I say accurate clinical observations with my fingers crossed because I'm not sure how far any of these criteria are really a good indication at the present time. By measurement of the total amount of fluid in the body and the interstitial fluid and observation of the shifts between them, we may be able to check on these things and in a few years be able more accurately to say how much fluid a patient needs.

When you come to giving patients fluid, you give them enough first of all to take care of the depletion they've already undergone, and enough more to enable them to carry on in all functions of the body. Here is the point of looking at the volume of the urine and also at the renal functions behind it. It seems to me a little homely thing that's too often neglected when physicians are apt to ask for a sodium determination that can't possibly be done short of twenty-four hours.

DR. HANSEN: The studies on diabetic children are not my major work but that of Dr. John Anderson here. I saw the observations on eight or ten subjects and saw the general form of the responses I mentioned.

DR. JOHN ANDERSON: I think Dr. Peters may be right that one of the chief defects in our studies was the lack of full balance studies with the several types of salt solutions used.

BLOOD REGENERATION IN THE ANEMIAS

Chairman: DR. HAL DOWNEY
Professor of Anatomy
University of Minnesota

Leader: DR. GEORGE H. WHIPPLE
Professor of Pathology and
Dean of the Medical School
University of Rochester

In a few introductory remarks the chairman called attention to the complexity of the subject, and cited as one of the major problems for future study the reason for the continued normoblastic regeneration in the bone marrow of pernicious anemia on liver treatment, while other normoblastic anemias show little or no response to this treatment. It might be argued that the megaloblasts which are so numerous in the marrow of pernicious anemia during relapse are primarily responsible for the marked reaction of this marrow to liver. While this may be true during the first few days of treatment it does not account for the continuous erythropoietic response after the marrow has become normoblastic, nor for the complete change of the histological structure of the marrow, and the normalized maturation of the neutrophil leukocytes which are so characteristic of pernicious anemia blood and marrow.

Dr. Whipple was introduced at this point and attention called to the great importance of his researches on the regeneration of blood in anemic dogs, this work having led directly to the first trials on the effect of liver in the diet of pernicious anemia patients.

DR. WHIPPLE: Artificially produced radioactive iron is an extremely sensitive agent for use in following iron in the course of its changes in body metabolism, lending itself to studies of absorption, transport, exchange, mobilization, and excretion.

The need of the body for iron in some manner determines the absorption of this element. In the normal dog when there is no need for the element, it is absorbed in negligible amounts. In the anemic animal iron is quite promptly assimilated.

One may choose to believe that the iron absorption is largely a concern of the small intestine and furthermore that the mucosa is the tissue responsible for its acceptance or rejection. It may be possible to show that the epithelium of the mucosa is conditioned by the an-

DR. GEORGE HOYT WHIPPLE of Rochester, New York, has been Professor of Pathology and Dean of the School of Medicine and Dentistry of the University of Rochester since its founding in 1921. Doctor Whipple and Doctors Minot and Murphy of Boston were made joint recipients of the Nobel Prize in Medicine in 1934 for their discovery of the cause and also a successful method of treating the previously fatal disease, pernicious anemia. Other outstanding honors received by Doctor Whipple have been the *Popular Science Monthly* Award and Medal in 1930 and the Kober Prize in 1939.

Doctor Whipple was Director of the Hooper Foundation for Medical Research and Dean of the Medical School of the University of California between 1914 and 1921. Prior to the latter period he had been Pathologist at the Ancon Hospital in Panama and Associate Professor of Pathology at the Johns Hopkins Medical School in Baltimore. He is a graduate of Yale College and received his medical training at the Johns Hopkins Medical School. Since 1927 he has served as a trustee of the Rockefeller Foundation and for several years has been a member of the Board of the Rockefeller Institute of New York. He is a member of the National Academy of Science, the American Physiological Society, the Association of American Physicians, the Society for Experimental Pathology, and other scientific organizations. While his fundamental medical research work has covered a wide range of subjects, his most outstanding contributions have been those pertaining to liver function, pigment metabolism, various forms of anemia, formation and regeneration of the blood proteins, and the diseases of metabolism.

mic state of the circulating blood so that absorption of iron takes place. At any rate the curve of iron absorption by the anemic dog indicates that the peak absorption (four to eight hours after feeding) takes place when the food materials are largely in the small intestine. At the end of eighteen to twenty-four hours the radioactive iron is practically all in the colon and no significant absorption of iron is demonstrable. It would seem that the colon is not concerned with iron absorption.

The plasma is clearly the means of transport of iron from the gastro-intestinal tract to its point of mobilization for fabrication into hemoglobin.

The speed of absorption and transfer of iron to the red cell is spectacular. The importance of the liver and bone marrow in iron metabolism is confirmed.

Radioactive iron as ferrous gluconate given by vein enables us to study *iron excretion* in urine, bile and feces.

There is an initial extra output in urine and feces during a few days (three to fifteen days) following the iron injection and this may total 2 to 8 per cent of the injected iron. Following this initial reaction the urinary excretion of radio-iron drops to traces or even to zero.

The feces always contain measurable amounts of radio-iron. In five dogs receiving 100 to 250 mg. of radio-iron the fecal excretion per day settled down to 0.05 to 0.4 mg. per day.

Blood destruction by acetyl-phenylhydrazine causes a definite increase in radio-iron eliminated in the feces (0.1 to 1.0 mg. per day). Probably most of this excess iron comes through the biliary tract (bile fistula). The bile under usual conditions contributes very little iron to the intestine (0.01 mg. radio-iron per day or less).

The body controls its iron stores by absorption or lack of it rather than by its capacity to eliminate it. The evidence is overwhelming that the dog excretes iron with difficulty and in small amounts, even in the plethoric state, by means of the biliary and gastro-intestinal tracts.

Perhaps we may hazard a guess as to the capacity of the dog, whether he be anemic or plethoric, to eliminate surplus iron in comparison with the amount of iron in circulation. Dog 37-180, weight 9 kg., had a blood volume of 700 ml. and a total amount of hemoglobin in circulation amounting to 140 gm. (equivalent to 480 mg. of iron). This dog received injections of iron (or red cell equivalent of iron) amounting to 400 mg. of which 130 mg. was labeled radio-iron. The base line of radio-iron excretion was approximately 0.18 mg. per day. If the excretion of labeled iron is typical of the behavior of all surplus iron in this dog this would represent an iron excretion of about 0.6 mg. per day. If this excretion of assumed surplus iron represents the normal ability of the dog to excrete excess iron it would require about two and a half years for the animal to eliminate excess iron, equivalent to the amount in circulation as hemoglobin—evidence of the difficulty of this task for the dog.

DR. C. J. WATSON: Coproporphyrin isomer type I is regularly excreted in increased amount in hemolytic jaundice, and in pernicious anemia during relapse. Splenectomy, or administration of liver extract, respectively, brings about a significant decrease in the amount of coproporphyrin

rin I excreted. This isomer type does not correspond in configuration to the porphyrin contained in hemoglobin, so that there is no reason to believe that the increased amounts are related to the destruction of hemoglobin. On the other hand, there is much reason to consider that coproporphyrin I formation and excretion is correlated, perhaps quantitatively, with erythropoietic activity in the bone marrow. Thus, megaloblasts and erythroblasts, especially in embryonic, and in pernicious anemia bone marrow, have been shown to contain coproporphyrin. Although the significance of this is by no means clear, it appears certain that increased amounts of coproporphyrin I are formed when there is increased erythropoiesis, and this is particularly true in the group of anemias in which hemoglobin formation is not disturbed (the normochromic group, or those with high color index).

The isomeric coproporphyrin III, which does correspond in configuration to the porphyrin of the hemoglobin molecule, is increased in various toxic states, such as poisoning due to lead, arsenic, mercury, sulfanilamide and others. There is much reason to believe that coproporphyrin III is not due to an abnormal destruction of hemoglobin. For example, it has been noted in cases of lead poisoning that an increased excretion of copro-III persists long after the initial blood destructive phase of the disease has passed. It is much more likely that coproporphyrin III formation in lead poisoning is due to a disturbed formation of hemoglobin, perhaps to a blocking of the entrance of iron, into a fraction of the porphyrin intended for the hemoglobin molecule. This view coincides well with the fact that the anemia of lead poisoning is distinctly hypochromic in type, pointing to an associated disturbance in hemoglobin formation. Studies of hemoglobin metabolism in patients treated with sulfanilamide, carried on in association with Spink, have shown that the effect is similar to that of lead in that the anemia is both hemolytic and yet hypochromic. Rimington has found coproporphyrin III in the urines of rats receiving sulfanilamide. This tends to liken further the effects of lead and sulfanilamide upon hemoglobin metabolism, although it should be noted that preliminary studies which we have carried out have not shown such a regular nor marked increase in excretion of coproporphyrin as observed experimentally by Rimington. The

difference may be in the fact that Rimington's rats were given very much larger per kilogram doses than what we employed therapeutically. Further studies of this problem are in progress.

The reticulocytes contain protoporphyrin and this has been identified by Grotepass as belonging to isomer type III, in other words, corresponding to hemoglobin. The function of the reticulocyte protoporphyrin is as yet unknown. Two possibilities must be considered: (1) that it simply constitutes a slight excess of porphyrin intended but not used in the construction of hemoglobin while the cells were yet in the bone marrow, or perhaps to be used for this purpose even after the reticulocytes have gained access to the circulation; (2) that the protoporphyrin serves the rôle of a respiratory enzyme, since it has been amply demonstrated that the reticulocytes have a measurable oxygen consumption, while the mature erythrocytes do not. As yet no evidence is available in favor of one or the other of these possibilities.

The reticulocyte protoporphyrin can not be regarded as the parent substance of coproporphyrin I, because of lack of correspondence in configuration of their molecules. On the other hand, it might very well be parent to coproporphyrin III, and is another possible source of origin for the excess of this porphyrin encountered in lead poisoning and other toxic states, as already mentioned.

DR. CHARLES H. WATKINS: Dr. Downey has asked me to discuss the morphologic changes in the blood associated with blood loss. In any condition in which there is chronic blood loss, whether relative or absolute, the erythrocytes are hypochromic but the total number per cubic millimeter of blood is normal or only slightly reduced. The individual erythrocytes are paler than normal owing to a decrease in hemoglobin concentration in the cells; anisocytosis of moderate degree is usually present although extremes of variations of size of cells are not uncommon; polychromatophilia is usually increased slightly above normal and consequently the percentage of reticulated erythrocytes is usually slightly increased. Ordinarily the leukocytes are unchanged in number and appearance. In cases of long standing iron deficiency the hemoglobin may be much reduced and under such circumstances the erythrocytes may contain only a very

faintly staining ring of hemoglobin around the periphery of the cell, a condition known as anochromasia. When the hemoglobin is reduced to this extent the erythrocytes per cubic millimeter of blood are usually decreased but not in proportion to the decrease in hemoglobin. There is evidence of slight increase in erythropoietic activity; the myeloid leukocytes are relatively unchanged.

In acute blood loss the picture ordinarily is quite characteristic. There is a rapid reduction in the hemoglobin as well as in the number of erythrocytes per cubic millimeter of blood. Morphologically there is evidence of increased regenerative activity and increase in polychromatophilia; the percentage of reticulated erythrocytes is higher than normal; anisocytosis is more marked with regenerative macrocytes much in evidence. Normoblasts may also appear in the peripheral circulation. Usually there is moderate leukocytosis with the increase largely in polymorphonuclear neutrophils. If the hemorrhage is very severe, immature myeloid leukocytes may appear in the peripheral circulation, resulting in a leukemoid reaction. The blood platelets are usually increased in number in severe hemorrhage. During the recovery phase, hemoglobin regeneration ordinarily falls behind the production of erythrocytes so that hypochromic anemia occurs.

A thorough morphologic study of blood smears is of value in all cases of anemia in order to eliminate, if possible, a primary blood dyscrasia. This examination also proves of value in determining the degree of hemopoietic activity at a given stage.

It is fortunate that in most cases of secondary anemia the cause is obvious but in obscure types identification of the etiologic factor may be difficult. Frequently obscure forms of secondary anemia are due to chronic loss of blood from the gastro-intestinal tract, which may be persistent or recurrent. The bleeding may be due to malignant lesions, benign polypoid tumors, or benign ulcers of the gastro-intestinal tract. In some instances relatively slight bleeding from hemorrhoids may produce secondary anemia of marked degree. It is certain that treatment of secondary anemia should not be instituted without a complete study of the patient and not until a satisfactory etiologic factor is found. Investigation of secondary anemia frequently entails de-

CLINICAL PROBLEMS OF THROMBOSIS

tailed examination and if this is slighted a serious disease may pass unrecognized, particularly if the blood responds to the treatment given. In addition to complete roentgenologic examination of the intestinal tract, examination of stools for occult blood should be made, for often bleeding lesions of the small intestine can be recognized

only by this means. Examination of stools for occult blood should be done over a period of days, for frequently bleeding is of a recurrent type and of relatively short duration. If blood is found persistently, abdominal exploration may be advisable provided there are no features of a primary hemorrhagic blood dyscrasia.

CLINICAL PROBLEMS OF THROMBOSIS

Chairman: DR. E. T. BELL
Professor of Pathology
University of Minnesota

Leader: DR. CHARLES H. BEST
Professor of Physiology
University of Toronto

DR. BEST: Dr. Gordon Murray has established that heparin is useful in certain types of vascular surgery—in embolectomy and anastomosis of blood vessels. He has had a number of cases of embolectomy and thinks that success has been greater in those in which heparin has been used. Dr. Radwin reported a case of a young doctor who had a coronary attack and then had a mural thrombus which lodged as an embolus in the aorta. This was removed and the blood vessels sewed up in the usual way. Heparin was used and the doctor is now back at work.

It is not proved that heparin is absolutely necessary, but the use of it apparently helps. Dr. Murray has also reported a case in which he resected 4 inches of the popliteal artery and inserted the same length of the patient's jugular vein; heparin prevented thrombosis at the site of sutures. There has thus been definite success in the use of heparin in vascular surgery. It is proved that heparin can be given to the patient without danger. There is interest in the use of heparin in subacute bacterial endocarditis. Several clinics are following Dr. Kelson in his lead of using sulfapyridine and heparin together.

It is easy to show, as Dr. D. Y. Solandt and I have done, that coronary thrombosis can be prevented in animals.

DR. BELL: If you are trying to prevent post-operative thrombosis, how often would you administer heparin?

DR. BEST: Only one way—continuously. Over 400 cases in Toronto have been heparinized

PROFESSOR CHARLES H. BEST is today one of Canada's outstanding medical men and one of America's best known men of science. In 1922, when he was only twenty-two and while still a medical student at the University of Toronto, he collaborated with Dr. F. G. Banting in a Nobel Prize winning research, the discovery of insulin.

With world wide renown at such a youthful period, some thought Charles Best would rapidly disappear from the scientific horizon. They were wrong. The high place in the world of science which Dr. Best has today is certain evidence that the scientific curiosity and ability which drove him to collaborate in the discovery of insulin were not a fly-by-night "lucky break" but the mark of inborn competence. After graduating in Medicine from the University of Toronto in 1925, Dr. Best went to England where he worked in the Physiological Laboratories of Professor C. Lovatt Evans and Sir Henry H. Dale. Later, when the chair of Physiology became vacant at Toronto, the University authorities wrote to England, in search of a bright young Englishman. The reply was sharp and to the point. They were told the most outstanding young physiologist of the day was on their own doorstep. Thus it was, that in 1929 Dr. C. H. Best became Professor and head of the Department of Physiology, University of Toronto.

Extending his scientific interests beyond the sphere of sugar metabolism, Dr. Best has made significant studies on histamine, choline and other biologically potent substances. He, with collaborators, isolated histamine from the liver and later demonstrated an enzyme, a ferment found in the body capable of destroying this highly toxic substance.

Recently Dr. Best's interests have turned toward the processes involved in the clotting of blood and the methods used in preventing clot formation. His studies have found their application in efforts to prevent thrombosis of various sorts.

over the so-called "danger" periods. Heparin was used continuously for over four weeks in one case.

DR. MOSES BARRON: Over how long a period were the 400 patients heparinized?

DR. BEST: One to four weeks. The period varies. Usually it is about seven to ten days.

DR. BELL: Dr. J. S. McCartney will speak on the danger period in postoperative thrombosis.

DR. MCCARTNEY: The period of danger varies tremendously. If you are thinking of the time in which embolic lesions are liable to occur, most of them occur within the first two weeks. There are occasional instances where the fatal embolism has occurred within twenty-four hours after operation, and a few in which the embolus has taken place two to three weeks subsequent to the operation. There is the question of how long it takes a large thrombus to form.

DR. BEST: Fifteen minutes. We have seen a thrombus big enough to close the aorta form in fifteen minutes. The platelet thrombus forms first, and once the blood stream is slowed or completely stopped, then clotting and thrombus formation occur with great rapidity. Once the thrombus has formed, heparin has no effect.

DR. BELL: How far in front of the embolism does the thrombus form?

DR. MCCARTNEY: There is good reason to believe that it will go beyond the next branch.

DR. BEST: In a series of experiments on dogs, Dr. Solandt and I opened the pericardium, tied off the descending branch of the left coronary artery, infiltrated sodium ricinoleate so that it would lie against the endocardium, sewed up the chest and started heparin immediately. The thrombus formed before we could get out of the chest.

In the dog you can tie off the coronary arteries and not get any mural thrombus. In the dog, tying off a single coronary artery does not lead to thrombus formation if the endocardium is not injured.

DR. BELL: It seems obvious that if we knew how far the thrombus formation precedes the detachment of the thrombus, we would be in a much better position to advise therapy.

DR. MCCARTNEY: Most patients who have thrombophlebitis do not get embolic lesions. There are a few patients who have it and then have the embolism let loose and cause either infarcts of the lungs or fatal embolism.

DR. BELL: Some lasting two to three months do that. You think that the reason why there is only a small percentage of clinical thrombosis which results in embolism is that the thrombi are adherent?

DR. MCCARTNEY: The clinical thrombophlebitis requires complete closure of the vessel. Those with embolism do not have complete occlusion.

DR. F. J. HIRSCHBOECK: Are there any criteria as regards age, obesity, etc., for cases in which you wish to use heparin? When do you begin using it?

DR. BEST: Some surgeons operate under a moderate heparinization. Dr. Murray says to use it from two hours to five or more hours after operation; this depends on the operation. They have started after splenectomies in an hour or so. When clotting is complete there is no reason to suppose that bleeding will recur. If there is a bleeding point, bleeding will be increased by heparin. Heparin is used in prostatectomies, splenectomies, etc.

DR. HIRSCHBOECK: Dr. McCartney, most of the thrombi form during the healing period, but now the belief is that the emboli that cause trouble break off rather early.

DR. MCCARTNEY: Statistics show that many patients who die of a massive embolism have had emboli earlier with or without symptoms.

DR. HIRSCHBOECK: Is the danger chiefly during the first two or three days or the second, third or fourth weeks?

DR. MCCARTNEY: I think it is in the early period.

DR. REA: Dr. Best, how do you give heparin to the patients? Have you noticed any hemorrhagic tendency?

DR. BEST: In dogs we give an initial injection of about 30 to 40 units per kilogram, then a steady injection to keep the clotting time at twenty minutes or higher. There is no way of telling what the clotting time of the patient or dog will be, *i.e.*, there is great variation in the reaction to heparin.

DR. BELL: Can you neutralize the effect of heparin?

DR. BEST: You can precipitate all of the heparin out of the body with protamine. This was first shown by Chargaff and Olson. Protamine should not be used clinically at present.

DR. PAYNE: When will the price of heparin get down so it can be used for clinics and hospitals inexpensively? I understand that recently the local use of heparin has been recommended. Two or three years ago, Dr. Olson in New York was working on a synthetic compound similar to heparin; what is your reaction to such substitutes?

DR. BEST: Heparin is being made in Toronto at the Connaught Laboratories; the process was worked out by Scott and Charles. The details of the process have been published. It takes large amounts of lung to get a gram of heparin. The initial cost was \$12.50 per 100 mgm. It is \$2.70 now. Two vials a day is the average amount.

With regard to regional heparinization and general heparinization, it is thought to be much better to heparinize generally than locally. It is far less expensive to do local heparinization, but it seems a little unreasonable. Synthetic anticoagulants have been made. They are cheaper but are much less effective and are much more toxic.

DR. BELL: The next topic is the influence of age on the formation of thrombi.

DR. MCCARTNEY: This is based upon the findings in our postmortems and what has been gathered from the literature. In a number of papers there is a marked discrepancy in the incidence of pulmonary embolism as reported both from series of operations and also from series of postmortems. They vary anywhere in the postmortems from 0.5 per cent to 12 per cent. This does not appear to be reasonable. It means either that the postmortems were not carefully done or that there was some difference in the material in various series. In order to get some of the background of the incidence of thrombosis and embolism, I went back to early literature and found that Virchow in the 40's made a study of seventy-six consecutive

postmortems and found eighteen thromboses and eleven embolisms of the lungs. With regard to the question of age—if we stop to think of it a moment, there are practically no thromboses in children except when related to definite infectious processes, such as otitis media. When you get to older people there are plenty of instances of thrombophlebitis where there is no suggestion of any infectious process at all. In our postmortems not only the incidence of venous thrombosis increases with age until you get up into the eighth decade, but the incidence of pulmonary embolism also goes up in the same way. Each instance of pulmonary embolism presupposes that there is a thrombus somewhere. The actual incidence of thrombosis is several times that of the incidence of pulmonary embolism whether you consider the fatal cases or the non-fatal, where it is an accident and an entirely unsuspected condition. I gathered a large number of reports of operations at various sites because we have always felt that there were certain operations which were likely to be followed by thrombosis and embolism. The pelvis and lower abdomen have been particularly mentioned. Appendectomy was mentioned frequently as an operation which was rarely followed by embolism. Most appendectomies are done before thirty years of age (76-80 per cent). Practically no emboli occur in these early decades. In later decades primary appendectomy is not infrequently followed by emboli. Practically no prostatectomies are done until after fifty years of age and then the incidence of thrombosis and embolism is very high. Hernias run practically a straight line through all decades and in the later decades most of the embolic lesions take place. Gynecologic operations reach their peak along about the fifth decade; not many are done before the age of thirty. In our material the incidence of embolism seems to be about as high after transurethral resection as after a suprapubic or perineal prostatectomy. One of the prime factors in the development of thrombus and embolus is the mere opening of the abdomen and the resulting splinting of the abdomen and the change in respirations. The question of age at which the operation is done more than the actual point of operative procedure should be considered.

DR. BELL: It is, then, not the operative site

but the age of the patient that gives thrombosis and embolism. Formerly it was thought that it was the operative site.

Shall we say something about the rôle of infection in thrombosis? Some years ago it was taught that there cannot be a thrombus without an infection. We have gotten away from that idea entirely. There still remain, however, a good many thrombi which have an infectious origin.

DR. MCCARTNEY: In the postoperative thrombosis and embolism, if it is the idea that the infection is at the site of operation, this simply won't stand scrutiny because most of the post-operative thromboses and emboli have no relation to the site of operation whatsoever. There are some cases, naturally, where they are related, but in many of them it is difficult to see

how infection can spread from the site of operation to the veins of the pelvis or lower extremities, where the primary thrombosis is found.

DR. T. A. PEPPARD: We have considered thrombosis and embolism as a postoperative, post-traumatic and obstetrical complication. This should be mentioned as a medical complication and mention made of certain influences, such as pneumonia, and its occurrence in cardiac failure.

DR. MCCARTNEY: With the material here, the incidence in the medical group is a little lower than the post-traumatic, but this is due to the lopsidedness of the material. When you get to the higher decades, it becomes much more frequent in the people with heart disease and is several times as frequent in the medical cases as in the traumatic and postoperative cases.

CURRENT TRENDS IN PUBLIC HEALTH*

Chairman: DR. GAYLORD W. ANDERSON
Professor of Preventive Medicine
and Public Health
University of Minnesota

Leader: DR. THOMAS PARRAN
Surgeon General
U. S. Public Health Service

DR. PARRAN: In observing the current trends in public health many questions immediately arise as to the paths along which these trends are taking us. It is important to stress at the outset that no one knows the answers to these many questions that confront both the public and the many agencies created by the people for the protection of their health. It is only by full and frank discussion of these questions and problems that rational means of solution may be evolved and subjected to trial.

It is obvious that the problems of public health today are very different from what they were several years ago. That was the time when the health officer was the man who was supposed to tack up a sign when a case of scarlet fever occurred, and after four weeks to return and take it down. His duties in the interim were few and equally simple. That was also the era in which the problems of the practitioner of medicine were likewise simple. He could carry in his little black bag most of the materials he

DR. THOMAS PARRAN, JR., is a native of Maryland. He was graduated from the Georgetown Medical School, receiving his degree at the age of twenty-two in 1915. He entered the United States Public Health Service in 1916 immediately beginning on a rather meteoric career. By 1918 he had been made Chief Medical Officer at Muscle Shoals. In 1919 he was transferred to Washington as Executive Officer in the Medical Division of the War Risk Insurance Bureau. After serving here for two years the United States Public Health Service transferred him to the midwest where he spent four years with the Missouri and Illinois State Health Departments developing local health work. In 1925 he returned to Washington to take charge of the venereal disease control work of the United States Public Health Service, a position that he occupied for five years. In 1930 the position of Commissioner of Health of New York State became vacant due to the resignation of the former Commissioner to enter a different type of work. Governor Roosevelt feeling that there was in the state no person who seemed particularly suited for this position at the moment requested the detail of an officer of the United States Public Health Service to serve as Commissioner in New York for a period of years. Dr. Parran was detailed to this work serving with distinction as Commissioner until 1936. That year he returned to Washington as Surgeon General of the United States Public Health Service succeeding Dr. Cummings who had reached the retirement age.

used in the practice of his art and in his head he might carry most of the medical knowledge of his time. Our knowledge of man and dis-

*The discussion here published is not verbatim but contains the essence of the speaker's statements as reported by the chairman.

ease was very restricted for the scientific laboratory had not yet made much progress in the evolution of elaborate tests and therapeutic armamentarium.

Today we find that all of this has changed. Just as the developments of science have added to our knowledge of disease so have they also created problems of prevention. Public health has made great advances in the control of certain specific diseases, notably the infections. It has been relatively simple to control typhoid through attention to the water supply, to prevent diphtheria through immunization, to limit the development of simple goiter through the ingestion of iodine. But with the control of certain specific diseases others over which equally effective control has not yet been established stand out in greater prominence. At times we have been so engrossed with our successes in one direction that we tend to lose sight of equally great problems in other directions.

The attack upon some of these is in large measure a problem of creating individual understanding and participation. Only a few of the public health problems can be solved by such simple expedients as putting a few drops of chlorine in the water. In public health work it is extremely important that individual members of the community should both understand the problems and participate in their solution, for the health of any community is the sum of the health of the individual members of that community. This has meant that those actively engaged in public health work and especially those in public health nursing have had to become teachers.

Another difficulty has arisen from the fact that the prevention of certain diseases necessitates the treatment of the individual. In some instances, as in syphilis and tuberculosis, the treatment has been necessary to diminish the likelihood of spread as well as to benefit the infected individual. In other instances medical service has as yet given us no effective means of prevention, but only methods of treatment to restore the patient to health. Yet it is just as important to the community to restore the sick patient to health as it is to safeguard him from becoming ill. Thus step by step in the development of public health as the simple problems of health have been solved and our attention turned to the more complex problems of community pro-

tection we have become more and more concerned with the manifestation of disease and the necessity of its treatment. We have realized that in our attempts to approach an ideal with respect to both personal and community health we must give attention to the alleviation of those diseases for which we have as yet no effective prevention. Just as the community attempts to safeguard its citizen through its licensing of qualified medical practitioners, so society, which must pay for the ravages of disease, turns to a consideration of all measures which will reduce human suffering and the economic burden from sickness and avoidable death.

During the past years in which we have witnessed unparalleled progress in the science of medicine we have seen an equally significant progress in public thinking about the application of this science. It is very true that medical science has "sold itself" to the public. Certainly the public of today is more interested than ever before in the changes that are occurring within our science. At the same time they are asking themselves to what extent these scientific findings can be put to more effective use and can be made more generally available so that their benefits may reach a greater number of persons. People are demanding that this knowledge which is ours be put to work promptly and widely for the use of all.

On the other hand we have seen some reluctance on the part of medicine to respond to this public demand. This reluctance has not been conditioned by any basic dislike to respond in those fields where the health of the public may be benefited. Yet there has been a very real concern over some of the methods that have been proposed for putting medical science more widely to work. In the various proposals a few salient points of controversy stand out.

Any attempt to bridge this gap between the scientific laboratory and the application of its findings to the health of the nation raises immediately the question of financing. If it is to be a measure of public concern and is therefore to be supported by taxes, there occurs immediately the situation that those who depend on public support receive more than do those who attempt to buy their own services. There is the important problem of distribution of medical care without the danger of too great political control. No one has as yet evolved a simple formula

which will solve these and countless other allied questions, nor is it likely that any formula will be found without the benefit of trial and error. It is necessary in approaching this social problem that we use the same type of experimental method which has given us the principal discoveries of medicine in the laboratory. Unless we experiment with various methods we will learn nothing and no progress will be made in the better application of the findings to the solution of some of our most pressing public health problems. Fortunately we have in our form of government forty-eight or more different experimental laboratories in which we may try out various plans that may be proposed, learning what is good from one and retaining it while discarding that part of another which has been found to be bad. Just as medical progress rests on experimentation so also does social progress.

The national health survey was an attempt to find out and measure some of the health problems of the country so that we might formulate rational plans for trial. It represents the most comprehensive approach that has ever been made to the many problems affecting the nation's health. From the findings of this survey and the proposals of the Interdepartmental Committee there evolved a national health bill. While this bill, the so-called Wagner bill, has many serious defects in its present form, these defects can be remedied. Little can be accomplished by paying money out of several unrelated brackets with no central planning and no adequate review of the needs of the program as a whole. We cannot have a unified health program if we build hospitals with funds from one source, operate them with different funds, use still different funds for the health of the children, others for the medical care of the indigent and still others to protect the health of the worker. It is unlikely that any program that lacks coördination of direction can be successful.

In the execution of any plan for solving current public health problems through the furnishing of more nearly adequate care, two factors are essential. The first of these is trained personnel; without trained and skilled workers, experi-

ments are unlikely to succeed. The other essential is that whatever federal participation is included shall not mean too great federal control or domination. Within reasonable limits the individual states should be allowed to work out their own methods and procedures. It is only by this freedom of planning that we can look forward to that degree of experimentation that is needed and the development within different states of programs best adapted to the local needs. So long as we can have experimentation we may hope for the evolution of practical plans to meet the increasingly important new challenges of the public health.

In the discussion that followed the informal remarks of Dr. Parran, President Ford and Dr. J. C. McKinley commented on the necessity of including problems of mental health. Dr. Parran agreed that all phases of the prevention and care of mental diseases were an essential part of the broad health program of a community and pointed out that such were included in the study and plan of the Interdepartmental Committee.

Dr. A. J. Carlson, commenting on the basis of acquaintance with the situation in the Scandinavian countries and Russia as well as this country, spoke of the importance of so planning that the individual would pay to the extent of his financial capacity. He stressed the dangers of creation of a plan that might tend to relieve the individual of any thought of personal responsibility and to develop a philosophy of utter dependence upon government. Dr. Parran concurred in believing that whatever plan was tried should provide that patients who are able should pay in proportion to their ability. This may lead to a system of insurance to prepare for such costs, possibly including levies upon employer as well as employee. The success of hospital insurance has created new interest in this possibility.

Other participants in the discussion included Professor Stuart Chapin, Dr. H. S. Diehl, Dr. A. J. Chesley, Dr. G. F. Amyot, and Mr. H. A. Whittaker.

CHEMOTHERAPY

Chairman: DR. ARTHUR D. HIRSCHFELDER
Professor of Pharmacology
University of Minnesota

Leader: DR. PERRIN H. LONG
Associate Professor of Medicine
Johns Hopkins University

DR. HIRSCHFELDER: We are celebrating the Fiftieth Anniversary of the Medical School; but though it is only a little past the thirtieth anniversary of the initiation of chemotherapy by Ehrlich's introduction of salvarsan for the treatment of syphilis, we might also celebrate the anniversary of that event. It is about twenty-eight years since Morgenroth with the discovery that ethyl-hydrocuprein exerted a specific action against the pneumococcus conducted the first chemotherapeutic attack upon bacterial diseases. In 1912 I found that although ethyl-hydrocuprein was effective against pneumococcic septicemia in mice it would not cure pneumococcus pneumonia in rabbits and Chesney and others showed that it would not cure human pneumonia. It is interesting that now the workers at the Mellon Institute have carried Morgenroth's work one step further and are finding that hydroxyethylapocuprein which is less toxic than ethyl-hydrocuprein has a definite curative value in human pneumonia. But the great revolution in the chemotherapy of bacterial diseases came a very few years ago when Domagk introduced prontosil and the French experimenters showed that the sulfanilamide portion of the molecule was the part that produced the chemotherapeutic effect. Our distinguished guest, Dr. Perrin H. Long of Johns Hopkins was the first to introduce sulfanilamide in America, and he and Dr. Marshall by introducing methods of precision into the use of this wonderful drug, and the related substances, have done the most to add to our knowledge of how they act and just how they should be administered. I have the honor of introducing Dr. Perrin Long.

DR. LONG: The average case fatality rate in lobar pneumonia in the Johns Hopkins Hospital during the past few years has been 20 per cent. Despite the use of new and more effective anti-pneumococci sera, the case fatality rate has not been appreciably lowered during the last three years. During the past year, since July 1, 1938, following the use of serum and sulfapyridine and sulfapyridine alone, the case fatality rate

DR. PERRIN H. LONG is associate professor of medicine at Johns Hopkins University, in charge of the bacteriological division of the Department of Medicine. Dr. Long graduated in medicine from the University of Michigan in 1924. During the period from 1927-29, he was first assistant, then associate at the Rockefeller Institute for Medical Research in New York. Because of his valuable contributions in the field of infectious disease, he was then invited to become a member of the department of medicine at Johns Hopkins University. First as an associate and later, after promotion to the rank of associate professor, Dr. Long continued to carry on important investigation in clinical bacteriology and infectious disease. He was the first to point out to the medical profession in the United States the value of sulfanilamide in the treatment of various infections, notably those due to the streptococcus. His intensive research and numerous publications dealing with various aspects of sulfanilamide therapy have been of major importance in quickly bringing this valuable remedy into general use.

in pneumococcal infections in the Johns Hopkins Hospital has been cut to 7.2 per cent. This is the lowest in the history of the hospital. Since July 1, 1938, we have treated thirty-one patients with anti-pneumococci serum, eight with serum and sulfapyridine and 126 with sulfapyridine alone. In this group of patients, two were suffering from pneumococcal infections in which the pneumococci proved to be resistant to sulfapyridine therapy both in the clinic and in experimental animals. It has been shown that sulfapyridine given by mouth may be irregularly absorbed by different individuals and also that certain individuals acetylate the drug to a high degree. Hence, therapy with sulfapyridine by mouth is more difficult than when sulfanilamide is used. It has been our practice in adult patients to use the following dosage schedule. As soon as the diagnosis of pneumonia is made, the patient is given 4 grams of the drug in a single dose, then 1 gram is given every four hours until the temperature has been normal for forty-eight hours, then 1 gram every six hours until resolution is well under way, and finally 0.5 grams four times a day until the lungs are clear. It has been our practice on the day following the admission of a patient to the hospital to give the sodium salt of sulfapyridine by the intravenous route if the patient's temperature is not below 101° by rectum and the concentration of free

sulfapyridine in his blood is below 4 mgm. per cent. If such is the case, a single dose of sodium salt of sulfapyridine based on 0.06 grams per kilogram of body weight and made up in a 5 per cent solution in distilled water is given by the intravenous route. This dose will raise the blood concentration of sulfapyridine by about 5 mgms. per cent. If a patient is severely ill on entry into the hospital, we generally start therapy with an intravenous dose of sodium sulfapyridine based on 0.06 grams per kilogram. This may be repeated in four hours if necessary. Oral therapy is carried on as previously outlined with the exception of the omission of the initial dose. A further example of the effectiveness of sulfapyridine and sodium sulfapyridine in pneumococcal infections may be gained from the experience of Dr. Horace Hodes of Sydenham Hospital in Baltimore. During the past year, he has treated seventeen cases of pneumococcal meningitis with sulfapyridine given by mouth alone or in conjunction with the sodium salt administered by the intravenous route. Of these seventeen patients, eight have recovered. Of those patients who have recovered, seven were treated with the sodium salt by the intravenous route as well as by sulfapyridine. It is our practice now to establish blood concentrations of 15 to 20 mgms. per cent in pneumococcal meningitis by administering an adequate amount of the sodium salt of sulfapyridine by the intravenous route. This concentration is maintained until the temperature has been normal for from twenty-four to forty-eight hours. Oral therapy is also started as soon as is possible. Sodium salt of sulfapyridine cannot be given by the intraspinal route because it causes a severe myelitis which is frequently fatal. It can only be given by the intravenous route.

DR. GEORGE E. FAHR: Can the administration of alkali prevent hematuria and formation of stones?

DR. LONG: Theoretical consideration would lead one to believe that if the urine was kept very alkaline, pH 7.5 to 8, that the precipitation of acetyl sulfapyridine crystals would be decreased. Hence it would be less likely that renal stones would be formed.

DR. ERLING S. PLATOU: May the drug be used by the intrathecal route?

DR. LONG: Never by the intrathecal route.

DR. FAHR: You can usually tell very promptly if the treated patient is going to make a quick response to sulfapyridine.

DR. LONG: That is our experience. Improvement comes rapidly and should be marked within forty-eight hours. During the past year, we have had a large experience at the Sydenham Hospital with pneumonia secondary to measles. In this type of measles, sulfapyridine is highly effective and as Dr. Hodes has reported the drug brings about a spectacular improvement within thirty-six to forty-eight hours.

Dr. Hodes has also reported that the drug is of definite value in the therapy of whooping cough pneumonia. Some one has asked me if the drug is valuable as a prophylactic agent. Only under exceptional conditions should sulfanilamide or sulfapyridine be used as a prophylactic agent. Our experience leads us to believe that the only instance of proven prophylactic value of sulfanilamide is in the treatment of crushing wounds and compound fractures. In these types of injuries, the administration of sulfanilamide in full prophylactic doses prevents gas bacillus infections and facilitates markedly the healing of the wounds.

DR. FAHR: On account of the fact that Dr. Bieter found that too large doses causes too high blood levels in mice which was harmful to the mice, I keep the blood level of sulfapyridine in my patients at about 5 mgms. per 100 c.c.

DR. THOMAS MYERS: Do increases in the concentration of the drug in the blood increase the incidence of toxic effect?

DR. LONG: Not as far as we know. We have noted that children are more prone to develop leukopenia when they are receiving sulfapyridine than is the case when sulfanilamide therapy is being used.

DR. DONALD C. CREEVY: How about post-operative pneumonia?

DR. LONG: We employ sulfapyridine in our patients in whom the clinical diagnosis of pneumonia has been made, so this includes the post-operative pneumonia. We feel that if an attempt is made to make a definite bacteriological

diagnosis before instituting treatment that valuable time will be lost.

DR. FAHR: What has been your experience in trying to retype pneumonia in the course of sulfapyridine therapy? We have sometimes found it difficult to retype the organisms found in the sputum.

DR. LONG: This has not been our experience. We do not feel that sulfapyridine therapy interferes with the subsequent typing of pneumococci in the sputum.

DR. CREEVY: Do you use sulfapyridine in the urinary tract diseases?

DR. LONG: We have not used sulfapyridine because of its high acetylation rate in the urine.

DR. MYERS: When would you stop treating a case of otitis media?

DR. LONG: We think it best to continue sulfanilamide for at least two weeks after a complete clinical cure has been effected. During this period but small doses should be given. We have had very few mastoids develop in our nose and throat patients ill with hemolytic streptococci otitis media since we instituted the routine use of sulfanilamide in the treatment of this disease. It is of importance when continuing treatment to watch the white blood cell count. Acute hemolytic anemia generally makes its appearance within the first five days of therapy with sulfanilamide, while agranulocytosis most frequently occurs after ten days of therapy and generally from the seventeenth to the thirtieth day of treatment. Hence it is important to follow the white blood cell count as long as sulfanilamide therapy is being continued.

DR. HAROLD N. WRIGHT: The present intense interest in the chemotherapy of bacterial diseases must, necessarily, carry over some of its advances to other forms of chemotherapy, and particularly to the treatment of protozoan and meta-zoan infections, especially the treatment of syphilis.

One of the important facts brought out in the clinical use of sulfanilamide in the treatment of pneumonia is the necessity for maintaining an effective concentration of the drug in the blood stream throughout the period of treatment.

The usual plan of antisyphilitic treatment with arsenical drugs, namely eight to ten injections at five to seven day intervals, requires at least eight to ten months continuous treatment in order to render the disease non-communicable.

Following a single intravenous injection of one of the arsphenamines an effectively spirocheticidal concentration of the drug can be maintained in the blood stream at best for a matter of hours.

The avoidance of toxic reactions, particularly the cumulative effects of the arsphenamines, has been the principal reason for the comparatively discontinuous form of therapy. It is true, of course, that the complete excretion of a single dose of any of the arsphenamines may require fourteen to twenty-one days. The prolonged retention of these drugs is, however, closely connected with their colloidal properties, the therapeutic properties being roughly inversely proportional to the degree of colloidality. I see no reason why it should not be possible in the not too distant future to manufacture the arsphenamines in such a way that their antisyphilitic properties may be enhanced from four to ten times, in all probability with less danger of cumulative effects than at present. Mapharsen, which probably possesses no colloidal properties whatever, we have found in rats to be 80 per cent excreted in the first twenty-four hours.

Hyman and his collaborators in New York appear to have shown that much more rapid disappearance of the symptoms of early syphilis can be obtained by practically continuous intravenous infusion of the arsphenamines for a period of five days, the disease being rendered non-communicable and 86 per cent of the cases becoming seronegative in an average time of twelve weeks. Although this work is still only in the experimental stage, it points to the necessity for further investigation of the optimum conditions for the administration of arsenical antisyphilitic drugs.

DR. N. K. JENSEN: In all compound fractures treated at the General Hospital since March of 1938, we have placed sulfanilamide powder in the wounds upon the completion of debridement. The wounds have then been closed with skin sutures only, and the fractures completely immobilized. To date seventy-five fractures have been so treated. Infection has occurred in only four of these wounds, giving a percentage of infection of 5.3. In the first forty-

one cases so treated, only one wound became infected. These cases were reported in the journal *Surgery* for last July. Two of the wounds that became infected were so extensive that satisfactory closure could not be accomplished due to loss of skin. In another instance, the patient had a recurrence of his compound fracture eight days after injury while maniacal in delirium tremens. The fourth infection occurred in association with internal fixation of a compound fracture of the ulna; our only attempt at internal fixation of a compound fracture. No gas gangrene or tetanus infection has occurred, and the infections have been mild.

Before the use of sulfanilamide locally, the incidence of infection in compound fractures treated at the General Hospital during the last five years ranged from 26 to 30 per cent. In 1937 alone, five patients developed gas gangrene. The statistics for each year previously have shown approximately the same incidence. Besides these cases developing gas gangrene, it has been found necessary in the past to perform several amputations each year because of infections resulting from compound fractures.

We have found that by local introduction of sulfanilamide powder directly into the fresh wound, the concentration of the drug in the extent of the wound can be maintained at levels approaching saturation (800 mgm. per cent) for approximately thirty-six hours. Experimental study in animals reveals that an equal amount placed directly in a contaminated wound is much more effective than given parenterally at a separate site. In this series of patients reported no other sulfanilamide therapy was used.

Dr. King's findings that a small amount of autolyzing tissue inhibits the action of sulfanilamide suggests that all devitalized tissue must be removed from the wound. This we have found to be true, both in our clinical and experimental study.

DR. JOSEPH T. KING: The group using tissue cultures in the study of the effects of the sulfonamide compounds on the streptococcus includes Dr. Henschel, Mrs. Green and myself.

We have observed that strains of beta streptococcus grow in tissue culture clots in two forms. Some strains grow as dense colonies showing no diffuse periphery, while the colonies of other strains show a dense center and wide diffuse

periphery. This periphery is not composed of long chains of streptococci but of single organisms or small groups of two or three.

The response of the two colony types of sulfanilamide differs. In the living state, at a magnification of 60X, the compact type of colony shows no characteristic qualitative change; it is simply smaller. When the colony with diffuse periphery is treated with sulfanilamide the normal periphery is completely inhibited. Occasionally such an inhibited colony will show a few long, thick chains growing, usually from a small segment of the periphery. In older cultures one may rarely find a colony showing a complete periphery of such chains. Such a periphery is easily distinguished, even in the living state, from a normal diffuse periphery.

On the basis of colony diameter the inhibition is more striking in the case of strains whose colonies grow with diffuse peripheries. One can hardly escape the impression that the drug inhibits the invasion of the clot by the organisms.

It has also been observed that effects of sulfanilamide are antagonized by the products of tissue disintegration. If small fragments of fresh, sterile tissue are planted in tissue culture clots inoculated with a suitable dilution of a strain of beta streptococci showing diffuse peripheries, it has been found that sulfanilamide fails to produce typical inhibition of the periphery of those colonies close to the fragment while colonies further away show the expected inhibition. Not all tissues are equally effective in producing this "release" of colonies from sulfanilamide inhibition. There is evidence, however, indicating that even those tissues which are least effective in preventing the qualitative response do interfere with the bacteriostatic property of sulfanilamide. Studies on this point are in progress.

It was shown by Lockwood that peptones reduced the bacteriostatic effect of sulfanilamide for the streptococcus. Hoyt and Levine found that peptones interfered with the bacteriostatic effect of sulfapyridine on the pneumococcus.

The adsorption experiments of Larson, Bieter, Levine and Hoyt suggest that peptones and certain amino acids interfere with the adsorption of sulfapyridine.

It is evident that such products would be liberated by tissue undergoing proteolysis, and, while the precise mechanism by which such substances interfere with the activity of the sul-

fonamide compounds is not entirely clear, it is important to realize that disintegrating tissue protects the streptococcus from the action of sulfanilamide.

DR. RAYMOND N. BIETER: In our work on chemotherapy using Type II pneumococcus in mice, we have come to believe that the following factors are important and are to be considered:

1. Compounds or a series of compounds of related or unrelated chemical structure should be studied in a sufficient number of mice of the same strain to be statistically significant. To help answer the question of how many mice are necessary for one experiment, we have made use of the studies of Halvorson and Ziegler. They have attempted to show how the change in error varies with the number of times an experiment is repeated. Their experiments consisted of a study of bacterial growth in vitro. They have found that if one goes from a relatively few experiments up to about 30 repetitions, a rapid decrease in the percentage of error due to chance occurs. Above thirty the decrease in error due to chance takes place much slower. In other words if an experiment is repeated thirty to forty times, chance is eliminated to a high degree, and in order to get a marked improvement over thirty to forty repetitions of an experiment, one must go well up into the hundreds.

2. When chemotherapeutic drugs are used clinically they must be used against a wide variety of strains of a single organism. Therefore, it behooves investigators to study the actions of these drugs on as many strains of a given organism as possible. It is well known today that sulfanilamide has a more marked action on certain strains of the beta hemolytic streptococcus than in others. Undoubtedly this effect will be noted with this and other drugs acting also on other bacteria.

3. For the most quantitative results, surely it is agreed that the dose of infecting organisms given to an experimental animal should be described in terms of the organism's M. L. D. (minimum lethal dose). For mice this can be easily determined by simply injecting a suitable number of these animals. It is our belief that the M. L. D. in terms of dilution alone is not enough, but that these inoculations be paralleled

using an organism count. Many different multiples of the M. L. D. are used by the investigators, but as yet no one knows the optimum number of M. L. D.'s to use. In most of our work, we have used from 4,000 to 8,000 M. L. D.'s of our Type II pneumococcus.

4. The age of the culture used for inoculating mice or other animals is perhaps of paramount importance. It is well known, for example, that a culture of pneumococci aged from eighteen to twenty-four hours can be more easily phagocytized by human leukocytes than a younger culture. This difference may result in a different chemotherapeutic picture in the experimental animal. In our work with the Type II pneumococcus, we have adhered to the principles laid down by Chesney, Ward and Ender, and Neufeld and Handel. That is, actively growing young cultures are most resistant to phagocytes, and when explants of these cultures are made, maximum growth occurs. Alternate passage through mice and artificial media assures uniform virulence. An eight-hour culture satisfies the conditions of maximum virulence and no lag in growth.

5. The experimental technic best suited to each organism should be worked out and used for each bacterium. For example, in pneumococcus infections in mice, it appears to us that the subcutaneous method of inoculation is superior to the intraperitoneal method. This is believed to be true for the following reasons:

- a. Human pneumonia for the most part is a localized infection. The subcutaneous inoculation of mice with Type II pneumococcus results in a localized infection in the mice lasting about twenty hours, as compared to less than one-half hour following intraperitoneal inoculation.
- b. This then results in a *in vivo* experiment more equivalent to the average speed of a human pneumonia infection.

6. To obtain data most satisfactory for statistical treatment, the death times of mice should be determined quite accurately. We have, therefore, determined the death rates in our mice more or less on an hourly basis. In addition, by this method, smaller differences between chemotherapeutic substances can be noted which would not appear on a day to day determination of death rate.

7. In all of our work to date, we have employed the method of drug administration by simply mixing the pulverized drug with ground food and giving it to the mice in waste-proof food cups. This method has several advantages.

- a. It is very simple and easy to use.
- b. When the mice are once inoculated, no further handling is necessary. We have found that repeated handling of mice interferes with their food intake. Therefore, when mice are injected repeatedly with a drug, the element of starvation may play a rôle.
- c. We have found that mice eat quite regularly during six hour periods both day and night. Their food intake is greater during the night than during the morning. Other than for this variation, their food intake tends to run quite uniform per twenty-four hours after the first day or two. It requires one or two days for the mice to become accustomed to the food cups and thereby assume their maximum food intake per twenty-four hours. By weighing the food at twenty-four hours or shorter intervals, the drug intake can be easily computed. Inasmuch as Marshall and his collaborators have found that a mouse eliminates a given dose of sulfanilamide in about six hours, we believe that our method of food plus drug administration is superior to all other forms of drug administration unless the drug is given at intervals of six or fewer hours. Further reason of the efficacy of drug administration is to be found in the results we have obtained with sulfanilamide and its derivatives on Type II pneumococcus infections in mice. These results can be briefly summarized as follows: With 0.5 per cent of each of the following drugs in the food cups of 50 mice, each showed the following survival rates at thirty to sixty days.

- a. Control group..... 0 survivors
- b. Neoprontosil 6% survivors
- c. Sulfanilamide 20% survivors
- d. Sulfapyridine 44% survivors

The question of why survival rates in inoculated mice uniformly seldom approach 100 per cent has interested us very much. Undoubtedly a number of factors in the animal body of which

we know little play great rôles. One of these has to do with the temperature of the animal. This is especially important because of the observations of White to the effect that when the temperature in vitro studies is raised above 37° C., the bactericidal effect of sulfanilamide and its derivatives becomes greater. We have first of all constructed a micro-thermocouple using a copper constantine junction. This is made small enough so that it can easily be inserted beneath the mouse's skin. The mouse is held in the left hand as if one were to make an intraperitoneal inoculation. In a large series of normal mice, we have found that their normal temperatures most often run between 100 and 101° F. If now a group of mice are given an intraperitoneal injection of our Type II pneumococcus, the temperature begins to drop at about five hours and then thereafter shortly drops precipitously to about 85°. On the other hand, when the organisms are given by subcutaneous inoculation, the temperature begins to drop at seventeen to twenty hours and soon thereafter drops precipitously. As can be seen, the time elements correlate with our observations on blood stream invasion. It should be noted that at no time have these mice shown an elevated body temperature. Another factor that we have found is that mice appear to be very susceptible to environmental temperature changes. For example, mice placed in an environment at 37° C. show a 2° F. rise in half an hour. In addition to these preliminary findings, we have also collected the following preliminary observations:

- a. Control mice inoculated with our Type II pneumococcus and placed in an incubator at 37° C. die more rapidly than if kept at room temperature.
- b. Mice on 0.5 per cent sulfanilamide in the food and placed in the incubator show a more rapid and greater death rate than an equivalent number of mice maintained on the same amount of drug at room temperature. The sulfanilamide intake in both groups was approximately the same. We know further that normal mice and mice on sulfanilamide in the food maintained in the incubator showed no toxic effects. These experiments in the incubator were conducted with from 15,000 to 20,000 M. L. D.'s of our Type II pneumococcus per mouse. It can be seen, therefore, that

the survival rates or therapeutic effects at $37\frac{1}{2}^{\circ}$ C., that is in the incubator, are not as good as in mice at room temperature. In other words, these results do not all parallel the in vitro observations of White.

DR. WESLEY W. SPINK: At the University Hospital, we have been interested in certain toxic manifestations of sulfanilamide and sulfapyridine.

In association with Drs. C. J. Watson and I. Vigness, the problem of cyanosis due to sulfanilamide has been studied. Spectroscopic analyses of the bloods of several of these patients showed that in every instance the cyanosis was due to the presence of methemoglobin and, rarely, sulfhemoglobin. The intravenous administration of a 1 per cent solution of methylene blue to these cyanotic patients was followed by the disappearance of the cyanosis, and the characteristic absorption band of methemoglobin was found to be absent in their bloods. Methylene blue had no effect upon sulfhemoglobin. We have quantitated the amount of hemoglobin converted into methemoglobin in patients with cyanosis by spectrophotometric and spectrophotometric methods. In markedly cyanotic patients as much as 30 per cent of the hemoglobin was found to be present as methemoglobin. Clinical observations lead us to conclude that sulfapyridine seldom causes cyanosis. The blood of one patient with a slight degree of cyanosis was found to have 7 per cent of methemoglobin. After methylene blue had been given, the cyanosis abated, and methemoglobin could no longer be demonstrated in the blood.

Dr. Watson and I have studied the pigment metabolism and liver function of patients receiving sulfanilamide and sulfapyridine. Using quantitative methods, we have found that the majority of patients receiving therapeutic doses of sulfanilamide or sulfapyridine for several days will develop some anemia. In some patients it is of marked degree. It is of interest that this anemia is of macrocytic or normocytic hypochromic type. This, in conjunction with the usual finding of a very significant increase in feces urobilinogen, indicates not only an increased destruction of erythrocytes, but a disturbance or retardation of hemoglobin formation. An analogous situation is found in lead poisoning. Sixteen patients receiving sulfanilamide

developed jaundice. We have not observed jaundice in any patient to whom sulfapyridine was given. We regard jaundice as an indication of liver dysfunction. In addition to the jaundice, the Van den Bergh reaction was prompt or biphasic, and the serum bilirubin was elevated. Further evidence of liver dysfunction was the increased excretion of urobilinogen in the urine. Jaundice was not observed in any patient who received less than 3 grams of sulfanilamide a day. We have not encountered any patients where extensive liver damage due to sulfanilamide alone was the cause of death. However, four of our patients had serious hepatic injury because of infections, and we are certain that sulfanilamide therapy accentuated the process, and hastened a fatal outcome. We are very reluctant to give sulfanilamide to any one with jaundice, and have done so only in a few instances. For the most part, the liver dysfunction is only temporary, and returns to normal after sulfanilamide therapy has been stopped.

DR. E. N. COOK: We are all greatly interested in the opportunity to hear Dr. Long discuss the use of sulfanilamide and its derivatives in the field of chemotherapy. In the short time allotted to me today I wish to call your attention to the excellent results we have obtained in the use of sulfapyridine in the treatment of gonorrhea.

The usual gastro-intestinal upsets so frequently seen when this drug is administered are greatly diminished in our experience, because of the fact that in most cases we use only 45 grains daily, and by splitting the dose and giving it with milk each time these untoward reactions have been very infrequent.

We have used sulfapyridine in the treatment of the acute and chronic Neisserian infections with equal results. Almost always the discharge disappears in three to five days, and as soon as this takes place it has been our custom to begin local therapy, including massage of the prostate. With no other form of therapy have we seen such spectacular results as we have noted in patients suffering with gonorrhea who have been treated with sulfapyridine. In no instances have we seen blood dyscrasias, but on two or three occasions when giving a second course of the drug we have noted a dermatitis similar to that seen when sulfanilamide is administered. In

each case it cleared up rapidly upon discontinuing the sulfapyridine.

If the 45 grain dosage does not bring about the expected results in five days, we would advise increasing the dosage to 60 grains daily and continuing it for a period of seven to ten days in addition to the previous five days of therapy with the smaller dosage. English observers have stressed the importance and value of local therapy in conjunction with sulfapyridine by mouth.

DR. ERLING S. PLATOU: With the collaboration of Dr. Wallace Sako and Dr. Paul Dwan I have treated two hundred cases of scarlet fever with sulfanilamide at the Minneapolis General Hospital in the past two years. The drug was usually administered orally in initial doses of 0.05 grams per pound of body weight per twenty-four hours and maintenance doses of 0.03 gm. in twenty-four hours. The dosage was usually decreased but the drug was continued for an average of twelve days. In patients with nausea or severe toxemia we gave the drug subcutaneously in the form of the one per cent solution in sodium chloride. It is our impression that, per unit of weight, children tolerate the drug better than adults. With the exception of the development of leukopenia in two cases and fever and rash in two additional cases in which we were compelled to discontinue the use of the drug, no serious complications were encountered.

In 1938 we reported the results in 100 treated cases, compared with 100 control cases which were admitted to the hospital during the same period. In our treated cases the rate of recovery from the acute toxemic phase of the disease

(six days) was no more rapid than in the controls (six days). The patients treated with sulfanilamide did not show prompt subsidence of toxic symptoms such as we have observed following the administration of serum. However, in the cases treated with sulfanilamide the incidence of complications was only 8 per cent, as compared with 41 per cent in the control series. We believe that the best results were obtained when sulfanilamide was continued during the entire convalescent period and that early discontinuance of the drug was the cause of the appearance of complications in a few of our cases.

Since 1938 we have treated 100 additional cases with sulfanilamide, and the incidence of complications remained the same as in the previous series. During this period we have seen a number of rather severely complicated cases to whom physicians had given adequate dosage of sulfanilamide early in the disease only to discontinue it when the temperature reached normal. Continued therapy for at least twelve days has proved to be effective in preventing such eventualities.

Sulfanilamide also seems to have a prophylactic effect in preventing the development of scarlet fever. We have given therapeutic doses for seven days to ninety-four intimate "contacts." None of them developed scarlet fever but three developed severe cervical adenitis. None of the contacts who received both convalescent serum and adequate sulfanilamide treatment developed either scarlet fever or its complications, but we have seen seventeen cases of scarlet fever which developed after the prophylactic use of sulfanilamide in inadequate dosage.

CLINICAL ASPECTS OF THE VEGETATIVE NERVOUS SYSTEM

Chairman: DR. FRANK C. MANN

Professor of Experimental Medicine
The Mayo Foundation, Rochester, Minn.

Leader: WALTER B. CANNON

Professor of Physiology
Harvard University

DR. MANN: We are very fortunate in having with us as the leader of this discussion the man who has done probably the most of any other from the physiological standpoint, in giving a certain amount of basis for the clinician's viewpoint that the vegetative nervous system does have something to do with clinical medicine.

Now there are many titles by which I could introduce the leader of the discussion. I might introduce him as a home-town boy, because we are all happy to own him as a Minnesotan. I might also introduce him as the first roentgenologist, because historically that would be a true title to give him. However, I shall introduce him as I have always thought of him since the time I first entered physiology and studied the fine type of work he did on the pylorus and the use of the x-ray for visualizing the gastro-intestinal tract, namely, as the professor of physiology of Harvard University. Professor Cannon.

WALTER CANNON: I've had very little experience with round tables; I've seen round tables of various shapes; I think this is the strangest shape of a round table that I've ever come across. A round table, I presume, is given that name because it was expected that there would be a sort of family feeling among those who are gathered, and that the discussion would be an informal one.

In order that we may be reminded of the subject under discussion, I'm going to ask for the first lantern slide which will present a diagram of the autonomic system. Here are the central axis, the spinal cord, the cranial division above the medulla, the sacral division below the sacral enlargement of the cord, and the thoracico-lumbar divisions between the sacral and the brachial enlargements. On either side, of course, there are the chains of ganglia connected by the pre-ganglionic fibers with the spinal cord, and the post-ganglionic fibers reaching out to the nictitating membrane, to the heart, to the liver, to the stomach and intestines, and to the adrenal medulla which, as you know, produces a substance

DR. WALTER B. CANNON of Harvard University is the accepted dean of American physiologists. For the last forty-one years, ever since his first publication in the very first issue of the *American Journal of Physiology* in 1898, on the movements of the stomach as observed by means of Roentgen rays, Dr. Cannon has made outstanding contributions to physiology which have been of tremendous significance in the development of medicine, pharmacology, and psychology. His major interest has always been the influence of the autonomic nervous system on the functions of the organism, which has led him from control of the stomach through emotion, hunger, surgical shock, exercise, and homeostasis to his most recent achievement: the discovery of humoral transmission at the endings of the sympathetic nerves. This year he has been honored by his fellow scientists, who elected him president of the American Association for Advancement of Science.

imitating in its effects all the effects which are brought about by sympathetic nerve impulses. So we may regard this as a sympathal adrenal system.

Now we are to be concerned mainly today with the functions of this sympathal adrenal system in relation to clinical interests. You will find in a book by Miller, a rather large compendious work, these nerves referred to as layman's nerve as if they were absolutely necessary for life. The next lantern slide will show you a cat with her two kittens. Here she is with her paw lifted, her teeth showing, her ears back because a dog is barking at her; there's no hair rise here because the conveniences for hair rise are up here on the chart. This is the sympathetic system of this cat. Here are the two chains from the superior cervical sympathetic ganglion on either side, here down to this other ganglion in the upper part of the thorax, then the splanchnic coming off here to the celiac superior mesenteric ganglia and the sympathetic—and the abdominal chains reaching down to the pelvis. There is the possibility of these ganglia to some degree being omitted if the chains were taken out in piecemeal as in this case, so we devised the method of taking them out whole as the next lantern slide will show. Here are the two—here are chains taken out complete from the stellate ganglia high in the chest down to the rim of the pelvis. These are the splanchnics

coming off here. What inference can we draw from that situation? In the first place it proves that there is no danger to life.

In the next lantern slide is a cat from which the sympathetic system was removed entirely and this photograph was taken of the cat three years after the system had been taken out. There is no danger to existence in removal of any part of the sympathetic system because these experiments show it's possible to remove the entire system and individuals continue to live for an indefinite period. It is true not only of horizontal animals like the dog and the cat but also true of monkeys that take the upright position.

Furthermore, it is compatible with growth. This system is often spoken of as the vegetative system, and the implication there is that it is concerned with growth. We have, however, removed the system on one side from kittens and allowed them to grow to adulthood and then examined carefully various organs which are bilaterally symmetrical in size; and in those circumstances have not been able to find any difference on the two sides as a consequence of the absence of the sympathetic on one side and its presence on the other.

That's another point which can be made; it's quite possible that operations on the sympathetic might be done on young children and there'd be no danger doing that sort of operation because of fear that growth might be interfered with. It is not interfered with.

It is compatible with reproduction in the female, as the next lantern slide will show. Here is a bitch from which the sympathetic is removed and this is one of nine offspring. There is a rather infantile uterus as a consequence of removal; and there is a serious defect in lactation. This animal had a litter of nine puppies and this is the only one that survived; and it survived because it was particularly vigorous and by pressing and tugging and sucking it managed to get enough milk so that it lived to an age which allowed it to drink milk from a pan. The others all succumbed. The nipples of the dog were hard and dry and the only substance which could be got from them was a very thick creamy substance. As soon as this pup was able to drink milk the curve of growth which we had followed immediately began to rise sharply and it wasn't long before it had reached the usual growth curve of the growing dog.

Apparently when the sympathetic control of the blood vessels of the mammary gland is absent there is a failure of the blood vessels to dilate during nursing and therefore the fluid which is used to carry out the substantial part of the milk is not present and the young, therefore, do not get the nourishment which they should have. Operations on the thoracic part of the sympathetic are very likely to have serious effects so far as lactation is concerned. Then there is a defect which results when the sympathetic of the male is removed from the lower abdominal region.

Bacq, working in the Harvard laboratory, clearly showed that in rats and in rabbits the mating processes would occur in the male up to the point of ejaculation, and at this point there was failure, so the males were sterile. That observation was apparently not known by some surgeons and operations were performed which resulted in precisely that effect in human cases. A point which, of course, ought to be clearly kept in mind when the sympathetic system is interfered with.

It is quite possible to have the entire sympathetic system out of the picture and still have a fairly normal blood pressure. That was first shown by Bradford Cannon, my son, in the Harvard laboratory and later was confirmed by Phemister and collaborators in Chicago. The next lantern slide will show their record in which there was complete sympathectomy and you observe that after the final operation the blood pressure varied between 100 and 120 millimeters of mercury.

In a dog it is quite possible for the animal to exercise vigorously within a short time after the sympathetic has been removed without any serious fall of blood pressure. In a cat, this does not occur at once. The next lantern slide will show what happens; if there is struggle the blood pressure falls instead of rising. Here is a typical rise of blood pressure which accompanies vigorous muscular activities; but in the cat, there is a fall. The same thing happens in the dogs in the first week or so after removal of the sympathetic, but after that a recovery takes place and the animal may exhibit even the violent, vigorous actions of fighting with a perfectly normal dog without showing any signs of defect so far as blood pressure is concerned. This, of course, is if the entire sympathetic is removed.

I don't believe that there would be any serious interference with blood pressure in man on removal of a very considerable part of it.

Now there is another effect which is interestingly related to old clinical observations and that is the effect of the sensitization of the smooth muscle which is deprived of its sympathetic control. Here are the contractions of the nictitating membrane in response to various amounts of intravenous injections of adrenalin diluted 1 to 100,000. This is immediately after resection of the right cervical sympathetic and the removal of the left—the removal of the left ganglion here and the section of the right pre-ganglionic fibers above. At the end of fourteen days the same doses which previously produced these effects now produce these effects. You observe on the side from which the superior cervical ganglion was removed, the smooth muscle nictitating membrane of the cat gave a very much larger response than it did before and to a lesser degree there was a magnification of response on the other side where the preganglionic fibers had been severed. Now the superior cervical ganglion was removed on this side and fourteen days after the second operation, twenty-eight days after the beginning, you observe that there was a greater effect here, indicating a greater sensitization on that side.

The next lantern slide will bring out these same facts graphically. This is a course of sensitization of the smooth muscle of the nictitating membrane, with a consequence of removal of the post-ganglionic fibers, the direct innervation; and here is the effect of merely cutting the pre-ganglionic fibers, disconnecting the smooth muscles from the central nerve systems but still having it connected with the fibers coming out from the superior cervical ganglion.

Now, you observe that the results are similar to that produced by the ganglionic removal on the other side.

Now, that's a very important observation because of the fact that when an operation is done on the sympathetic there still remains the adrenal gland which I called your attention to earlier as the source of a substance which is capable of stimulating the smooth muscle which is affected by this adrenalin given off from the adrenal medulla.

There is a case on record that occurred at the Massachusetts General Hospital. A sur-

geon was very much interested in a patient, a woman, who had Raynaud's disease. He had removed the ganglia connected with the muscles that were in spasm and the contracted blood vessels of the fingers had changed from being blue, cold, and painful to a condition of being warm and pink, and comfortable. He took a lot of medical students, strange medical students, to the patient's room shortly thereafter, and with a good deal of dramatic vividness he described the operation which had been performed. And then in order to have a good show he swept down the coverlet to show this hand and there it was as blue and cold as it ever was. He was very much chagrined and went back to the office and told the tale. It happened that Norman Freeman, a young surgeon who had spent a couple of years in our physiological laboratory recognized the possibilities and suggested that he take another look. He went back and looked at the fingers and there they were nice and warm and pink again. Well, then they introduced into the veins of this patient adrenalin at the rate of its ordinary production in times of excitement, and the fingers turned blue; or if they gave insulin and caused a discharge of adrenalin from the adrenal medulla, again the blue, or cold condition appeared.

Now what the surgeons are doing at the present time is not to remove the ganglia directly connected with the smooth muscle of the blood vessels but they cut the pre-ganglionic fibers which run out from the central nervous system to the ganglia so that there is a separation of the muscles from the central nervous system, and there is not so great a sensitization of the smooth muscles to the circulating adrenalin.

Now from the experience which we've had in the laboratory, there is only one defect to that situation and that is the possibilities of regrowth. The pre-ganglionic fibers, as we've learned to call them, are cholinergic fibers; that is, they give off at their terminals acetylcholin and the post-ganglionic fibers to the blood vessels are adrenergic fibers and they give off at their endings adrenalin. You cannot connect adrenergic fibers to cholinergic fibers. You can, however, connect cholinergic fibers of any sort with any other. For instance, cholinergic fibers of skeletal muscle can be connected with these

ganglia and they will then operate. If, therefore, you disconnect the nerve of the smooth muscles by cutting the post-ganglionic fibers, the fibers beyond the ganglia, there is no possibility of regrowth. On the other hand, if you cut the pre-ganglionic fibers almost any other fiber in the neighborhood will make connections there and it is very characteristic of the ordinary pre-ganglionic fibers to make the connections which they've had previously.

Repeatedly, we have had occasion to note connections with the celiac ganglion and the upper part of the abdominal cavity after we've cut the splanchnic nerves and even cut out a considerable part of the splanchnic connection; and recently we've shown that the nerve fibers coming through the stellate up into the inferior cervical ganglion will regrow through several centimeters of empty space, even after efforts were made to prevent precisely that thing happening. That's something that ought to be looked into. This regrowth is so remarkable that it almost seems as though there were courses which the nerves took in spite of everything that you did to prevent regrowth taking place.

There's been a good deal of talk about periarterial sympathectomy; that is the possibility of removing sympathetic control of blood vessels by cutting through the outer layers of blood vessels. Along the length of the blood vessel there may be a slight enervation up and down but not to a great degree. The effect, therefore, when this is done is a local one.

Another matter of considerable interest, clinical interest, that's been brought out by operations in complete sympathectomy, is the differentiation between two types of hypertension. You've all become acquainted with the hypertension which is produced by the application of the Goldblatt clips reducing the amount of blood flow into the kidneys. Now that's a type of hypertension which is not affected by complete sympathectomy. Freeman, whose name I mentioned earlier, and Page have shown that after that sort of hypertension, you may call it renal hypertension, has been produced you can remove the entire sympathetic system without altering the hypertension to any degree whatever. Or you can take an animal like this dog that I showed you without any sympathetic system in it, and apply the Goldblatt clips and produce typical hypertension.

On the other hand, the next lantern slide will show that if the carotid sinus nerves are severed and the depressor nerve is cut there develops a hypertension, in this case running up from approximately 120 millimeters of mercury to the neighborhood of 300, a hypertension which persisted here, as you observe, for many months, for two years; when the entire sympathetic system was removed from this animal, the blood pressure came down as you observed to normal limits. So you must learn somehow to distinguish between hypertension of renal origin and hypertension of some other sort before having any rational occasion for operating.

There is no good evidence of sympathetic control of skeletal muscle. For some years operations were done on the sympathetic system in order to diminish the tone of skeletal muscle. That was done on the assumption that the sympathetic had an important effect in maintenance of muscular tones. Royal, whose name is associated with that interest, came to the laboratory and I presented him with an animal with the lower abdominal sympathetic removed on one side, and I said, "You test the knee jerks and tell me on which side the sympathetic has been removed," and he made the test and told me that he couldn't tell.

There's no better test than that, it seems to me, to show whether there is or is not a sympathetic control of muscular tone, and the test when put up to the person who has made the claim had such results that he couldn't tell the difference.

Then there is a further matter that ought to be perhaps considered in connection with a somewhat thoughtless removal of control of the adrenal glands. The adrenal glands are very important agents for liberation of sugar from the liver. We recently got evidence that it's only by the circulating adrenalin or by the substance given off from the liver or blood vessels, sympathin, that sugar is liberated from the liver. And if normal animals with a normal innervation of the adrenals are given insulin, this is usually per kilo, you observe that the convulsions from hypoglycemia occurred in only one instance and then after three and a half hours of endurance of the hypoglycemic condition which might result from the insulin injections. In animals with the adrenals inactivated, that is with the sympathetic supply severed on one side and the adrenal removed on the other, similar

doses of insulin, smaller in most instances, brought on convulsions in all but three instances and these convulsions occurred in the neighborhood of about an hour and a half after the insulin was injected.

Those are the main points which I would call to your attention from experimental observations on animals deprived of the sympathetic system and now I suppose the meeting is to be turned over to someone else.

DR. MANN: I should like to call on Dr. S. Marx White for discussion of the medical aspects of the problem.

DR. WHITE: To me Dr. Cannon's presentation is as those he has so many times made before, of extreme—not only importance, fundamentally—but interest. The clinician, of course, has no right to discuss the experimental side of this unless he makes himself an experimental physiologist, and yet the clinician must be something that many of us were, in my student days at least, a pseudo-physiologist. He must at least listen with a great deal of care to what the physiologist has to tell him.

Dr. Cannon's application of his study to the problem of hypertension, for instance, brings into the discussion one of the fields in which very active interest is manifested today, on the part of the physician and of the surgeon. Those of you who are interested in the development of our knowledge of hypertension, may recall a very interesting discussion which Volhard gave as long ago as ten years in discussing the different types of hypertension. And to me it is of extraordinary interest to see that the physiologist has brought out now by experimental work that Volhard had previously emphasized from inductive reasoning. Volhard, if you will remember, divided roughly, for the purposes of clinical discussion, hypertension into two groups which he divided into the red and the white hypertension.

Now I remind ourselves of that because to my mind it has a very interesting bearing on the problem that we are concerned with in medicine today, one of the problems of the possibility of effective surgical approach upon essential hypertension. If all this is true, and the application in animals and its analogies in man seem to make it so, then the usual surgical

attack on the malignant type of hypertension would seem to be directed at the wrong point; because there are many facts which make it probable that the malignant hypertension is a type in which a humoral mechanism has come into play, the arteries of the kidney having been involved up to the point where some substance, possibly elaborated in the kidney, possibly related to what some writers have called rennin, and what not—a humoral substance is elaborated. Dr. Cannon brings out the combinations that can be brought about by surgical operation. I remember having heard a few months ago of the experiments to which he has alluded by Anley and Herring; both produced a hypertension by ablation of the connections of the carotid sinus. They then caused a disappearance of this hypertension by removal, complete removal, of the sympathetic nervous mechanism and then followed this by the use of Goldblatt clamps and again produced hypertension; the conclusions of these writers, on the basis of accuracy of these experiments were that this form of hypertension at least, was humoral in origin. The kidneys possibly are the source.

If all this is true, and there is much to make us believe that it is so, then if we are to indulge in an attack on the problem of hypertension from the surgical standpoint, it drives us back to the surgery of the benign, so-called essential, benign hypertension. Many of us physicians believe that such an attack as that is probably unnecessary but it may be that we'll come to just such an attack as that; but for the present it seems to me that our attack is probably along the line of teaching these individuals the proper adaptation to their environment from the affective, so-called emotional, side.

Now if I have a minute, there is one other reference that I would like to make, and that is to a part of the autonomic mechanism to which Dr. Cannon has not addressed himself—and that is to the carotid sinus as a pit of this autonomic mechanism. The knowledge that has been acquired of the means, the modes, by which the carotid sinus can be stimulated has added very greatly to our means of diagnosis in heart diseases. The recognition of certain types of syncope in which there may be slowing even to asystole on the part of the ventricles, dropping blood pressure or some form of cere-

bral reflex which causes syncope, and our knowledge along this line, too, enables us to recognize these cases. We can by stimulation of the carotid sinus, under the finger, reproduce the symptoms and in certain cases where the malady is severe enough, the carotid sinus can be disconnected. But also our knowledge of the effects of the carotid sinus as a part of this regulatory mechanism aids us very greatly in that we can in many instances abate tachycardia and can help often in the diagnosis in the type of mechanism that is occurring not only with but without electro-cardiographic recording. I am just mentioning these very few brief points concerning the knowledge of the autonomic mechanism so marvelously brought out by the physiologists in recent years which aid us in medicine.

DR. MANN: Professor Visscher will now discuss some of the less appreciated results of activities of the vegetative nervous system.

DR. VISSCHER: When Dr. Mann first asked me whether I would contribute to this round table discussion I hesitated a number of days because I felt it would be presumptuous on my part to suggest that I could really contribute anything worthwhile. On considering the question a little further, it occurred to me that there were some points in which the autonomic nervous system had come into some of our observations on aspects of physiology that would not seem to be immediately connected with that subject; and I have rather surmised that those who are experts in the field of autonomic nerve physiology would probably slip over, or at least not be as concerned with these mechanisms, as some of us who look upon the autonomic nervous system as something less than our major interest. It occurred to me on considering the things I've been interested in the last few years, in which some autonomic nerve effects have come into the picture, that I might profitably refer to one or two of them. In view of the time, I shall refer to only one.

In studying the process of absorption from the small intestine, we've been interested in the ability of the intestine to move substances against concentration gradients, placing solutions of mixtures of sodium sulphate and sodium chloride, in isotonic solution in the gut. Over the period of a very few minutes, fifteen

to thirty in the waking dog with surgically prepared loops, the sodium chloride concentration in these loops will fall to very low values—perhaps one per cent or just a few per cent of the blood levels for these constituents. Dr. Dennis made the very interesting observation, it seems to me, that a few dogs on whom these surgically prepared loops were made just simply did not show absorption from the intestine when they were made to lie on the table, quietly, without being tied down, and that, instead, the volume of fluid in the loops of intestine, these surgically prepared loops, increased. Well, now to make a very long story short, we anesthetized these dogs and found under anesthesia their intestinal loops absorbed fluid just as well as other dogs. And it came out that these were dogs that were very excitable. On inspection of the mucosa of the exposed loops we found that when they were placed on the observation tables the mucosa was blanched and white and obviously there was diminished or perhaps very little blood flow. It was an emotional reaction probably mediated by autonomic nerves, and if we had more time I should like to ask Professor Cannon some questions on this point but I shall not do so because there are two people who must have some time on this round table program.

I would like to make this observation, however, which comes out of my thinking in connection with talking to this group—that there are undoubtedly very many physiological reactions in the carrying out of which we cannot afford to ignore the importance of the autonomic nervous system in the real life situation. When one sees in such a simple matter as the absorption of water and salt from the intestine, the effect of the sympathetic nerve stimulation, which was undoubtedly the mechanism in this case, it cannot be doubted that more complicated processes that are going on in the alimentary tract are likewise involved. We know they're involved, of course, and this happens to be simply a very striking demonstration of that involvement.

DR. MANN: Some of the more recent clinical work on the subject will be discussed by Dr. B. T. Horton.

DR. HORTON: Dr. Mann, Dr. Cannon, ladies and gentlemen, As I listened to Dr. Cannon's

presentation, I could not help but think of a saying which I learned in high school that comes from Shakespeare, many of you will remember it, when I quote it: "There are more things in heaven and earth, Horatio, than is dreamt in our philosophy." And I have a feeling that there are more signs and symptoms in clinical medicine and surgery produced by the autonomic nervous system than have yet been recorded in our textbooks and in our medical journals. I could not help but wonder as Dr. Cannon showed the picture of his cats without a sympathetic nervous system what the human individual would do or how he would behave if the sympathetic nervous system were removed. Certainly I think from a standpoint of Raynaud's disease that that disease would cease to exist.

Not long ago I saw a patient who developed Raynaud's disease in this particular climate, some twenty-odd years ago. She moved to the Canal Zone and lived there for twenty-odd years and the Raynaud's disease ceased to exist; she came back to this country, to this section, not many months ago; the Raynaud's disease reappeared and she came into the clinic and Dr. Adson operated on her, and relieved that condition.

From the standpoint of our other peripheral vascular diseases, particularly thrombo-angiitis obliterans, it's quite obvious that patients would be much better off, and we would have fewer amputations, if the sympathetic innervation to the involved extremities, was completely interrupted. And as a matter of fact our statistics show, and of this Dr. Adson is well aware, that after sympathectomy for thrombo-angiitis obliterans our percentage of amputations is considerably less than that of the unoperated cases. There are many other phases of this subject which I would like to discuss but time does not permit.

DR. MANN: We have a few more minutes left before it is necessary to go to the other meeting. Who will very quickly keep on with this discussion, so that we will have no delay and these precious minutes will not be lost? If no one responds I am going to call on someone to continue the discussion. All right, Dr. Best, have you anything to say on the subject?

DR. C. H. BEST: I wouldn't like to let you down but I really haven't anything to say except

that I was very much interested in Professor Cannon's remarks. It seems that almost every laboratory in the country is taking keen interest in hypertension. One shouldn't always refer to things going on in one's own laboratory but a portion of it comes to mind. Two of my colleagues have worked out a very convincing demonstration of the fact that some humoral substance does appear in these hypertensive animals, the Goldblatt hypertension, which can be transmitted to normal animals. Some evidence of this was, of course, brought forward by Housay and his collaborators and also by others. But by means of what we've called exchange transfusions, by a pump which will interchange at the rate of 20 or 30 liters an hour blood from one animal to the other, and yet not interfere with the blood volume of either, it's possible to show that this substance can be transferred from a hypertensive animal to a normal one and a very significant rise of pressure occurs in the unoperated animal. Instead of using the Goldblatt clamps, which of course are very efficient, it's equally satisfactory just to take out one kidney and put a plaster of Paris cast on the other, to prevent the compensatory hypertrophy, and tremendous hypertension, of course, develops very rapidly. Then when these dogs are joined, it's really just a transfusion of equal volumes both ways, the hypertensive effect becomes immediately apparent in the recipient.

DR. MANN: The surgical phase of our subject will be discussed by Dr. A. W. Adson.

DR. ADSON: I think we're very fortunate in having Dr. Cannon here today to give us his summary of his physiological experimentation on the autonomic nervous system, because it is apparent that there are a number of diseases that result from abnormal conditions of the sympathetic nervous system. And as a clinician and surgeon I've been very much interested in this problem for a number of years. All of you are familiar with the fact that Leriche suggested that by periarterial sympathectomy you might alter the vasomotor tone of the peripheral arteries. But as Dr. Cannon told you in his address, it is apparent that the nerve supply follows the artery for but a short distance, and that new fibers enter the sheath of the artery at corresponding levels, and this fact has led

to some of the more or less radical sympathectomies with the hope perhaps that we may alter the spasticity that does exist and is responsible for such diseases as Raynaud's and other allied peripheral vascular diseases where vasospasm plays a role.

Shortly after Royle advocated ramus section, I attempted to reproduce the same result in the hope of relieving spastic conditions. Instead we learned that an extensive lumbar sympathectomy, removing the trunks and dividing the rami, produced a vasomotor change apparently permanent; we then applied it to Raynaud's disease. This was done first in 1925, and that same person today is completely relieved of a Raynaud's disease affecting toes and feet and in the lower part of the legs. But when we began to attempt to treat the conditions of the hands, we met with some difficulty and some disappointments. Apparently the distribution to the arteries of the hands and fingers is somewhat more complicated than is the distribution of the lumbar group which supplies ultimately the vessels of the toes and feet.

At the present time, there's some argument as to whether or not we should divide the pre-ganglionic rather than post-ganglionic fibers. I think I can state very definitely because we've had quite an extensive experience, and speak this fact—that from our own experience, it would appear that the thoroughness of the operation plays a much larger role than the mere question of pre- or post-ganglionic section. At the present time there are some operations that have been advocated which consist of dividing the trunk of the thoracic chain below the third thoracic sympathetic ganglion with an avulsion or division of the rami to the second and first. We have tried this operation and find that we have not obliterated all of the vasospasms. Therefore, in reviewing our own cases, it is ap-

parent that if we can carry out a thorough interruption of all of the vasomotor fibers whether they're pre- or post-ganglionic to the hands, a permanent vasodilatation takes place, and we have many patients who have been very carefully studied before and after operation, years afterward, to substantiate this statement. So that this work in which Dr. Cannon has been a pioneer I am sure will contribute more and more as time goes on in the control of these various diseases.

Time does not suffice to take up a discussion of hypertension in which I've been very much interested and shall discuss tomorrow, except to say that my first stimulus came from the fact that when a spinal anesthetic was given to a patient for some abdominal or perineal operation, a drop in blood pressure always developed. And in the early history of spinal anesthesia this drop in pressure was a serious situation. As I watched these hypotensions, it occurred to me that if it would be possible to rob a vascular bed of sufficient size, of its central influence we might create a reservoir and reproduce the same changes that took place when you administered a spinal anesthetic. And naturally our first method was to do a laminectomy and divide the anterior roots from the sixth dorsal to the second lumbar inclusive on both sides.

That operation is a rather heroic procedure and has been altered. I shall be pleased to review tomorrow our experiences, our successes, our failures; but I want to emphasize one point whether you are attempting to treat Raynaud's disease or peripheral vascular disease or hypertension, the only ones that you can hope to alter are those patients who present a vasospastic phenomenon. And above all, select patients in whom there is some likelihood of securing the results you desire to accomplish.

CLINICAL PHYSIOLOGY OF THE GASTRO-INTESTINAL TRACT

Chairman: DR. OWEN H. WANGENSTEEN

Professor of Surgery

University of Minnesota

Leader: DR. ANTON J. CARLSON

Professor of Physiology

University of Chicago

DR. WANGENSTEEN: We are celebrating now the Fiftieth Anniversary of the establishment of this medical school. In that original group of teachers at this school the only full-time preceptor was the professor of chemistry, who in all likelihood was an adjunct from the department of chemistry. Whereas throughout the country, schools boasted men who professed an interest in physiology, there were very few departments of physiology. At the invitation of President Eliot of Harvard, Bowditch organized the first department of physiology in a medical school in this country in 1871.

In the last two decades there has been a general pyramiding of interest in functional studies. Yet, today, physiology in the ordinary curriculum does not have assigned it the number of hours which the importance of the field justifies. The apparent lack of interest on the part of the clinician in clinical physiology has probably been due in no small part to his inadequate orientation obtained in the subject while an undergraduate medical student. However, the interest of the clinician in physiology is being augmented daily by observations in the wards which show the great importance of physiology for the practice of medicine. Those who concern themselves with disturbances of the alimentary canal have the opportunity to observe daily the necessity of employing physiologic approaches to the solution of gastro-intestinal problems.

On the part of physiologists who term themselves general physiologists there have been many who have given the alimentary canal and its appendages their best thought. The leader of this discussion is, amongst that group, one of the keenest exponents of the physiology of the intestinal canal. It was in this Northwest Territory that William Beaumont, now somewhat more than a century ago, made one of the most important and original contributions to the understanding of digestion that has ever been made. Our speaker too has had his Alexis St. Martin and, together with his pupils, has contributed a great deal to a better understanding of the physiology of gastric secretion.

DR. ANTON J. CARLSON is at present Professor of Physiology and Chairman of that Department at the University of Chicago. Doctor Carlson was born in Sweden and came to America at the age of sixteen. He had his early training at Augustana College and after an interval began his scientific studies at Stanford University in California where he earned the Doctor of Philosophy degree. Aside from a brief interval in 1904 when he was engaged in research at the Carnegie Institute he has spent his whole scientific life at the University of Chicago, where he has had a profound influence on educational and research policies and where he has carried on his scientific work.

Doctor Carlson's studies have dealt mainly with the physiology of the digestive system and of the endocrine glands. He has studied the physiology of hunger and appetite and provided much important information about such disease states as gastric ulcer. He has had a great influence on American physiology through many students who have been trained under him and who now hold important positions in other American universities and research institutions. His students hold professorships in about twenty other American universities.

There are many clinical problems in the gastro-intestinal canal that will be more readily understood when gaps in our knowledge of the normal function of the alimentary canal are less numerous. What specific theme Dr. Carlson has chosen for this discussion, I do not know. The title affords him unusual latitude. Clinicians interested in gastro-intestinal disorders are happy that general physiologists of the stamp of Dr. Carlson interest themselves in these problems. Confronted with the enigmas of etiology and the baffling problems of therapeutics presented by such conditions as ulcer, appendicitis, constipation, bowel obstruction, and deficiency diseases having their origin in malfunctioning of the digestive tract, like the Apostle Paul, the clinicians cry out to the physiologists, "Come over into Macedonia and help us." It affords me great pleasure to present to you Dr. A. J. Carlson, Professor of Physiology at the University of Chicago, whom all of you know. Dr. Carlson will take over the reins of the discussion.

DR. CARLSON: The clinical physiology of the gastro-intestinal tract obviously can not be discussed adequately in an hour's time. The cardia, the pylorus, the stomach, intestinal peristalsis

and paralytic ileus, and the large bowel alone—any one of these could not be exhausted in such a discussion.

The logical man to open this discussion is Dr. Cannon of Harvard who did the earliest significant work on the gut with the x-ray. Dr. Cannon also was the first to establish the motility of the empty stomach in connection with hunger. I first became specially interested in the alimentary tract years ago partly because I had an "Alexis St. Martin," and some of the work on motility and secretion of the stomach in normal man was followed out, of course, on animals.

For the last five or six years my students and I have been interested in problems of the large bowel, so far confining these studies to the dog. In beginning this discussion I just don't know where to start. It remains to be seen if I know when to stop. The best way would be for the clinicians to take charge of the discussion entirely, while I listened. Perhaps my experience might throw some light on the difficult scene. Many of these problems are still in the "No Man's Land."

Take the motility problem alone. We have now pretty well explored the action of the efferent extrinsic nerves of the gastro-intestinal tract. We have two types of nerve action: one producing increased motility or increased tone, the other producing inhibition, by direct action or by liberation of choline or of sympathin. This seems very uniform in man and the animals. But in the experimental animal the effect of loss of action of these nerves produces but slight and temporary effects. Section of the nerves may produce a temporary disturbance in motility of the stomach, but it is astonishing how quickly the stomach, pylorus, large and small intestine adjust themselves and carry on the work very well. One puzzle to me in regard to the large bowel is this: the removal of all extrinsic nervous control of the gut in animals like the dog produces far less disturbance of the large bowel than section or crushing of the spinal cord in the thoracic or lumbar region in man. Important as is the study of these nervous relationships to motility of the large intestine in the dog, cat, rabbit, rat, we shall undoubtedly find species variation in the capacity of adjustment. Those of you who are bald-headed and gray will recall the old days of

gastro-enterology when our main problem was "dyspepsia" and the universal remedy was pepsin and hydrochloric acid. "Dyspepsia" has disappeared, I hope, even from the prairies of Minnesota and I don't know how many tons of pepsin and hydrochloric acid were administered while this theory was green. I can see very well how hydrochloric acid can be useful under certain circumstances but the astonishing thing to me has been the ability of the human gut to adjust itself with little or no gastric digestion going on, as is well known in the chronic case of achlorhydria, apparently from early childhood, if not from birth, and with fair intestinal digestion still taking place.

Then came the period of "autointoxication," the period of Metchnikof. I don't know what you think of autointoxication as the universal cause of human ills, but I am quite certain it is overdrawn. I can give you an instance in my own experience, discovered by accident. In the early days when yeast was supposed to be the "cure" of many gastro-intestinal ills, I was asked to make a study on the effects of yeast on alimentary function in man. I did it on some hundred medical students, men and women. One medical student, an ex Texas cowboy, proved to have on the average, one to one and a half bowel movements per week. He was a boy between twenty-three and twenty-four. When I saw his record I thought he must be either dying or half dead. He really did have only one and a half bowel movements per week but he was perfectly healthy, with no evidence of autointoxication. I am perfectly certain that if the other students had done something to suddenly delay their large bowel evacuation for four or five days they would have had all kinds of trouble, headache and malaise. If changes come on gradually, apparently there are capacities for adjustment to distension without disturbance and possibly even capacities for diminished absorption of toxic substance.

Now, so far as the extrinsic gastro-intestinal nerves are concerned, the local motor and secretory tissues carry on without them through chemical factors. It doesn't mean at all that when these nerves are present and active they cannot under certain conditions produce serious motor and secretory disturbances. In other words, the fact that the gut can carry on without the extrinsic nerves doesn't mean that these

nerves can be forgotten when the doctor is confronted by his patient.

A great many chemical factors have been assigned the role of motor control of the gut, particularly acetylcholine. I haven't yet seen any experiments that are conclusive enough to demonstrate to me that we have yet put our finger on a specific motor hormone of the gut as a whole. But we have a specific hormone aiding in the motor control of the gallbladder, and the depression of gastric motility by fats appears to be due to a hormone developed by the gastro-intestinal mucosa when acted on by these fats.

We have become rather interested in the cause of the partial to complete suppression of the gut motility in peritonitis. There are apparently reflex mechanisms, from the peritoneum through the central nervous system, to explain this paralysis of the gut on reflex grounds. I am inclined to think that, even with all the extrinsic gut nerves eliminated and central reflexes gone, motor paralysis of the gut by direct action or toxic bacterial products or acting by local reflexes in the gut, may still occur. Certainly bacterial toxins intravenously administered in the dog will cause total paralysis of the motility of the colon at least for twenty-four hours but we have not yet totally denervated the whole length of the gut.

I don't think the problems of secretion of bile, pancreatic juice or of gastric juice are of primary clinical significance except, possibly, with ulcers. It is remarkable, if other factors are right, how much one can suppress pancreatic secretions and gastric secretions without causing symptoms (at least in the experimental animal).

In the early years I was interested in the sensitivity of the gut in connection with the problems of pain, hunger, and thirst. There is no doubt that dull pain or even acute pain can be produced through naked nerve endings in the wall of the gut. These pain nerves may be activated either by muscular spasm or by distention, as by gas or fluid, yet one can have spasms without producing conscious pain both of the cardia and the pylorus. I haven't seen any evidence that the pyloric spasm of infants, sometimes called hypertrophic pyloric stenosis, is especially painful.

However, there is a still bigger problem on

which I have not seen any way of getting on. The reason is that you can't do very much with it on the experimental animal. It is this: the change in the efferent stream of impulses from the gut that leads to the depression which we see where there is disturbance of the normal gastro-intestinal mucosa plus possibly some disturbance of motility. That disturbance of the general state of consciousness seems to me out of all proportion frequently to the extent of the mucosal lesions or degree of the disturbance of motility that we find. This is one of the large terra incognita in the pathological physiology of the gut.

I am afraid I don't take my own medicine. I really should have sat down and let the clinicians question me. I may have gathered some insight through years of labor. At least I have learned to observe my own gut. I think that early observations of Cannon on the cat still apply to dog and man. I know it applies to me. I was in the midst of the study on motility of the empty stomach in man, and attempted to demonstrate some of the new findings to members of the Physiological Congress in Holland. To be sure that my stomach was empty I begged off from dinner with Professor Hamburger the evening before. I knew we were not only to be dined but wined as well and I didn't know what condition my gut would be in the next morning. My stomach was empty and I thought everything was all right and when I got the balloon in, with physiologists standing around, all I demonstrated was a perfectly flat line on the kymograph with complete gastric inhibition. Pavlov remarked: "This is also a physiological demonstration," which was perfectly true.

Dr. Wangensteen, when a physiologist follows the rabbit and a gastro-enterologist follows the rabbit they invariably meet because the machinery in health also figures in disease. I have lately been concerned with a chapter in a projected book. The chapter is on the criteria of normalcy. Normalcy is not a line but it is a broad band and it is in that broad band where the physiologist and the gastro-enterologist who does something else than worship the follies of the best, will invariably meet.

DR. WANGENSTEEN: Dr. Walter Alvarez has been particularly interested in the influence of the autonomic nervous system upon the digestive tract. Dr. Carlson's remarks, I am cer-

tain, have stirred up in Dr. Alvarez some interesting experiences that he would like to comment upon now.

DR. ALVAREZ: As clinicians we are interested in the colon when it doesn't do its work, or when it does it too thoroughly and too vigorously. So often we hear that constipation should be divided into two great groups, those in which the colon is either atonic and those in which it is hyperactive and spastic. My feeling is that the colon would always be strong enough to do its work if the nervous system would only leave it alone. Many of you here must have had experiences which showed you that constipation is primarily a nervous disease. For instance, I know a woman whose bowels moved regularly twice a day until years ago she contracted an unhappy marriage. She immediately became severely constipated and started going from one physician to another. After many years of this she fell in love with another man, and with the coming of happiness she lost her constipation and the resultant indigestion and headache.

An old physician once told me about a rancher's wife who came a long distance over mountain roads to consult him in regard to severe constipation. Because static electricity was popular in that day, the doctor put an electrode into the woman's rectum and gave her twenty minutes of sparks. She wrote later that she was entirely cured and very happy. A few years later when she returned for another treatment, the doctor had lost interest in static electricity and his friction machine was not running. The woman, however, wouldn't be put off. The doctor tried his wall plate, but that too was dead. Then he found the metronome would still run so he connected her up and gave her twenty minutes of "tic tocks." To his astonishment she reported later that this had cured her, and then he knew that she had a psychic type of constipation.

I know that in my own case a bowel which is as regular as a clock when I am on a vacation can become constipated when I am under strain and fatigue from overwork. I can remember times when I became constipated suddenly because of worry over the illness of one of my children.

We all know that in many persons the colon

is very sensitive to emotion. We have all seen patients who developed diarrhea when anxious or worried or frightened. Many of the diarrheas which I see are due at least partly to a congenital tendency to the emptying of the colon under excitement. This tendency is very marked in the apes and the monkeys. Whenever a physician cannot find a physical cause for diarrhea he should make certain that the patient isn't worrying over a lawsuit or an impending divorce.

One of my patients one day said, so wisely, "Doctor, if I could only be worried to the right degree my bowels would be perfect. If I worry a little they get constipated, and if I worry much they get loose." I have known many persons who have diarrhea all day when they are going to take a train in the evening. I have known many girls who couldn't go out with a beau without getting diarrhea or being much frightened for fear that they would get it.

You clinicians know that one of your greatest problems is that of the woman with a sensitive colon. I beg of you not to tell her that she has colitis simply because her roentgenograms show a spastically contracted descending colon with perhaps a little crinkliness on the edges due to spasm. There are two reasons why we shouldn't tell these people that they have colitis. One is that we all know they haven't a true colitis. If one opens the abdomen one finds a perfectly normal looking colon, and if one looks through a tube into the sigmoid loop one sees a normal mucosa. Furthermore, these people, even if they live into their eighties, never come to any bad end because of their sensitive colon and their excessive secretion of mucus.

The other tremendous objection to telling these women that they have colitis is that the victim will promptly ask her friends if anyone knows anything about colitis, and then if someone speaks up and says, "Why yes, my brother had chronic ulcerative colitis and he was dead in six months," the patient becomes scared to death, and then no amount of reassurance may ever straighten her out again.

I tell these patients that they have a highly sensitive colon which they inherited from their ancestors. They will have it all their days and they must learn to live with it. It will become

less sensitive as they grow older. I tell them it would be a perfectly good colon if only their nerves could leave it alone.

Today we realize that when autonomic nerves are stimulated, chemical substances, which have powerful effects on smooth muscle and glands, come out of the endings. Interestingly, when Dr. Chester Jones and one of his associates took some normal students and injected them with acetylcholine, the substance which is formed at parasympathetic nerve endings, he could see through a sigmoidoscope that the mucous membrane changed in appearance, and mucus and fluid came out of it. Interestingly also, one day when Dr. Jones called an artist to make a water color drawing of the appearance of the mucosa, the student happened to glance up, and when he saw a pretty girl looking into his rectum, he blushed violently all over the inside of his bowel!

I have long felt almost certain that such changes in the circulation of the bowel must take place under emotion, and they must account for some of the sudden attacks of flatulence and bloating which are suffered by nervous people. Years ago Sinelnikoff transplanted a segment of jejunum under the skin of the thorax, preparatory to making an artificial esophagus for a patient. He could see then that under the influence of emotion the mucosa changed from a dull pink to red. Similar changes were observed by Beaumont when he looked into the stomach of Alexis St. Martin.

Years ago the question occurred to me, Why is it that the colon is so much more reactive to emotion than is the rest of the digestive tract? Then as I thought a little more, I said to myself, "No, the esophagus at the other end is perhaps even more responsive to emotion." The other night I sat in the theater alongside of a man who suddenly, when the hero of the play got into an extremely dangerous and unpleasant situation, began to belch repeatedly and apparently painfully. He obviously was almost strangled by the waves which, because of his excitement, began to run back up his esophagus. How many of us physicians there are who have "the burps" and heartburn all afternoon simply because we took guests to the club for luncheon. We wouldn't have had any distress if we had eaten quietly by ourselves at home.

It seems to me that the reason why the two

ends of the digestive tract are so reactive to emotion and nervous strain is that they are most influenced by the spread of impulses from the somatic nerves, which come close to the autonomic ones at the orifices of the body. Clinically, then, whenever we see a woman with a tale of woe about a sensitive colon that hurts and burns and won't empty itself right, let us first have great sympathy for her because her distress is very real. I know it is real, because my mother bequeathed me such a colon, and occasionally under heavy psychic strain I have suffered the same type of constant torture that these patients so often describe. When a woman tells you that she takes two or three enemas a day to try to get relief from a constant burning and consciousness of her rectum, don't sneer at her and don't get angry at her. I assure you that if you had the same distress you would soon be nearly frantic, and if you could get relief from frequent enemas, you would take them.

I beg of you also that when such a woman comes you do not tell her immediately that she has a redundant colon or a spastic colon or a long sigmoid loop or some other common and harmless anatomic variant that she can worry herself sick about. Usually I have to x-ray the colon of such a woman once or twice simply to help get rid of a fear which, with the best of intentions, someone implanted in her mind. Often she says, "But Dr. So-and-So told me that I had a long sigmoid loop. What are we going to do about it?" And then sometimes I remind her that my cook is four feet ten and my son-in-law is six feet five. Are they diseased? No, neither of them is diseased; they are both very healthy, normal persons. They simply represent varieties of the human species. Similarly, the woman's colonic peculiarity does not represent disease and is not responsible for her many aches and pains or even for her constipation. As you know, colons come in all shapes and sizes, and you can find all these shapes and sizes in the big husky members of your football squad here at college.

Furthermore, I would suggest that you not try to treat a sensitive colon with medicated enemas and diets and attempts to change the bacterial flora. The best results that I have ever seen have been obtained by finding out what sort of strain the woman is under. Find out why she is

unhappy and worried, and then try to help her to live more sensibly, to get more rest, and to live with her sensitive bowel. Many of these women can be greatly helped in this way. Occasionally, when the colon is burning and "raising Cain" a quarter of a grain of codein will bring peace and comfort. I don't think it is dangerous to prescribe this drug for sensible persons who will use it only occasionally. In thirty years I have never seen a habit produced by codein. I don't like the present day common practice of filling these poor people with phenobarbital. Sometimes it helps a great deal, but then it should be used intermittently and only on "bad days."

DR. WANGENSTEEN: Method is as important as an idea in the solution of a problem. There are many who have had an excellent idea who have failed in their objective because of want of a proper approach or technic with which to attack their problem. When a man with good, original ideas possesses as well, mastery of technical methods, worthwhile contributions follow as a matter of course. Dr. George H. Whipple, who is in the audience, made an abiding contribution to the knowledge of intestinal obstruction when he devised the "closed-loop" method of studying the effects of obstruction. I am wondering whether Dr. Whipple will not, on this occasion, say something of his first scientific love—intestinal obstruction.

DR. WHIPPLE: I came here today to listen and have enjoyed the discussion very much, and particularly this opportunity of chatting with my old friend, Dr. Alvarez. It is so long since I worked with the subject of bowel obstruction that I should prefer to remain one of the audience.

DR. CARLSON: I, of course, followed Whipple's pioneering work and some work was done in my laboratory upon the machinery inducing the symptoms of bowel obstruction. The problem is not completely solved yet, but I ought to add a little to what Dr. Alvarez said. There is no doubt that those conditions he described are in the main correct. I can verify some of them on my own person. But here is the puzzle that there are any number of people, men and women, who are under equal or greater strain and they don't show gut disturbances. Where is the differential?

DR. ALVAREZ: May I mention you said once that you hoped that day might come when you could cut your systemic nerves and go about your work in peace and quiet?

DR. CARLSON: The trouble is I delayed too long; now we know perfectly well we would have to cut the whole mess.

DR. WANGENSTEEN: As most of you know, Dr. Edward A. Boyden of the department of anatomy in this school has been very much interested in the mode of origin and transmission of painful stimuli having their origin in the intestine. Dr. Carlson's discussion of visceral pain has undoubtedly brought to Dr. Boyden's mind some things upon which he would like to comment.

DR. BOYDEN: Visceral pain is a large subject and one that I would not venture to discuss in this short time. But while listening to Dr. Carlson and Dr. Alvarez I have been impressed by the attention given to the action of extrinsic nerves upon the colon. I should like to ask Dr. Carlson to discuss the reverse effects—what is known about the action of nerves from the colon upon the rest of the body, as, for example, the effect of distention of the colon upon the secretion of bile. Perhaps, also, he would tell us something about the hormones secreted by the large intestine?

DR. CARLSON: There is no difficulty of showing, of course, that distention of the colon through stimulation of sensory nerves in the colon will induce many kinds of reflexes. So far, we have done it only on experimental animals. I did some of it years ago when I started this work on visceral sensibility. But in any individual human patient, it is going to be difficult to say whether the gas, distention, or spasm is the cause of pain that leads to disturbance in the body. Of course, these are "hormone days" and I have, I think, unfortunately assumed some, or labeled some in connection with the gut, prematurely, in past years. I don't know whether we have real hormones from the large bowel or not; it is going to be very difficult to prove or disprove it, in my judgment. Certainly by the exclusion method, by the removal of the entire large bowel, no defects are produced that have so far been detected, mainly because it is just

one factory of the hormones and some are produced somewhere else. In other words, the method of extirpation, which works in the case of parathyroids, anterior pituitary, etc., is of little value here. Concerning hormones which govern gut motility in health and in disease, it seems to me that on that subject we are where we were forty years ago when we started to study the effects of intravenous injection of crude tissue extracts on the blood pressure. This was before the discovery of adrenalin and of pituitrin. Many actions may be induced by parenteral administration of crude extracts, in acute experiments. But it is another story to prove that the substances responsible for such actions in acute and crude experiments are also produced in the body as part of the machinery of health and of disease. Have I been sufficiently vague, Dr. Boyden? In that case, come again.

DR. LEO G. RIGLER: For many years we have heard roentgenologists discuss the observations of Forssell anent the independent movements of the mucous membrane of the digestive tract, but physiologists appear to have given his theories scant attention. Forssell believes that the mucous membrane of the stomach moves freely and without reference to the remaining segments of the gastric wall. Furthermore, he believes this results in the formation of small, independent digestion chambers. I should like to hear Dr. Carlson's comments on the validity and importance of these theories.

DR. CARLSON: I am quite familiar with the apparently independent motility of the intestinal villi, following the work of my pupil, Dr. King, now at Vanderbilt. In some species these villi are not present in the intestinal mucosa. When present, they seem to move quite independently of the neuromuscular machinery of peristalsis. Certainly the villi are absent from the stomach. Mucosal motility in the stomach must be governed by the muscularis mucosa, because there is no other machinery. There is nothing to suggest the gastric mucosa has ameboid power. But anybody who has studied the swaying and pumping action of the intestinal villi will realize that where present the villi are a physiological mechanism of the first order.

DR. JAMES B. CAREY: The explanation of gastric pain with respect to the lesion involved

has always interested me, particularly since I have been doing gastroscopic work. It isn't hard for me to explain, very crudely perhaps, the occurrence of gastric pain, given a deep indurated ulcer involving all of the layers of the stomach; but when I visualize with the gastroscope what seem to be insignificant punctate submucous erosions or a condition of atrophy of the mucosa or single submucosal hemorrhages, it is difficult to reconcile the complaint with the lesion. Some of these people complain quite bitterly of pain, comparable to that of an ulcer; on the other hand, individuals with objectively extensive lesions have no pain at all.

Dr. Schindler has mentioned numerous times that he has noted the occurrence of pain of severity equal to that of ulcer, the only explanation he could find being one or more submucosal hemorrhages in the stomach. I can't imagine such a condition enduring more than a few days. On the other hand, one of the most extensive hemorrhagic ulcerative gastritis patients that I ever saw (probably secondary to a cirrhosis of the liver), involving the upper third of the stomach, observed gastroscopically on three different occasions, each time presenting the same hemorrhagic eroded condition, was accompanied by no symptoms referable to the stomach at all.

Certainly the relation between the visible changes in the mucosa and submucosa and the symptomatology puzzles me very much. For that reason it has been so very difficult to arrange a symptomatological picture for gastritis.

DR. CARLSON: Well, I don't know either but maybe in the future some of these puzzles which I have been seeing and hearing about during thirty years of attention to the problem will clear up by better experiments and clearer thinking. The great individuality and chameleon-like character of the gut is obvious. Early I ran up against this fact. In some perfectly healthy individuals powerful contractions of the stomach, the hunger contractions, produce no sensations. On the other hand, in other individuals, more or less nervous, the same degree of gastric contractions will call forth agony and cold sweat.

DR. WANGENSTEEN: The hour is growing late, I know, but before we adjourn there is one question I should like to ask Dr. Hal Downey of the department of anatomy in order that we

may have his reaction as well as that of Dr. Carlson.

It is my impression, Dr. Downey, that there are problems in gastro-intestinal functional studies that may be attacked most effectually through a joint approach of microscopic morphologist (histologist) and physiologist. We all know of the corroboration lent the functional studies upon the secretion of isolated gastric pouches (Heidenhain) by the splendid morphologic studies of Bensley. Could not the morphologist, working in intimate collaboration with the physiologist, give us helpful information concerning other physiologic processes?

DR. DOWNEY: I think it would be possible to carry on experiments on the physiology of the digestive tract from different standpoints, that is, coöperative research in the best sense of the word.

Many problems which seem to be primarily of interest to the surgeon, some of which Dr. Wangenstein has been considering recently, depend on the fields of physiology, histology, pathology, and even hematology for their final solution. One can think of many problems in the physiology of the digestive tract which require the coöperation of men working in these different fields.

DR. CARLSON: I agree with Dr. Downey, but the use of the microscope, alone, on the gut has reached a sort of impasse, unless combined with other technics. A budding medical investigator said, forty years ago, that at that time everything that could be discovered by the microscope had been discovered. That is not so, even today. Histologists can surely help, but the days when the clinical pathologists can use the microscope on dead tissue alone, and help us forward, that day, I think, has passed. What does the physician do, who attempts to answer nature's ques-

tions now? He does physiology, even on his patients. What does the anatomist or the pathologist do? The pathologist is working mainly, not on the structure of dead tissue, but on pathological processes, and so in the entire field. What do the pediatricians, the gynecologists do? They are dealing with functions, with processes! That is one of the reasons why I have not lost much sleep over the fact that physiology is not given a greater amount of attention in the medical curriculum. Now, all doctors become physiologists, some good ones, others not so good. With reference to the way we do it at Chicago, we give the students some free time to think or to waste, then if there is a physiologist, like Luckhardt, who really has something to teach these medical students, these students have pretty good noses and they find it, and as a result in Chicago a large per cent of medical students elect advanced work in physiology, sometimes up to 50, 60, or even 70 per cent above the so-called prescribed medical course. I think that is best. When the students have an opportunity to select what they want, they are not driven. Moreover, I think the teacher, under these conditions, is a little more on his or her toes. I don't object at all. Medical education is in some places so regimented that the student has little or no time, for elective work, no time to find himself in the particular field where his love is directed at present, where ultimately his life work is going to be done. I think the answer lies in more freedom for election because, somehow, the kind of men and women that now get into the medical school are mostly far beyond the idea of getting snap courses. They really are after the facts.

DR. WANGENSTEEN: I am certain, Dr. Carlson, that I bespeak the genuine sentiment of this group when I say that we are grateful to you for this very interesting round-table discussion relating to the clinical physiology of the gastro-intestinal canal.

NEUROPHYSIOLOGY*

Chairman: DR. J. CHARNLEY MCKINLEY

**Professor of Nervous and Mental
Diseases
University of Minnesota**

Leaders: DR. DETLEV W. BRONK

**Professor and Director, Institute of
Neurology
University of Pennsylvania**

DR. HERBERT S. GASSER

**Director, Rockefeller Institute for Medical
Research**

Drs. Bronk and Gasser opened the round table with a general discussion of the pedagogical and practical relationships of neurophysiology to general medicine, neurology and psychiatry, covering the following principal points:

The minor position which neurophysiology has held seems unjustified when one considers, for example, the diagnostic importance of pain and a rising temperature in general medicine, both of which are fundamentally neurological mechanisms which still need much clarification. A tendency exists among many of our colleagues to think of neurophysiology as an abstract laboratory science which has not contributed to the solution of practical medical problems in proportion to the effort and expense which are necessary for its prosecution. But the fact is a commonplace that medical science advances so rapidly that the members of the profession must continually labor and strain in order that their concepts may not become obsolete. Pedagogically, therefore, the teaching of basic physiologic mechanisms in neurophysiology provides the student with the knowledge which enables him to adapt with facility to new revisions in clinical neurologic and psychiatric practice.

Advances in the practical field are most likely to arise from the broadening of our base through the elucidation of all available facts such as the functioning of the synapse and the perikaryon. As these points become more understandable they can be applied more and more to nervous system integration and, it is hoped, finally to the total behavior of the individual. It is not too far-fetched, therefore, to think that the study of isolated neural phenomena may provide explanations which can be carried over into the solution of many of the mechanisms not only of organic neurology but also of civilization's most devastating group of illnesses, namely, the mental disorders.

DR. D. W. BRONK is Professor of Biophysics and Director of the Johnson Foundation for Medical Physics at the University of Pennsylvania. In his laboratory the brains and skill of electrical engineers and physicists are put to work to explore the physics of the human machine.

Professor Bronk's rise to leadership in a new type of Medical Research has been rapid (he is only forty-two years old) and his path is of interest. In the early 1920s he was a young scientist doing brilliant studies in the field of astrophysics. He became convinced that the viewpoint and many of the methods of the professional physicist could be applied to biological and medical problems and set himself to learn biology and especially physiology. Studies at Michigan, Swarthmore, Cambridge University and London quickly showed his ability in his new field and in 1929 he was selected to head the project for a biophysical institute in Philadelphia.

DR. HERBERT S. GASSER is at present Director of the Rockefeller Institute for Medical Research in New York City. He is a graduate of the Medical School of Johns Hopkins University and has been Professor of Pharmacology in Washington University in St. Louis, Missouri and Professor of Physiology at Cornell University, School of Medicine, in New York. He served as pharmacologist in the Chemical Warfare Service in 1918. He is a member of the National Academy of Sciences, the American Philosophical Society and numerous other scientific societies in this country and abroad.

Some recent dividends of this general approach are already in evidence; for instance, the use of liver in combined sclerosis, vitamin B₁ in neuritis, and potassium in familial periodic paralysis. The relationships of increased metabolic activity (hyperthyroidism) to nervous hyperexcitability has long been known and the indications for therapy reasonably well outlined.

Discussion

Dr. Starke R. Hathaway asked for an opinion as to the outcome of the problem of inhibition; whether this will be in terms of the general laws of peripheral conduction as we now know them, or whether new discoveries will be needed in the sense of an inhibitory type of neuron discharge or an inhibitory substance.

Drs. Bronk and Gasser both felt that, though

*Reported by the chairman, Dr. J. Charnley McKinley.

opinion should necessarily be rather guarded, the solution will probably be in accord with laws of the nervous system as now being discovered and elaborated, and that new laws or new functional systems need not at present be invoked.

Dr. A. B. Baker raised the point that frequently the neuropathologist can determine no histological alterations in cell groups in the brain which before death gave obvious clinical evidence of being damaged. He wondered if others

felt as he did that the limitations of the microscopic technic were not the determining factor in such paradoxical situations and what suggestions could be reasonably entertained for shedding more light on such a dilemma.

Dr. Bronk said he had also been troubled by that problem. In his opinion, contributions from related fields (chemistry, electrophysics, for example) might ultimately clear up many phases of the problem.

THE MECHANISMS AND MANIFESTATIONS OF THE IMMUNE RESPONSE

Chairman: DR. A. T. HENRICI
Professor of Bacteriology
University of Minnesota

Leader: DR. MICHAEL HEIDELBERGER
Professor of Biochemistry
Columbia University

Dr. Henrici opened the discussion by relating some experiments which indicate that following extreme infections with ringworm fungi in rabbits there can be demonstrated two sorts of hypersensitivity. When polysaccharide is injected, there develops a diffuse redness and desquamation of the skin. When protein is injected, there develops a circumscribed area of purpura, followed by necrosis and ulceration. Dr. Henrici asked Dr. Heidelberg if he had any other evidence regarding specific differences in the reactions of animals to different fractions of microorganisms. Dr. Heidelberg replied that he had isolated two specific polysaccharides from tubercle bacilli, which gave skin reactions in sensitized animals, as well as several other polysaccharides which were inactive. He stated that polysaccharides extracted from tubercle bacilli in earlier experiments had been drastically handled and were probably therefore inactive. One polysaccharide fraction was degraded by treatment with alkali, which splits off magnesium palmitate. The polysaccharide gives in tuberculous patients either an immediate wheal, or an area of redness which begins to develop in six hours and persists for 24 to 48 hours. This polysaccharide was considered to contain a residue protein. All traces of this protein were finally removed by treating the carbohydrate fraction with trypsin, which destroyed the antigenic property of the protein, and then destroying the trypsin by treatment with alkali. After this treatment, the polysaccharide no longer gave late re-

Dr. MICHAEL HEIDELBERGER is associate professor of biochemistry at Columbia University and chemist in charge of the Mount Sinai Hospital Laboratories. He is widely known for his work on the chemistry of bacterial toxins and of immune reactions. His discovery that complex sugars found in bacterial organisms are of specific importance in immune reactions has been of the highest importance and has attracted worldwide attention. Professor Heidelberg holds the Ehrlich medal for his work in immunology.

actions, but only an immediate wheal, or redness beginning 6 to 8 hours after injection and lasting only a few hours. Dr. Cournand found that the immediate wheal reaction was nonspecific, but that the 6 to 8 hour reaction was highly specific.

Dr. W. P. Larson asked Dr. Heidelberg's opinion regarding the relationship between the size of the globulin molecules and the efficiency of immune serum. Dr. Larson pointed out that in rabbit serum the globulin molecules are considerably smaller than in horse serum, and that rabbits produce more potent antipneumonia serum than do horses. Dr. Heidelberg agreed that there was a definite correlation, but stated that he could not explain the greater efficiency of rabbit serum unless on the basis that the small molecules could diffuse more readily into inflamed tissues than could larger molecules, and that weight for weight, rabbit antibody will combine with more pneumococcus polysaccharide than will horse antibody. Dr. Larson suggested that this might be due to the larger surface exhibited by the smaller molecules of the rabbit antibody.

Dr. C. H. Bailey discussed observations concerning an antigen extracted from tubercle bacilli, which was an ester of one of the inositols. Dr. Heidelberger stated he had not worked with lipid soluble fractions of the tubercle bacillus, but had confined his work to the protein and carbohydrate fractions of defatted cells. Dr. Bailey said he was impressed by the simplicity of the inositol molecule, and Dr. Heidelberger replied that this substance is antigenic only in the complement-fixation reaction, and is not concerned in the agglutination or precipitation reactions. Complement fixation is a more sensitive reaction, and antigens composed of small molecules may work in such a sensitive reaction.

Dr. C. P. Fitch asked Dr. Heidelberger if he had worked with human or bovine type tubercle bacilli, and regarding the nature of the medium upon which they had been cultivated. Dr. Heidelberger stated that he had used human, bovine and avian types of tubercle bacilli, and timothy grass bacilli, all grown on Long's synthetic medium. He could not demonstrate any certain difference in the antigenic properties of the proteins in the human and bovine types. There are, however, definite differences between the protein fractions of human and avian type bacilli. He is working with rabbit serums, and with two horse serums. Dr. Fitch stated that avian type tuberculosis occurs in horses, and it might be possible to use serums from infected animals.

Dr. R. V. Ellis asked if it would be possible to read the tuberculin reaction earlier than is now the case if we used Dr. Heidelberger's polysaccharide fraction. Dr. Heidelberger stated that not enough clinical material had as yet been studied, but that it would probably be possible to read the reaction in 6 to 8 hours.

Dr. L. F. Richdorf asked Dr. Heidelberger concerning the relative merits of old tuberculin and the fractions which he is studying. Dr. Heidelberger replied that testing with old tuberculin was quite different from testing with definite fractions. In old tuberculin the antigens are partially degraded, and the polysaccharide in crude tuberculin is much less active than in the purified material. He pointed out that Dr. Seibert had found it possible to sensitize animals with carefully prepared unheated tuberculin, whereas this cannot be done with Koch's old tuberculin.

Dr. H. O. Halvorson discussed the mechanism

by which antibodies are produced, and asked Dr. Heidelberger if the following statement accurately restated what Dr. Heidelberger had said in his morning lecture regarding this mechanism: The antigen affects the enzyme which produces globulin, and leaves its imprint upon this enzyme so that when new globulin is formed, it has impressed upon it a mirror image of the hapten groups of the antigen. Dr. Heidelberger stated that this was essentially correct, except that Dr. Halvorson had stressed the enzymes more than Dr. Heidelberger was willing to, and that the term "mirror image" was perhaps too definite. Dr. Halvorson asked Dr. Heidelberger to explain the tremendous increase in antibody after the second and third injection. Dr. Heidelberger stated that it was difficult to picture the exact mechanisms, but if antibody has already been formed, any antigen introduced is removed and transported more quickly and efficiently to the cells that form globulin. He pointed out that particulate antigens are better than soluble ones. Dr. Halvorson asked why all the antibodies should appear in the globulin fraction, and none in the albumin. Dr. Heidelberger replied by referring to the work of Dr. Florence Sabin, who suggested that globulins are secreted as a surface film from the cells of the reticulo-endothelial system in the liver, spleen and lymph nodes. Antigen introduced into the blood stream is phagocytized by these cells. This has been shown by the introduction of dye-antigen, in which case the colored antigen can be seen in the reticulo-endothelial cells. These cells apparently first split the dye from the protein molecule. It appears possible that the antigen molecules then affect subsequent globulin production in these cells.

Dr. Ellis asked if dye antigen localizes at all in the skin, and Dr. Heidelberger stated that it does not, unless it has been injected into the skin. Dr. Henrici pointed out that there is some evidence that in trichophytosis there occurs an actual sensitization of the epithelial cells, and that possibly one should not therefore generalize regarding the reticulo-endothelial cells being the site of all antibody reactions. Dr. Heidelberger replied that it would be highly desirable to study intracellular antibodies but that this is technically a difficult problem. The relative distribution of antibodies in the tissue juices and in the blood stream would be interesting. He has found that

rabbits may contain as much as 6 to 9 milligrams of antibody nitrogen per c.c. of serum, indicating that from $\frac{2}{3}$ to $\frac{3}{4}$ of the total globulin may actually be antibody in extreme cases.

Dr. Heidelberger asked Dr. R. A. Gortner his opinion regarding the role of salts in immunity reactions, whether he still believes that agglutination and precipitation occur in two phases—a preliminary combination of the antigen and antibody, followed by a precipitation due to the effect of an electrolyte on colloids. Dr. Gortner replied that this was still his opinion, and asked what other mechanism could be proposed to explain the actual flocculation. Dr. Heidelberger admitted that the antigen and antibody are combined in the absence of salts, but believed that there was another explanation for the influence of salt upon flocculation. He believes that agglutination and precipitation reactions represent a mutual interaction of multivalent compounds, namely the antigen and the antibodies. These combine to form large aggregates. In the absence of electrolytes, this reaction is limited by the accumulation of Coulomb forces due to the many ionized groupings on the forming aggregate. The presence of salt provides an ionic atmosphere which abolishes these forces and tends to allow the formation of large aggregates.

Dr. Gortner replied that such a phenomenon is essentially a coacervation between the antigen and the antibody, separating a liquid phase. Dr. Heidelberger replied that he considers the agglutination to be a purely chemical reaction from start to finish, and that the reduction of surface potential is merely a by-phenomenon. To support this he related an experiment in which type I pneumococci were added to excess of specific serum. The organisms were agglutinated as very fine aggregates which did not settle. The bacteria were then centrifuged and washed with salt solution until no antibody could be detected in the supernatant fluid. They were then re-suspended in salt solution, and the suspension was divided into two parts. One part was allowed to stand, and the organisms were found to remain in suspension. To the second part,

more type I pneumococci were added, and it was now found that complete agglutination took place. Dr. Heidelberger believes that with an excess of antibody the chemical reaction is interrupted in an early stage. If now we add an excess of bacteria, the new bacteria become linked to free side chains on the previously treated bacteria, and large aggregates are formed. It was found that if to the previously treated type I pneumococci one adds a nonspecific antigen, that is, type II pneumococci, no agglutination takes place. Dr. Heidelberger believes that this indicates that the reaction is a chemical one.

Dr. Gortner admitted that the phenomenon of *specificity* was the primary stumbling block to a purely colloid-chemical interpretation of the antigen-antibody reactions since colloid chemical reactions are ordinarily not highly specific, depending as they do purely upon surface forces. On the other hand, he insisted that one could not wholly ignore colloid surface behavior in immunity reaction, since to do so would be to set such reactions apart as a wholly separate class and to assume that the colloidal systems which are present no longer show the characteristic behavior which such systems should exhibit. The proper interpretation and the greatest chance for advancement of knowledge, in his opinion, lies somewhere in the middle ground between (1) specific chemical (or physical) reactions which are determined wholly by the nature and probably as well by the location in space, (on the surface) of reacting groups (e.g. $-\text{NH}_2$, $-\text{COOH}$, etc. etc.) and thus bring about specific and induced space orientation of the reacting micelles; and (2) the physico-chemical behavior characteristic of lyophilic colloid systems in general. Since electrolytes do profoundly affect the electrokinetic potential and lyophilic colloid hydration in the most diverse types of systems, they must contribute something to the net result of agglomeration and flocculation in the phenomenon of agglutination of bacteria. The big problem to which colloid chemistry cannot as yet contribute the answer is that of *specificity*. To answer that problem we will have to use all the tools and ingenuity we possess!
